An increase in multiple pregnancies, especially in the United States, is attributed to the increased use of fertility drugs. As the number of fetuses in a pregnancy increases, the risks for abnormal development and premature delivery also increase. Children from twin pregnancies have four times the risk of developing CP as children from single pregnancies. This is because more twin pregnancies are delivered prematurely or, in some cases, overcrowding occurs in the uterus causing pressure on one infant from contact with the other. The risk for CP in a child of triplets is up to 18 times greater. Furthermore, evidence suggests that a baby from a pregnancy in which its twin died before birth is at increased risk for CP.

By definition, the defect in cerebral function causing CP is nonprogressive. However, the symptoms of CP often change over time. Most of the symptoms of CP relate in some way to the aberrant control of muscles. To review, CP is categorized first by the type of movement or postural disturbance(s) that are present, then by a description of which limbs are affected, and finally by the severity of motor impairment. For example, spastic diplegia refers to continuously tight muscles that have no voluntary control in both legs, while athetoid quadraparesis describes uncontrolled writhing movements and muscle weakness in all four limbs. These three-part descriptions are helpful in providing a general picture, but cannot give a complete description of any one person with CP. In addition, the various presentations of CP do not occur with equal frequency. For example, spastic diplegia is seen in more individuals than is athetoid quadraparesis. CP can also be loosely categorized as mild, moderate, or severe, but these are very subjective terms with no firm boundaries between them.

A muscle that is tensed and contracted is hypertonic, while excessively loose muscles are hypotonic. Spastic, hypertonic muscles can cause serious orthopedic problems, including **scoliosis** (spine curvature), hip dislocation, or contractures. A contracture is shortening of a muscle, usually affecting muscles involved in flexion or extension of a joint, and are aided sometimes by a weak opposing force from a neighboring muscle. Contractures may become permanent or they may resolve without some sort of intervention. Fixed contractures may cause postural abnormalities in the affected limbs. Clenched fists and contracted feet (equinus or equinovarus) are common in people with CP. Spasticity in the thighs causes them to turn in and cross at the knees, resulting in an unusual method of walking known as a scissors gait. Any

of the joints in the limbs may be stiff (immobilized) due to spasticity of the attached muscles.

Athetosis and dyskinesia often occur with spasticity, but do not often occur alone. The same is true of ataxia. It is important to remember that the terms mild CP or severe CP refer not only to the number of symptoms present, but also to the level of involvement of any particular class of symptoms.

Mechanisms that can cause CP are not always restricted to motor-control areas of the brain. Other neurologically based symptoms may include:

- mental retardation or learning disabilities
- behavioral disorders
- seizure disorders
- visual impairment
- hearing loss
- speech impairment (dysarthria)
- abnormal sensation and perception

These problems may have a greater impact on a child's life than the primary physical impairments of CP, although not all children with CP are affected by other problems. Many infants and children with CP have growth impairment. About one-third of individuals with CP have moderate-to-severe mental retardation, one-third have mild mental retardation, and one-third have normal intelligence.

Diagnosis

The signs of CP are not usually noticeable at birth. Children normally progress through a predictable set of developmental milestones through the first 18 months of life. Children with CP, however, tend to develop these skills more slowly because of their motor impairments, and delays in reaching milestones are usually the first symptoms of CP. Babies with more severe involvement with CP are usually diagnosed earlier than others.

Selected developmental milestones, and the ages for normally acquiring them, are given below. If a child does not acquire the skill by the age shown in parentheses, there is some cause for concern:

- sits well unsupported (6–10 months)
- babbles (6–8 months)
- crawls (9–12 months)
- finger feeds, holds bottle (9–12 months)
- walks alone (12–18 months)
- uses one or two words other than “dada” or “mama” (12–15 months)

- walks up and down steps (24–36 months)
- turns pages in books; removes shoes and socks (24–30 months)

Children do not consistently favor one hand over the other before 12–18 months of age, and doing so may be a sign that the child has difficulty using the other hand. This same preference for one side of the body may show up as asymmetric crawling or, later on, favoring one leg while climbing stairs.

It must be remembered that children normally progress at somewhat different rates, and slow beginning accomplishment is often followed by normal development. Other causes for developmental delay, both benign and serious should be ruled out before considering CP as an explanation. CP is nonprogressive, so continued loss of previously acquired milestones indicates that CP is not the cause of the problem.

No single test is diagnostic for CP, but certain factors increase suspicion. The Apgar score measures a baby's condition immediately after birth. Babies that have low Apgar scores are at increased risk for CP. Presence of abnormal muscle tone or movements may indicate CP, as may the persistence of infantile **reflexes**. Imaging of the brain using ultrasound, x rays, MRI, and/or **CT scans**, may reveal structural anomalies. Some brain lesions associated with CP include scarring, cysts, expansion of the cerebral ventricles (hydrocephalus), periventricular leukomalacia (an abnormality of the area surrounding the ventricles), areas of dead tissue (necrosis), and evidence of an intracerebral hemorrhage or blood clot. Blood and urine biochemical tests, as well as genetic tests, may be used to rule out other possible causes, including muscle and peripheral nerve diseases, mitochondrial and metabolic diseases, and other inherited disorders. Evaluations by a pediatric developmental specialist and a geneticist may be of benefit.

Treatment

Therapy

Spasticity, muscle weakness, lack of coordination, ataxia, and scoliosis are all significant impairments that affect the posture and mobility of a person with CP. Physical and occupational therapists work with affected persons and their families to maximize ability to move affected limbs, develop normal motor patterns, and maintain posture. So-called assistive technology, items such as wheelchairs, walkers, shoe inserts, crutches, and braces, are often required. A speech therapist and high-technology aids, such as computer-controlled communication devices, may make a tremendous difference in the life of those who have speech impairments with CP.

Medications

Before fixed contractures develop, muscle-relaxant drugs such as diazepam (Valium), dantrolene (Dantrium), and baclofen (Lioresal) may be prescribed. Botulinum toxin (Botox), a newer and highly effective treatment, is injected directly into the affected muscles. Alcohol or phenol injections into the nerves controlling specific muscles are another option. Multiple medications are available to control seizures, and athetosis can be treated using medications such as trihexyphenidine (Artane) and benztropine (Cogentin).

Surgery

Fixed contractures are usually treated with either serial casting or surgery. The most commonly used surgical procedures are tenotomy (tendon transfer) and dorsal rhizotomy. In tenotomy, tendons of an affected muscle are cut and either repositioned or reattached in a different position, and the limb is then immobilized in a cast in a more normal position while the tendons regrow. A neurosurgeon performing dorsal rhizotomy carefully cuts selected nerve roots in the spinal cord to prevent them from stimulating the spastic muscles. Neurosurgical techniques in the brain, such as implanting tiny electrodes directly into the cerebellum or cutting a portion of the hypothalamus, have very specific applications and have had mixed results.

Education

Parents of a child newly diagnosed with CP are not likely to have the necessary expertise to coordinate the full range of care their child will need. Although knowledgeable and caring medical professionals are indispensable for developing a care plan, a potentially more important source of information and advice is other parents who have dealt with the same set of difficulties. Support groups for parents of children with CP can be significant sources of both practical advice and emotional support. Many cities have support groups that can be located through the United Cerebral Palsy Association, and most large medical centers have special multidisciplinary clinics for children with developmental disorders.

Prognosis

Cerebral palsy can affect every stage of maturation—from childhood through adolescence to adulthood. At each stage, those with CP, along with their caregivers, must strive to achieve and maintain the fullest range of experiences and education consistent with their abilities. The advice and intervention of various professionals remains crucial for many people with CP. Although CP

KEY TERMS

Asphyxia—Lack of oxygen. In the case of CP, lack of oxygen to the brain.

Ataxia—Impaired balance and coordination.

Athetosis—A condition marked by slow, writhing, involuntary muscle movements.

Coagulopathy—A disorder in which blood does not coagulate normally; it can coagulate (clot) either abnormally slowly or abnormally quickly.

Contracture—A shortening of a muscle causing a joint to become stiff or immovable.

Cytokine—A protein associated with inflammation that, at high levels, may be toxic to nerve cells in the developing brain.

Diplegia—Paralysis of corresponding parts on both sides of the body.

Dorsal rhizotomy—A surgical procedure that cuts nerve roots to reduce spasticity in affected muscles.

Dyskinesia—Difficulty with voluntary movement of a muscle.

Hemiplegia—Paralysis of the limbs on one side of a body.

Hypotonia—Reduced tone, referring to a muscle that is loose or flaccid.

Quadripareisis—Partial or incomplete paralysis of all four limbs.

Quadriplegia—Paralysis of all four limbs.

Serial casting—A series of casts designed to gradually move a limb into a more functional position.

Spastic—A condition in which the muscles are rigid, posture may be abnormal, and fine motor control is impaired.

Static encephalopathy—A disease of the brain that does not get better or worse.

Tenotomy—A surgical procedure that cuts the tendon of a contracted muscle to allow lengthening.

itself is not considered a terminal disorder, it can affect a person's lifespan by increasing the risk for certain medical problems. People with mild cerebral palsy may have near-normal life spans, but the lifespan of those with more severe forms may be shortened. However, more than 90% of infants with CP survive into adulthood.

The cause of most cases of CP remains unknown, but it has become clear that birth difficulties are not to blame in most cases. Rather, developmental problems before birth, usually unknown and generally undiagnosable, are responsible for most cases. The rate of survival for preterm infants has leveled off, and methods to improve the long-term health of at-risk babies are being sought. Current research is also focusing on the possible benefits of recognizing and treating coagulopathies and inflammatory disorders in the prenatal and perinatal periods. The use of magnesium sulfate in pregnant women with preeclampsia or threatened preterm delivery may reduce the risk of CP in very preterm infants. The risk of CP can be decreased through good maternal **nutrition**, avoidance of drugs and alcohol during pregnancy, and prevention or prompt treatment of infections.

Health care team roles

The number of health care professionals who provide care for persons with CP is extensive. Pediatricians or family physicians may make the initial diagnosis. However, in the growing environment of primary care, the pediatric nurse practitioner may be the first to describe symptoms or developmental delays associated with CP. Care and treatment is then provided by many health professionals, including general or orthopedic surgeons and neurosurgeons. Radiologists assist in diagnosis and monitoring; speech and language specialists and physical and occupational therapists provide rehabilitative therapy. Psychologists, pastoral counselors, and social workers may provide emotional support to patients and their families, while social workers will help families access resources for care and equipment. Manufacturers of prostheses and assistive devices may also provide services. For most persons with CP, assistive care is a life-long need. In an outpatient environment, nurses play a continuing role as educators for such needs as medication administration and side-effect recognition, in-home adaptations for **physical therapy** necessary between visits to physical therapists, and as a conduit for connecting parents with support groups. Should the child require surgery, the nurse has a perioperative role in caring for the patient.

Prevention

Several maternal-to-fetal cross infections are known to increase the risk for CP, including rubella (German measles, now rare in the United States), cytomegalovirus (CMV), and toxoplasmosis. Each of these infections is considered a risk to the fetus only if the mother contracts it for the first time during that pregnancy. Even in those cases, though, most babies will be born normal. Most

women are immune to all three infections by the time they reach childbearing age, but a woman's immune status can be determined using the so-called TORCH (for TOxoplasmosis, Rubella, Cytomegalovirus, and Herpes) test before or during pregnancy.

Cerebral palsy cannot be cured, but many of the disabilities it causes may be managed through planning and timely care. Treatment for a child with CP depends upon the severity, nature, and location of the primary muscular symptoms, as well as any associated problems that might be present. Optimal care of a child with mild CP may involve regular interaction with only a physical therapist and occupational therapist, whereas care for a more severely affected child may include visits to multiple medical specialists throughout life. With proper treatment and an effective care plan coverage, most people with CP can lead productive, happy lives.

Adequate prenatal monitoring by competent health care professionals is needed to prevent CP. Risk factors should be identified and appropriate tests conducted. Pregnant women who discontinue the use of substances that are potentially harmful to their fetuses significantly reduce the risk of CP in their children.

L. Fleming Fallon, Jr., M.D., Dr.P.H.

Cerebrospinal fluid (CSF) analysis

Definition

Cerebrospinal fluid (CSF) analysis is a set of laboratory tests that examine a sample of the fluid surrounding the **brain** and **spinal cord**. This fluid is an ultrafiltrate of plasma. It is clear and colorless. It contains glucose, electrolytes, amino acids, and other small molecules found in plasma, but has very little protein and few cells. CSF protects the **central nervous system** from injury, cushions it from the surrounding bone structure, provides it with nutrients, and removes waste products by returning them to the **blood**. CSF is withdrawn from the subarachnoid space through a needle by a procedure called a lumbar puncture or spinal tap. CSF analysis includes tests in clinical chemistry, hematology, immunology, and microbiology. Usually three or four tubes are collected. The first tube is used for chemical and/or serological analysis and the last two tubes are used for hematology and microbiology tests. This reduces the chances of a falsely elevated white cell count caused by a traumatic tap (bleeding into the subarachnoid space at the puncture site), and contamination of the bacterial culture by skin flora.

Purpose

The purpose of a CSF analysis is to diagnose medical disorders that affect the central nervous system. Some of these conditions are:

- **meningitis** and encephalitis, which may be viral, bacterial, fungal, or parasitic infections
- metastatic tumors (e.g., leukemia) and central nervous system tumors that shed cells into the CSF
- **syphilis**, a sexually transmitted bacterial disease
- bleeding (hemorrhaging) in the brain and spinal cord
- **multiple sclerosis**, a degenerative nerve disease that results in the loss of the myelin coating of the nerve fibers of the brain and spinal cord
- guillain-Barré, a demyelinating disease involving peripheral sensory and motor nerves

Routine examination of CSF includes visual observation of color and clarity and tests for glucose, protein, lactate, lactate dehydrogenase, red blood cell count, white blood cell count with differential, syphilis serology (testing for antibodies indicative of syphilis), **Gram stain**, and bacterial culture. Further tests may need to be performed depending upon the results of initial tests and the presumptive diagnosis. For example, an abnormally high total protein seen in a patient suspected of having a demyelinating disease such as multiple sclerosis dictates CSF protein electrophoresis and measurement of immunoglobulin levels and myelin basic protein.

GROSS EXAMINATION. Color and clarity are important diagnostic characteristics of CSF. Straw, pink, yellow, or amber pigments (xanthochromia) are abnormal and indicate the presence of bilirubin, hemoglobin, red blood cells, or increased protein. Turbidity (suspended particles) indicates an increased number of cells. Gross examination is an important aid to differentiating a subarachnoid hemorrhage from a traumatic tap. The latter is often associated with sequential clearing of CSF as it is collected; streaks of blood in an otherwise clear fluid; or a sample that clots.

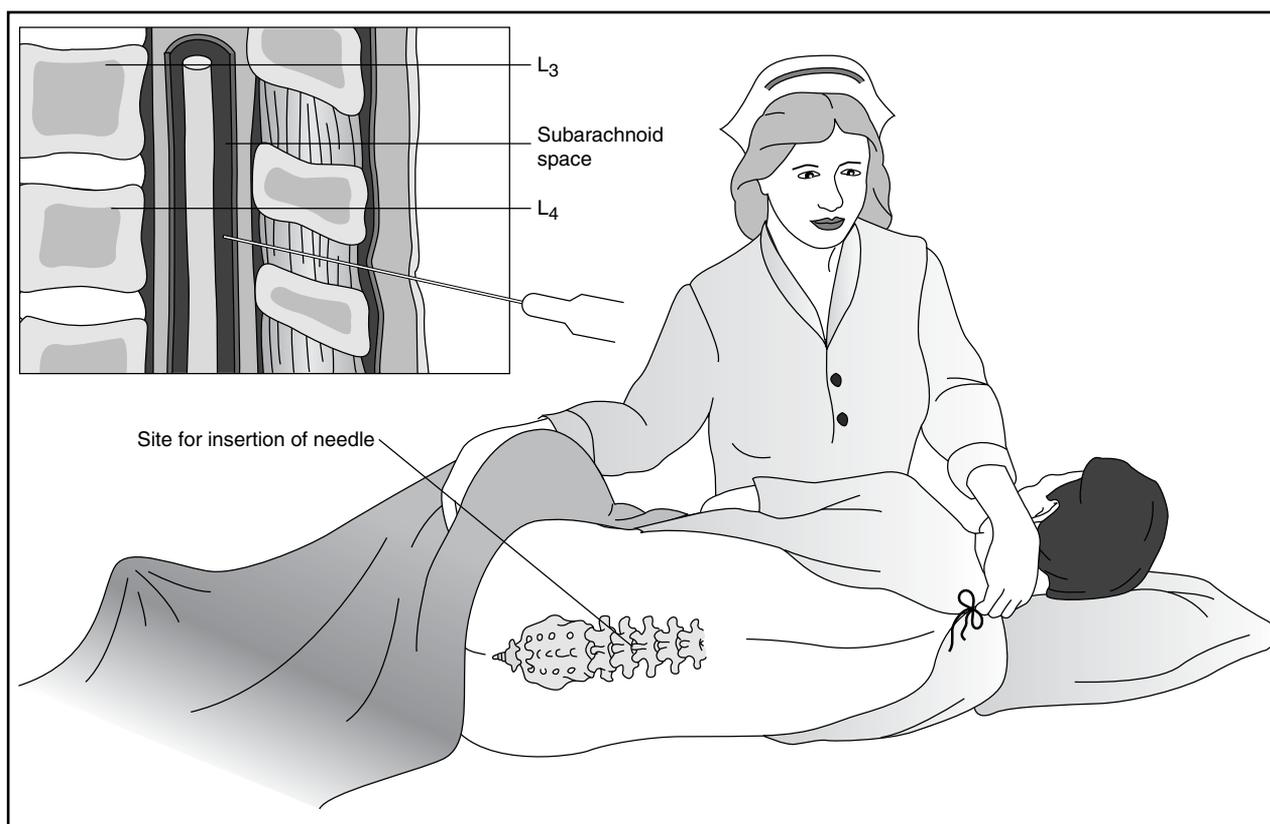

GLUCOSE. CSF glucose is normally approximately two-thirds of the fasting plasma glucose. A glucose level below 40 mg/dL is significant and occurs in bacterial and fungal meningitis and in malignancy.

PROTEIN. Total protein levels in CSF are normally very low, and albumin makes up approximately two-thirds of the total. High levels are seen in many conditions including bacterial and fungal meningitis, multiple sclerosis, tumors, subarachnoid hemorrhage, and traumatic tap.

LACTATE. The CSF lactate is used mainly to help differentiate bacterial and fungal meningitis, which cause increased lactate, from viral meningitis, which does not.

LACTATE DEHYDROGENASE. This enzyme is elevated in bacterial and fungal meningitis, malignancy, and subarachnoid hemorrhage.

WHITE BLOOD CELL (WBC) COUNT. The number of white blood cells in CSF is very low, usually necessitat-

Collection of cerebrospinal fluid (CSF) by lumbar puncture. (Delmar Publishers, Inc. Reproduced by permission.)

ing a manual WBC count. An increase in WBCs may occur in many conditions including infection (viral, bacterial, fungal, and parasitic), allergy, leukemia, multiple sclerosis, hemorrhage, traumatic tap, encephalitis, and Guillain-Barré syndrome. The WBC differential helps to distinguish many of these causes. For example, viral infection is usually associated with an increase in lymphocytes, while bacterial and fungal infections are associated with an increase in polymorphonuclear leukocytes (neutrophils). The differential may also reveal eosinophils associated with allergy and ventricular shunts; macrophages with ingested **bacteria** (indicating meningitis), RBCs (indicating hemorrhage), or **lipids** (indicating possible cerebral infarction); blasts (immature cells) that indicate leukemia; and malignant cells characteristic of the tissue of origin. About 50% of metastatic cancers that infiltrate the central nervous system and about 10% of central nervous system tumors will shed cells into the CSF.

RED BLOOD CELL (RBC) COUNT. While not normally found in CSF, RBCs will appear whenever bleeding has occurred. Red cells in CSF signal subarachnoid hemorrhage, stroke, or traumatic tap. Since white cells may enter the CSF in response to local infection, inflammation, or bleeding, the RBC count is used to correct the

WBC count so that it reflects conditions other than hemorrhage or a traumatic tap. This is accomplished by counting RBCs and WBCs in both blood and CSF. The ratio of RBCs in CSF to blood is multiplied by the blood WBC count. This value is subtracted from the CSF WBC count to eliminate WBCs derived from hemorrhage or traumatic tap.

GRAM STAIN. The Gram stain is performed on a sediment of the CSF and is positive in at least 60% of cases of bacterial meningitis. Culture is performed for both aerobic and anaerobic bacteria. In addition, other stains (e.g., the acid-fast stain for *Mycobacterium tuberculosis*, fungal culture, and rapid identification tests (tests for bacterial and fungal antigens) may be performed routinely.

SYPHILIS SEROLOGY. This involves testing for antibodies that indicate neurosyphilis. The fluorescent treponemal antibody-absorption (FTA-ABS) test is often used and is positive in persons with active and treated syphilis. The test is used in conjunction with the VDRL test for non-treponemal antibodies, which is positive in most persons with active syphilis, but negative in treated cases.

Normal cerebrospinal fluid values in adults

Measurement	Value
Volume	90–150 ml; child 60–100 ml
Clarity	Crystal clear, colorless
Pressure	50–180 mm H ₂ O
Total cell count	0–5 white blood cells/ μ l
Glucose	40–70 mg/dl
Protein	15–45 mg/dl (lumbar) 15–25 mg/dl (cisternal) 5–15 mg/dl (ventricular)
pH	7.30–7.40
CO ₂ content	25–30 mEq/L

SOURCE: Fischbach, F.T. *A Manual of Laboratory Diagnostic Tests*. 4th ed. Philadelphia: J.B. Lippincott, 1992.

Precautions

In some circumstances, a lumbar puncture to withdraw a small amount of CSF for analysis may lead to serious complications. Lumbar punctures should be performed only with extreme caution, and only if the benefits are thought to outweigh the risks. In people who have **bleeding disorders**, lumbar puncture can cause hemorrhage that can compress the spinal cord. If there is increased spinal column pressure, as may occur with a **brain tumor** and other conditions, removal of CSF can cause the brain to herniate, compressing the brain stem and other vital structures and leading to irreversible brain damage or death. Meningitis may be caused by bacteria introduced during the puncture. For this reason, **aseptic technique** must be followed strictly, and a lumbar puncture should never be performed at the site of a localized skin lesion.

Specimens should be handled with caution to avoid contamination with skin flora. They should be refrigerated if analysis cannot be performed immediately.

Description

Lumbar puncture is performed by inserting the needle between the fourth and fifth lumbar vertebrae (L4–L5). This location is used because the spinal cord stops near L2, and a needle introduced below this level will miss the cord. In rare instances, such as a spinal fluid blockage in the middle of the back, a physician may perform a spinal tap in the cervical spine.

Aftercare

After the procedure, the site of the puncture is covered with a sterile bandage. The patient should remain lying for four to six hours after the lumbar puncture. **Vital signs** should be monitored every 15 minutes for

four hours, then every 30 minutes for another four hours. The puncture site should be observed for signs of weeping or swelling for 24 hours. The neurological status of the patient should also be evaluated for such symptoms as numbness and/or tingling in the lower extremities.

Complications

The most common side effect after the removal of CSF is a headache. This occurs in 10–30% of adult patients and in up to 40% of children. It is caused by a decreased CSF pressure related to a small leak of CSF through the puncture site. These headaches usually are a dull **pain**, although some people report a throbbing sensation. A stiff neck and nausea may accompany the headache. Lumbar puncture headaches typically begin within two days after the procedure and persist from a few days to several weeks or months.

Results

- Gross appearance: Normal CSF is clear and colorless.
- CSF opening pressure: 50–175 mm H₂O.
- Specific gravity: 1.006–1.009.
- Glucose: 40–80 mg/dL.
- Total protein: 15–45 mg/dL.
- LD: 1/10 of serum level.
- Lactate: less than 35 mg/dL.
- Leukocytes (white blood cells): 0–5/microL (adults and children); up to 30/microL (newborns).
- Differential: 60–80% lymphocytes; up to 30% monocytes and macrophages; other cells 2% or less. Monocytes and macrophages are somewhat higher in neonates.
- Gram stain: negative.
- Culture: sterile.
- Syphilis serology: negative.
- Red blood cell count: Normally, there are no red blood cells in the CSF unless the needle passes through a blood vessel on route to the CSF.

Health care team roles

Spinal tap is performed by a physician, and laboratory tests are ordered by a physician. Nurses should check the patient's vital signs before the procedure, and monitor the patient for complications.

Laboratory tests are performed by a clinical laboratory scientist, CLS(NCA)/ medical technologist, MT(ASCP)

KEY TERMS

Encephalitis—An inflammation or infection of the brain and spinal cord caused by a virus or as a complication of another infection.

Guillain-Barré syndrome—A demyelinating disease involving nerves that affect the extremities and causing weakness and motor and sensory dysfunction.

Meningitis—An infection of the membranes that cover the brain and spinal cord.

Multiple sclerosis—A disease that destroys the covering (myelin sheath) of nerve fibers of the brain and spinal cord.

Spinal canal—The cavity or hollow space within the spine that contains the spinal cord and the cerebrospinal fluid.

Vertebrae—The bones of the spinal column. There are 33 along the spine, with five (called L1–L5) making up the lower lumbar region.

or clinical laboratory technician, CLT(NCA) or medical laboratory technician, MLT(ASCP).

Cerebrovascular accident

Definition

Cerebrovascular accident (CVA) is the medical term for what is commonly termed a stroke. It refers to the injury to the **brain** that occurs when flow of **blood** to brain tissue is interrupted by a clogged or ruptured artery, causing brain tissue to die because of lack of nutrients and oxygen.

Description

The severity associated with cerebrovascular accident can best be demonstrated by the following facts:

- CVA is the leading cause of adult disability in the world.
- Worldwide, one-quarter of all strokes are fatal.
- Stroke is the third leading cause of death in the United States and the leading cause of disability.
- It is estimated that four of every five families in the United States will be affected by stroke in their lifetime,
- More than half a million people in the United States experience a new or recurrent stroke each year.
- Stroke kills about 150,000 Americans each year, or almost one out of three stroke victims.
- Three million Americans are currently permanently disabled from stroke.
- In the United States, stroke costs about \$43 billion per year in direct costs and loss of productivity.
- Two-thirds of strokes occur in people over the age of 65.
- Strokes affect men more often than women, although women are more likely to die from a stroke.
- Strokes affect African Americans more often than Caucasians, and are more likely to be fatal among African Americans.
- The incidence of strokes among people ages 30 to 60 is less than 1%. This figure triples by the age of 80.
- The rate of occurrence for strokes in the United States fell by 15.52% between 1988 and 1998. But the number of deaths from stroke actually rose by 5%.

Causes and symptoms

Arterial blood carries oxygen and nutrients to the cells of the body. When arteries are unable to carry out this function due to rupture, constriction, or obstruction,

the cells nourished by these arteries die. There are two forms of stroke, ischemic, which is caused by a blocked blood vessel that supplies blood to the brain, and hemorrhagic, which is bleeding into or around the brain.

The most common type of stroke is ischemic, which refers to the loss of oxygen and nutrients for brain cells that occurs because the blood supply to a portion of the brain has been cut off. Ischemic strokes account for approximately 80% of all strokes, and can be further broken down into two subtypes: thrombotic, also called cerebral thrombosis, and embolic, also termed cerebral embolism.

Thrombotic strokes are by far the more prevalent of ischemic strokes, and can be seen in nearly all aging populations worldwide. As people grow older, atherosclerosis, or hardening of the arteries, occurs. This results in a buildup of a waxy, cholesterol-laden substance in the arteries, which eventually narrows the interior space, or lumen, of the artery. This arterial narrowing occurs in all parts of the body, including the brain. As the process continues, the occlusion, or shutting off, of the artery eventually becomes complete so that no blood supply can pass through. Usually the occurrence of the symptoms of a thrombotic stroke are much more gradual and less dramatic than other strokes due to the slow, ongoing process that produces it.

Transient ischemic attacks (TIAs) are one form of thrombotic stroke, and usually the least serious. TIAs represent the occlusion of a very small artery, or arteriole. This blockage affects only a small portion of brain tissue and does not leave noticeable permanent ill effects. These transient ischemic attacks last only a matter of minutes, but are a forewarning that part of the brain is not receiving its necessary supply of blood, and, consequently, an insufficient amount of oxygen and nutrients.

Embolic strokes are usually a more spectacular, emergency event. They take place when the heart's rhythm is changed for a number of reasons, and blood clot formation takes place. Such a blood clot can move through the circulatory system until it blocks a blood vessel and stops the blood supply to cells in a specific portion of the body. If the blood clot occludes an artery that nourishes **heart** muscle, it causes **myocardial infarction**, or heart attack. If it blocks off a vessel that feeds brain tissue, it is termed an embolic stroke. Normally, these blockages occur in the brain itself, as when arteries directly feeding portions of brain tissue are blocked by a clot. But occasionally, the obstruction is found in the arteries of the neck, especially the carotid artery.

Approximately 20% of cerebrovascular accidents are termed hemorrhagic strokes, and are generally classified as subarachnoid hemorrhage or intracerebral hemor-

rhage, depending upon the location of the hemorrhage. Hemorrhagic strokes occur when an artery to the brain has a weakness and balloons outward, producing an aneurysm. Such an aneurysm often ruptures due to this inflation and thinning of the arterial wall, causing a hemorrhage in the affected portion of the brain.

Both ischemic and hemorrhagic strokes display similar symptoms. However, which symptoms appear depends upon which portion of the brain is cut off from its supply of oxygen and nourishment. The brain is divided into left and right hemispheres, which control bodily movement on opposing sides of the body. For example, the left hemisphere of the brain is responsible for both motor control of the right side of the body, and its sensory discrimination, just as the right hemisphere is responsible for body movements and feeling on the left side. Deeper brain tissue in the left hemisphere of the brain directs muscle tone and coordination for both the right arm and leg. As the communication and speech centers for the brain are also located in the left hemisphere of the brain, interruption of blood supply to that area can also affect the person's ability to speak.

Besides age, high **blood pressure (hypertension)** is one of the foremost causes of thrombotic stroke. Heart disease, **obesity**, diabetes, smoking, oral contraceptives in women, polycythemia (an increased number of red blood cells), and sleep apnea are also risk factors for thrombotic stroke, as is a diet high in cholesterol-producing, or fatty, foods.

The risk factors for hemorrhagic stroke include high blood pressure that can, over a period of time, cause the ballooning out of arteries known as aneurysm, and also causes the hereditary malformation that produces defective and weakened veins and arteries. Substance abuse is another major cause of hemorrhagic stroke. Cocaine, stimulants such as amphetamine drugs, and chronic **alcoholism** can cause a weakening of **blood vessels** that can result in hemorrhagic stroke.

The symptoms of stroke depend upon the part of the brain that is affected, and how large a portion of brain tissue has been damaged by the CVA. Unconsciousness and even seizures can be initial components of a stroke. Other effects materialize over a time period ranging from minutes to hours, and even, in some rare instances, over several days. Headache, mental confusion, vertigo, **vision** problems, difficulty speaking and communicating, including slurring of words (**aphasia**), and weakness or **paralysis** of one side of the body (hemiplegia) are all symptoms of stroke that are frequently observed. Stroke victims often have facial drooping, or slackness of the facial muscles, on the affected side, as well as difficulty swallowing. The severity of these symptoms will depend

upon the amount of brain tissue that has been damaged and its location in the brain.

Diagnosis

Normally, initial diagnosis will be made based upon observation by health care professionals, and usually a complete neurological examination. Once stroke is suspected, a computed tomography (CT) scan or **magnetic resonance imaging** (MRI) scan is performed to distinguish a stroke caused by blood clot from one caused by hemorrhage, a critical distinction that guides therapy. Blood and urine tests are done routinely to look for possible abnormalities associated with ischemic activity within the body. Electrocardiogram (EKG), **angiography**, and lumbar puncture are all used to rule out any other possible causes of the symptoms.

Treatment

Emergency treatment

Strokes are always considered a medical emergency, and every minute is important in initiating treatment. With the possible exception of TIAs, all other types of stroke are a life-threatening event. A severe CVA that results in **coma** or unconsciousness will require medical monitoring and support, including oxygen and possibly intubation to ensure an adequate airway and to facilitate the patient's breathing. Providing fluids that the person may not be able to take by mouth due to swallowing difficulties may also be necessary.

Emergency treatment of stroke caused by a blood clot is directed at dissolving the clot. This thrombolytic therapy is currently performed most often with tissue plasminogen activator, or t-PA. As t-PA must be administered within three hours of the stroke event, people that awaken with stroke symptoms are usually considered beyond the time limit for t-PA therapy. A five-year clinical trial completed in 1995, and reported by the *New England Journal of Medicine*, showed that stroke patients treated with t-PA within three hours of the stroke were one-third more likely to be left with no permanent residual difficulty.

T-PA therapy carries a 6.4% risk of inducing a cerebral hemorrhage, and is not appropriate for patients with **bleeding disorders**, very high blood pressure, known aneurysms, any evidence of intracranial hemorrhage, or incidence of stroke, head trauma, or intracranial surgery within the past three months. Patients with clot-related (thrombotic or embolic) stroke who are ineligible for t-PA treatment may be treated with heparin or other blood thinners, or, in some cases, with aspirin or other anti-clotting agents.

Emergency treatment of hemorrhagic stroke is aimed at controlling intracranial pressure. Intravenous urea, or mannitol, plus hyperventilation are the most common treatment. **Corticosteroids** may also be used. Patients with bleeding disorders such as those due to anticoagulant treatment should have these disorders reversed, if possible.

Sometimes surgical removal of a clot obstructing an artery is necessary. Hemorrhagic stroke can cause a buildup of pressure on the brain that must be relieved as quickly as possible to prevent further brain damage. In extreme cases, this may require an incision through the **skull** to relieve the pressure. Surgery for hemorrhage due to aneurysm may be performed if the aneurysm is close enough to the cranial surface to allow access. Ruptured vessels are closed off to prevent bleeding. For aneurysms that are difficult to reach surgically, endovascular treatment may be used. In this procedure, a catheter is guided from a larger artery up into the brain to reach the aneurysm. Small coils of wire are discharged into the aneurysm.

Longer term or rehabilitative treatment

Rehabilitation refers to a comprehensive program designed to regain function as much as possible and to compensate for permanent losses. It is based on the patient's individual deficits and strengths. Strokes on the left side of the brain primarily affect the right half of the body, and vice versa. In addition, in left-brain-dominant people, who constitute a significant majority of the population, left brain strokes usually lead to speech and language deficits. Right brain strokes may affect spatial perception, and patients with right brain strokes may also deny their illness, neglect the affected side of their body, and behave impulsively.

Much of the needed care in the days and weeks following a stroke will be to prevent further damage than what has already occurred. The severely ill stroke patient will require frequent repositioning to prevent complications such as **pneumonia** and venous or pulmonary embolism. Deep venous thrombosis, in which a clot forms within a limb immobilized by paralysis, is one of the most common medical complications following stroke. Clots that break free often become lodged in an artery feeding the **lungs**. This type of pulmonary embolism often causes death in the weeks following a stroke. Resuming activity within a day or two after the stroke is an important preventive measure, along with use of elastic stockings on the lower limbs. Drugs that prevent clotting may be given, including intravenous heparin and oral warfarin.

CAT scan of a brain showing a stroke resulting in hemorrhage (white area). (Custom Medical Stock Photo. Reproduced by permission.)

Weakness and loss of coordination of the swallowing muscles may impair swallowing (dysphasia), and allow food to enter the lower airway. This may lead to aspiration pneumonia, another common cause of death shortly after a stroke. Because of the difficulty swallowing, the person who has suffered a stroke may need a temporary or permanent feeding tube inserted into the **stomach** to ensure adequate **nutrition**. Such tubes can be either nasogastric, a thin tube that is inserted through the nose, into the esophagus, and then into the stomach, or a gastric one, which is a wider-lumen tube surgically implanted into the stomach. Less extreme dysphasia may be treated with retraining exercises and temporary use of pureed foods.

Other possible medical complications can include urinary tract infections, pressure ulcers, and **falls**. Urinary catheters are often inserted into the bladder to prevent the skin damage that can be caused by incontinence, but the presence of a catheter may also contribute to infections and loss of bladder tone. Bladder training, which consists of regular interval exercises to regain bladder tone, should begin as soon as possible. Frequent repositioning and good skin care will prevent the development of pressure ulcers, or decubitus ulcers.

Paralysis requires prevention of contractures (the tightening up of paralyzed limbs). Contractures and spasticity may be treated with a combination of stretching and splinting and, besides **exercise**, may include the use of

supportive braces for arms or hands, or using footboards or wearing sneakers when in bed to prevent foot drop.

Occupational therapy improves self-care skills such as feeding, bathing, and dressing, and helps develop effective compensatory strategies and devices for activities of daily living. A speech-language pathologist focuses on communication and swallowing skills. When dysphasia is a problem, a nutritionist can advise alternative meals that provide adequate nutrition.

Rehabilitation may be complicated by cognitive losses, including diminished ability to understand and follow directions. Poor results are more likely in patients with significant or prolonged cognitive changes, sensory losses, language deficits, or incontinence. Depression occurs in an estimated 30–60% of all stroke patients, which is not surprising as they are typically dealing with a tremendous loss of abilities and independence. As such depression will impact upon the person's rehabilitation and recovery, it needs to be addressed, and may require the services of a psychiatrist and psychiatric nurse or mental health assistant. Antidepressants and **psychotherapy** may be used in combination.

Prognosis

The National Institute of Neurological Disorders and Stroke reports that 25% of people who suffer a stroke recover completely, while 20% die within three months after the stroke. Stroke is fatal for nearly twice as many people of African-American heritage as it is for European-Americans. Of the remaining 55% of people who have strokes, 5% will require long-term (nursing home) care. For the rest, rehabilitative and restorative services will be necessary in order for them to regain as much of their former capabilities as possible.

Brain tissue that dies in a stroke cannot regenerate, and stroke survivors may be left with significant deficits. It has been estimated that the most common irreversible damage from stroke is that done to intellectual functions. But as is increasingly shown, emergency treatment and comprehensive rehabilitation can significantly improve both survival and recovery. In some cases, many functions that are lost due to stroke may be performed by other brain regions after a training period, or compensatory actions may be developed to replace lost abilities.

Health care team roles

Rehabilitation is provided by a team of medical professionals, including the services of a neurologist, a physician who specializes in rehabilitation medicine, nurses to both provide care and assist the physician in

coordinating the necessary services the stroke patient needs, a physical therapist, an occupational therapist, a speech-language pathologist, a nutritionist, and a social worker. Rehabilitation services may be provided in an acute care hospital, rehabilitation hospital, long-term-care facility, outpatient clinic, or at home.

Several different physicians may be involved, at one time or another, in the care of the stroke patient:

- A primary care physician (PCP) provides basic medical care to patients.
- A physical medicine and rehabilitation specialist assists patients to recover from or overcome disability or impairment. Often physical therapists work under their supervision.
- A neurologist specializes in disease conditions of the nervous system, and may be consulted to evaluate the extent of actual damage from a stroke.
- In the case of cerebral hemorrhage, a neurosurgeon, a specialist in both neurology and the surgical correction of nervous system damage, may be called upon to do surgery.
- Psychiatrists are licensed medical doctors that are often called upon to evaluate cognitive ability and to treat depression.
- Registered nurses (RNs) or licensed practical nurses (LPNs) are the health care provider that deal most often with the person who has had a CVA. Their duties include taking **vital signs** and monitoring the patient for complications of the stroke. They also educate the patient and family about the nature of strokes, the importance of preventing contractures and maintaining good range of motion, and about adequate nutrition and fluid intake.
- Physical therapists work with disabled stroke patients to maintain and restore range of motion and strength in affected limbs, and to maximize mobility in walking, wheelchair use, and transferring (for instance, from wheelchair to toilet or from standing to sitting). The physical therapist advises on mobility aids such as wheelchairs, braces, and canes.
- A social worker may help coordinate services and ease the transition out of the hospital back into the home, or into an extended care facility, if necessary. Social workers may help counsel the patient and family during the difficult rehabilitation period.
- Nutritionists educate stroke patients about eating nutritious foods and following through on a therapeutic diet as ordered by the physician.

- Occupational therapists help stroke patients to relearn muscular control and coordination in order to carry out normal activities of daily living such as bathing, dressing, and preparing meals.
- Speech-language therapists assist stroke patients who have damage to the speech center in the brain.
- Clinical laboratory scientists draw blood samples or test urine or sputum specimens that are ordered by the physician.
- Radiologic technologists take x rays, **CT scans**, and MRIs to visualize and monitor the brain or other affected organs after a stroke.

All health care team members are aware that the person who has suffered a stroke and the family members who may care for the person at home will need to learn entirely new sets of skills and adaptations. Both the patient and family often experience **stress, anxiety**, and depression. They may need to learn about physical and mental symptoms that are common in stroke patients, and the family may even need to learn how to deliver necessary care. Support groups can provide an important source of information, advice, and comfort for stroke patients and for caregivers. For the stroke patient, joining a support group can be one of the most important steps in the rehabilitation process.

Prevention

An important facet of rehabilitation is preventing the recurrence of stroke. Control of blood pressure is the single most important factor in the prevention of strokes. People should regularly have their blood pressure checked, and if it is found to be consistently elevated (diastolic, or lower blood pressure beat above 90 to 100, systolic or top beat above 140 to 150), a physician should be consulted.

Diet, including the reduction of sodium (salt) intake, exercise, and weight loss, if necessary, are all non-drug treatments for lowering blood pressure. Other natural remedies include the consumption of artichoke, which lowers the fat content of the blood, garlic, now believed to lower cholesterol and blood pressure as well as reduce blood's clotting ability, and ginkgo, which improves circulation and strengthens arteries and veins. The use of **folic acid**, lecithin, and **vitamins B₆, B₁₂, C, and E** is recommended as supportive measures in reducing blood pressure.

Multiple studies have found that aspirin acts as a blood-thinning, or clot-reducing, medication when taken

KEY TERMS

Aneurysm—A pouch-like bulging of a blood vessel.

Angiography—The procedure that enables blood vessels to be seen on film after the vessels have been filled with a substance that shows up opaque on x rays.

Arrhythmia—An abnormality of the rhythm or rate of the heartbeat.

Arteriole—The tiny extensions that arteries eventually break down into as they circulate blood.

Artery—Pliable, three-layered vessels that carry the blood away from the heart.

Atherosclerosis—Disease of the arterial wall in which the inner layer thickens, causing narrowing of the channel and thus impairing blood flow.

Computerized tomography (CT) scan—The diagnostic technique in which the combined use of a computer and x rays passed through the body at different angles produces clear, cross-sectional images of the tissue being examined.

Ischemic—Insufficient blood supply to a specific organ or tissue.

Lumbar puncture—A procedure in which a hollow needle is inserted into the lower part of the spinal

canal to withdraw cerebrospinal fluid (the clear liquid which surrounds the brain and spinal cord), or to inject drugs or other substances.

Magnetic resonance imaging (MRI)—The diagnostic technique that provides high quality cross-sectional images of organs or structures within the body without x rays or other radiation.

Myocardial infarction—Heart attack; sudden death of part of the heart muscle characterized in most cases by severe, unremitting chest pain.

Polycythemia—Increased number of red cells in the blood.

Sleep apnea—A condition in which a person experiences episodes of cessation of breathing lasting 10 seconds or longer during sleep.

Thrombotic—Pertaining to a blood clot formed within an intact blood vessel as opposed to a clot formed to seal the wall of a blood vessel after an injury.

Transient ischemic attack (TIA)—Occlusion of smaller blood vessels to the brain that can produce stroke-like symptoms for anywhere from a few minutes to 24 hours, but leaves no permanent damage.

in small doses. One aspirin tablet per day provides this anti-coagulant prevention.

If necessary, a physician may also order medication to lower blood pressure. These medications include the following categories of drugs:

- Beta blockers are used to reduce the force and speed of the heart-beat.
- Vasodilators are used to dilate the blood vessels.
- Diuretics reduce the total volume of circulating blood and thus the heart's work by removing fluid from the body.
- Lipid-lowering drugs increase the loss of cholesterol from the body or prevent the conversion of fatty acids to cholesterol. This lowers fat levels in the bloodstream.

Chemotherapy

Definition

Chemotherapy is the treatment of **cancer** with **anti-cancer drugs**.

Purpose

The purpose of chemotherapy is to kill cancer cells. Not only is it often used to treat patients with cancer that has metastasized (spread) from the site in the body where it originated, today chemotherapy can be used to prevent metastasis as well. Chemotherapy destroys cancer cells throughout the body, killing cells that have broken off from the main tumor and traveled through the **blood** or lymph systems to other parts of the body.

Chemotherapy can cure some types of cancer. In some cases, it is used to slow the growth of cancer cells or to keep the cancer from spreading to other parts of the body. When a cancer has been removed by surgery, chemotherapy may be used to keep the cancer from recurring; this is known as adjuvant therapy. Chemotherapy also can ease the symptoms of cancer, helping some patients to have a better quality of life.

Precautions

There are many different types of chemotherapy drugs. Oncologists (specialists in cancer) determine which drugs are best suited for each patient. This decision is based on the type of cancer, the patient's age, health, and preferences, as well as other drugs the patient is taking. Some patients may not tolerate certain chemotherapy drugs if they have other illnesses such as **heart** disease, kidney disease, or diabetes.

Chemotherapy, whether administered in the hospital, clinic, or at home, is prepared by the pharmacist. The pharmacy and pharmacy assistants provide and reinforce **patient education** about common as well as infrequent side effects of chemotherapy. When administered in the hospital, clinic, physician's office, or other treatment setting, it is usually administered by a specially trained nurse, mid-level practitioner (physician assistant or nurse practitioner), or physician.

Description

More than 50 chemotherapy drugs are currently available to treat cancer, and many more are being tested for their ability to destroy cancer cells. Most chemotherapy drugs interfere with the ability of cells to grow or multiply. Although these drugs affect all cells in the

body, most useful treatments are more effective against rapidly growing cancer cells. Since chemotherapy affects rapidly growing cells, it often affects cells that normally grow rapidly such as cells in the bone marrow, **stomach** intestines, and hair follicles. This is why some of the most common side effects of chemotherapy are bone marrow suppression, nausea, vomiting, and hair loss.

Types of chemotherapy drugs

Chemotherapy drugs are classified based on their mechanisms of action (how they work). The main types of chemotherapy drugs are:

- Alkylating drugs kill cancer cells by directly attacking DNA, the genetic material of the genes. Cyclophosphamide is an example of an alkylating drug.
- Antimetabolites interfere with the production of DNA thereby preventing cells from growing and multiplying. An example of an antimetabolite is 5-fluorouracil (5-FU).
- Antitumor **antibiotics** are made from natural substances such as **fungi** in the soil. They interfere with important cell functions, including production of DNA and cell **proteins**. Doxorubicin and bleomycin belong to this group of chemotherapy drugs.
- Plant alkaloids prevent cells from dividing normally. Vinblastine and vincristine are plant alkaloids obtained from the periwinkle plant.
- Steroid hormones slow the growth of some cancers that depend on hormones. For example, tamoxifen is used to treat breast cancers that depend on the hormone estrogen for growth.

Combination chemotherapy

The oncologist decides which chemotherapy drug or combination of drugs will work best for each patient. The use of two or more drugs together often works better than a single drug alone. This is called combination chemotherapy. Scientific studies and clinical research trials of different drug combinations help determine which combinations are most effective for each type of cancer.

How chemotherapy is administered

Chemotherapy is administered in different ways, depending on the drugs to be given and the type of cancer. The prescribed dose depends on several factors, one of which is the patient's body weight.

Chemotherapy may be administered by one or more of the following methods:

- orally

Patient undergoing high dose stem cell chemotherapy.
(Custom Medical Stock Photo. Reproduced by permission.)

- intramuscular (IM) or subcutaneous injection
- through a catheter or port
- topically

Oral chemotherapy, given by mouth, may be in the form of a pill, capsule, or liquid. This is the easiest method of administration and can usually be done at home.

Intravenous (IV) chemotherapy is injected into a vein. A small needle is inserted into a vein on the hand or lower arm. The needle is usually attached to a small tube called a catheter, which delivers the drug to the needle from an IV bag or bottle.

Intramuscular (IM) chemotherapy is injected into a muscle. Chemotherapy given by **intramuscular injection** is absorbed into the blood more slowly than IV chemotherapy. Because of this, the effects of IM chemotherapy may last longer than chemotherapy given intravenously. Chemotherapy may also be injected sub-

cutaneously (under the skin). Injection of chemotherapy directly into the cancer is called intralesional injection.

Chemotherapy may also be given by a catheter or port permanently inserted into a central vein or body cavity. A port is a small reservoir or container that is placed in a vein or under the skin in the area where the drug will be administered. These methods eliminate the need for repeated injections and may allow patients to spend less time in the hospital while receiving chemotherapy. A common location for a permanent catheter is the external jugular vein in the neck. Intraperitoneal (IP) chemotherapy is administered into the abdominal cavity through a catheter or port. Chemotherapy administered by catheter or port into the spinal fluid surrounding the **brain** or spine is called intrathecal (IT) administration. Catheters and ports may also be placed in the chest cavity, bladder, or pelvis, depending on the location of the cancer to be treated.

Topical chemotherapy is given as a cream or ointment applied directly to the cancer. It may be used to treat certain types of skin cancer.

Treatment location and schedule

Patients may take chemotherapy at home, in the physician's office, or as an inpatient or outpatient at the hospital. Many patients stay in the hospital when first beginning chemotherapy, so they can be observed and monitored for any side effects.

The frequency and duration of chemotherapy given depends on the type of cancer, the patient response to the drugs, patients' overall health and ability to tolerate the drugs, and on the types of drugs used. Chemotherapy administration may take only a few minutes or may last as long as several hours. Chemotherapy may be given daily, weekly, or monthly. A rest period may follow a course of treatment before the next course begins. In combination chemotherapy, more than one drug may be given at the same time, or they may be given alternately, one following the other.

Preparation

A number of medical tests are performed before chemotherapy is started. The oncologist will determine the extent to which the cancer has spread from the results of x rays and other imaging tests and from biopsies. Radiologic technologists and technicians perform imaging studies. Analysis of the biopsy will be performed by a pathologist, assisted by laboratory technicians.

Blood tests, drawn by laboratory technicians or nurses, provide important information about the function of the blood cells and levels of chemicals in the blood. A **complete blood count** (CBC) is commonly performed

before and on a regular basis during treatment. The CBC shows the numbers of white blood cells, red blood cells, and platelets in the blood. Because chemotherapy affects the bone marrow, where blood cells are made, levels of these cells often drop during chemotherapy. The white blood cells and platelets are most likely to be affected by chemotherapy. A drop in the white blood cell count means that the **immune system** may not function properly and the patient may become prone to **infection**. Low levels of platelets may cause a patient to bleed from minimal trauma or even spontaneously with no trauma. A low red blood cell count can lead to anemia (deficiency of red blood cells) and fatigue.

Sometimes, patients taking chemotherapy drugs known to cause nausea are given antiemetics before chemotherapy is administered to lessen feelings of nausea. Two anti-nausea medications that may be used are Kytril and Zofran.

Patients may also be advised to prepare for chemotherapy and reduce nausea by eating and drinking normally until about two hours before a chemotherapy session. They should eat high carbohydrate, low-fat foods and avoid spicy foods.

Aftercare

Patient education about how to control side effects after chemotherapy includes:

- Encouraging patients to adhere to instructions given by their health care team.
- Reinforcing correct use of all prescribed medications.
- Advising patients to eat small amounts of bland foods and drink lots of fluids.
- Instructing patients to get plenty of rest.

Some patients find that breathing fresh air or mild **exercise**, such as walking, helps to relieve the **stress** and side effects associated with chemotherapy.

Complications

Chemotherapy drugs are toxic to normal cells as well as cancer cells. Doses that will destroy cancer cells will likely cause damage to some normal cells. Physicians adjust (titrate) doses to do the least amount of harm possible to normal cells. Some patients feel few or no side effects, and others may experience more serious side effects. In some cases, a dose adjustment is all that is needed to reduce or stop a side effect.

Some chemotherapy drugs have more side effects than others. The most common side effects include:

- nausea and vomiting

- loss of appetite
- hair loss (alopecia)
- anemia and fatigue
- infection
- easy bleeding or bruising
- sores in the mouth and throat
- neuropathy and other damage to the nervous system
- kidney damage

Nausea and vomiting are common, but can usually be controlled by taking antinausea drugs, drinking enough fluids, and avoiding spicy foods. Loss of appetite may be due to nausea or the stress of undergoing cancer treatment. Also, although some chemotherapy drugs cause alopecia, it is almost always temporary and reversible.

Low blood cell counts caused by the effect of chemotherapy on the bone marrow can lead to anemia, infections, and easy bleeding and bruising. Patients with anemia have too few red blood cells to deliver oxygen and nutrients to the body's tissues. Anemic patients feel tired and weak. If red blood cell levels fall too low, a blood transfusion may be given.

Patients receiving chemotherapy are more likely to get infections because white blood cells are reduced. It is important to take measures to avoid infections. When the white blood cell count drops too low, the physician may prescribe medications called colony-stimulating factors that help white blood cells grow. Neupogen and Leukine are two colony stimulants used as treatments to help fight infection.

Platelets are blood particles that make the blood clot. When patients do not have enough platelets, they may bleed or bruise easily, even from small injuries. Patients with low blood platelets should be advised to take precautions to avoid injuries. Medicines such as aspirin and other **pain** relievers can impair platelet function and slow the clotting process.

Chemotherapy can cause irritation and dryness in the mouth and throat. Painful sores may form that can bleed and become infected. Patients should be advised about actions they might take to prevent or reduce mouth irritation. Precautions to avoid this side effect include dental care before chemotherapy begins, brushing the teeth and gums regularly with a soft brush, and avoiding mouthwashes that contain salt or alcohol.

Results

The primary goal of chemotherapy is to cure cancer. Some cancers, such as Hodgkin's disease and acute lym-

KEY TERMS

Adjuvant therapy—Treatment given after surgery or radiation therapy to prevent the cancer from coming back.

Alkaloid—A type of chemical commonly found in plants and often having medicinal properties.

Alykylating drug—A drug that kills cells by directly damaging DNA.

Antiemetic—A medicine that helps control nausea; also called an anti-nausea drug.

Antimetabolite—A drug that interferes with a cell's growth or ability to multiply.

Platelets—Blood cells that function in blood clotting.

phocytic leukemia, may be cured by chemotherapy. Used as adjuvant therapy, in combination with surgery, it may prevent a cancer from spreading to other parts of the body. Some widespread, fast-growing cancers are more difficult to treat. In these cases, chemotherapy may slow the growth of the cancer cells.

Physicians determine the extent to which chemotherapy is effective by closely monitoring the results of medical tests. **Physical examination**, blood tests, and imaging studies are used to monitor and assess the effects of treatment on the cancer.

The outcomes of chemotherapy include:

- Complete remission or complete response. The cancer completely disappears. The course of chemotherapy is completed, and the patient is tested regularly for a recurrence.
- Partial remission or partial response. The cancer shrinks in size but does not disappear. The same course of chemotherapy may be continued, or a different combination of drugs may be tried.
- Stabilization. The cancer does not grow or shrink. Other therapy options may be explored. A tumor may remain stabilized for many years.
- Progression. The cancer continues to grow. Other therapy options may be explored.
- A new type of malignancy may develop, and this secondary cancer may require additional chemotherapy or other treatment.

Health care team roles

Patients with cancer are usually cared for by a multidisciplinary team of health professionals. The patient's family physician or primary care physician collaborates with other specialists, such as surgeons and oncologists. Radiologic technicians perform imaging studies, and nurses and laboratory technicians may obtain samples of blood, urine, and other laboratory tests.

Before and after chemotherapy, nurses explain the goals and effects of drug treatment and help to prepare patients and families. Depending on the treatment plan, cancer patients may also benefit from rehabilitation therapy with physical therapists, nutritional counseling from dietitians, and counseling from social workers or other mental health professionals.

Chest computed tomography scan *see*
Chest CT scan

Chest CT scan

Definition

Computed tomography (CT) of the chest is performed to diagnose a variety of symptoms, including vas-

cular, cardiac, airway disease as well as cancers that can occur in the thoracic region of the body.

Purpose

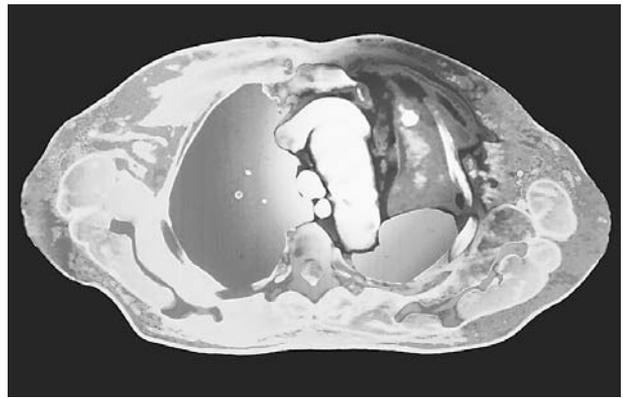

The purpose of the CT scan is to noninvasively and quickly visualize internal organs which may be damaged by disease or trauma.

Precautions

Pregnant women usually defer these types of scans due to the amount of radiation received during the examination; however due to an emergent situation, (e.g., trauma or pulmonary embolism) it may be necessary to scan a gravid woman. Proper shielding is always recommended in these situations. Radiation dose should always be limited to the amount necessary to adequately penetrate the selected body part. Lead shielding will also provide some protection to patients, although most radiation to other organs outside of the chest is from scattering within the body, which cannot be reduced by shielding. The greatest radiation protection is a well-trained technologist who understands the type of exam and who can assess the body habitus of the patient to determine the correct amount of radiation needed for the patient. Patients with a mild allergy to iodine may be premedicated to prevent sequelae of the administration of contrast. If a patient has a severe allergy, then a scan without IV contrast may be undertaken or a different imaging modality may be used to answer the clinical question. Diabetic patients who are taking Glucophage or Glucovance should stop taking the medication at the time of or before the scan and 48 hours after. The medications should only be reinstated after normal renal status has been established through lab values. Stopping and restarting of medications should only be done after consultation with the attending nephrologist.

Description

A brief list of these conditions, which can be imaged by CT, includes **infection**, trauma, aortic dissections, staging for **cancer**, and assessment of interstitial lung disease. The entire chest is imaged, unless a specialized limited exam is ordered to focus on a smaller area. The technique for CT examination of the chest is similar to other anatomic regions of the body. The patient lies on a special table, which moves a patient through an opened gantry, which contains a rotating combination of a x-ray tube and a complex array of sensitive detectors. A radiologic technologist gives the patient instructions to lie still and hold the breath while the images are being acquired. This limits the number of artifacts caused by voluntary

A chest computed tomography (CT) scan shows the collapse of the right lobe of a patient's lung. (Photo Researchers, Inc. Reproduced by permission.)

and involuntary motion. X rays are passed through a patient. As they pass through a patient, the energy of the beam is attenuated, or decreased by the density of the tissue they pass through. The denser the tissue, the fewer number of x rays that pass through the body. Sensitive detectors, which continually rotate around the patient, translate the beam into numbers, which then are translated into shades of gray and viewed as a final image for the radiologist to interpret.

The patient may be scanned with or without IV contrast depending on which type of pathology is to be demonstrated. If a tumor or vascular pathology is suspected, intravenous contrast is usually given. Certain exams do not require IV contrast to get high quality images. These exams include low-dose **lung cancer** screening, lung nodule work ups, and high-resolution chest exams for conditions such as asbestosis. If a lung nodule is the indication for the exam, a non-contrast study may be performed first, to confirm if there is **calcium** in the nodule. If calcium is present in the pattern, then no further examination is required because that is an indicator of a benign lesion. Occasionally, oral contrast will be used to demonstrate a hiatal hernia or a barium paste will be ingested to demonstrate esophageal lesions or stricture. As scanners become faster, patients do not have to hold the breath for as long a period. With current multislice technology, a standard chest CT can be completed in less than ten seconds. This is a great benefit to patients who are short of breath, due to any number of lung conditions, including **emphysema** and chronic obstructive pulmonary disease (COPD). As computer speed and detector sensitivity increases, examination time will continue to decrease with lower cost and radiation exposure.

KEY TERMS

Computed tomography—The technique of imaging a patient with ionizing radiation to diagnose disease process.

Non-ionic intravenous contrast—A injectable x-ray dye that mixes with the blood to enhance structures aiding their ability to be judged as health or diseased.

Preparation

If IV contrast is to be used the patient should remain NPO (not given anything by mouth) for at least four hours. Occasionally to view possible esophageal pathology, patients will ingest oral contrast to help delineate possible mediastinal lymph nodes or gastric tumors. Patients should also remove any metal jewelry or clothing accessories to prevent artifacts from decreasing the diagnostic quality of the images. Certain lab values may be necessary before the scan is undertaken. These would include the BUN (**blood** uria nitrogen) and creatinine levels to assess the patient's renal status. A high creatinine could contraindicate the use of IV contrast as the **kidneys** are the main organs which excrete the contrast. If a patient is on renal dialysis, then the values are usually higher, and the scan is prior to that day's dialysis treatment.

Aftercare

If the patient received IV contrast, a small bandage will be placed over the injection site, and it should be treated with the same care one would receive after donating blood. Patients should also drink plenty of clear fluids to help flush the iodinated contrast out of their kidneys to prevent any kidney damage.

If the patient is in renal failure then it will be necessary to dialyze the patient soon after the procedure. These arrangements should be made before hand with the knowledge and consent of the consulting nephrologist.

If the patient received any oral contrast it will pass through the GI tract with the next day or two. As the contrast used for CT is much thinner than the standard barium used for GI fluoroscopy studies there should be no problems with constipation.

Complications

Several complications are possible, though are relatively unlikely as long as care is taken during the procedure. These precautions would include the careful super-

vision of the injection of the IV contrast as an infiltration could result in a painful collection of contrast around the IV site. If the patient has a known allergy to iodine, then premedication will be necessary to prevent any sort of histamine reaction. The reaction can be mild, such as **hives**, to life-threatening if the patient were to have a larygospasm. With newer and safer non-ionic contrast, reactions have become less frequent, however this does not mean that technologists should be any less vigilant for signs of a mild reaction to the contrast media. There is also a small risk of renal failure in certain high-risk patients.

Results

The results are given in a written report that is sent to multiple locations including the patients referring physician, the file room of the radiology department and to the patient's permanent medical record if they were an inpatient at the time of their study. A verbal report will occasionally be used as well to help speed up the communication of results to the appropriate physicians. If there are previous examinations, the radiologist will consider if there has been a change as judged by the appearance of any pathology on the images.

Health care team roles

The main team member involved in the CT of the chest is the radiologic technologist who has been trained to perform CT exams. If the physician ordering the procedure can confirm the lab values before the patient arrives, and if they are an inpatient, assuring that the patient's IV line is patent and safe for use will streamline the examination.

Chest drainage therapy see **Chest physical therapy**

Chest physical therapy

Definition

Chest **physical therapy** (CPT) is the term for a group of treatments designed to improve respiratory efficiency, promote expansion of the **lungs**, strengthen respiratory muscles, and eliminate secretions from the **respiratory system**.

Purpose

The purpose of chest physical therapy, also called chest physiotherapy, is to help patients breathe more freely and to get more oxygen into the body.

Chest physical therapy includes postural drainage, chest percussion, chest vibration, turning, breathing exercises, coughing, and incentive spirometry. CPT is usually done in conjunction with other treatments to rid the airways of secretions. These other treatments include suctioning, nebulizer treatments, and the administration of expectorant drugs.

Chest physical therapy can be used with newborns, infants, children, and adults. People who benefit from chest physical therapy exhibit a wide range of problems that make it difficult to clear secretions from their lungs.

Patients who may receive chest physical therapy include those with **cystic fibrosis**, neuromuscular diseases (such as Guillain-Barré syndrome), progressive muscle weakness (such as myasthenia gravis), or tetanus. People with lung diseases such as **pneumonia**, bronchitis, and some forms of chronic obstructive pulmonary disease (COPD), including chronic bronchitis, also benefit from chest physical therapy. CPT should not be used in the treatment of patients diagnosed with **asthma**.

People without specific lung problems but who are likely to aspirate their mucous secretions because of diseases such as **cerebral palsy** or **muscular dystrophy** also receive chest physical therapy, as do those who are bedridden or confined to a wheelchair. In addition, CPT may be part of treatment after surgery for patients who develop difficulty taking deep breaths.

Precautions

While the doctor ultimately determines which type of therapy can be performed, health care professionals know that not all forms of chest physical therapy are appropriate for all patients. Postural drainage and percussion should not be administered to patients who:

- have just eaten or are vomiting
- have acute asthma or tuberculosis

- have brittle bones or broken ribs
- are bleeding from the lungs or are coughing up **blood**
- are experiencing intense pain
- have increased pressure in the skull
- have head or neck injuries
- have collapsed lungs or a damaged chest wall
- recently experienced a **heart** attack
- have a pulmonary embolism or lung abscess
- have an active hemorrhage
- have injuries to the spine
- have open **wounds** or burns
- have had recent surgery

Description

Chest physical therapy can be performed in a variety of settings including critical care units, hospitals, **nursing homes**, outpatient clinics, and in the patient's home. Depending on the circumstances, chest physical therapy may be performed by anyone ranging from a respiratory care therapist to a trained member of the patient's family. Patients can be taught to perform some therapies.

Lengths of therapies and their costs vary. Some therapies may be part of ongoing treatment for a chronic condition. Special equipment may be needed for some procedures, such as percussion, and may be covered by the patient's health plan.

Chest physical therapy encompasses a variety of procedures; which ones are applied depends on the patient's needs. Hospitalized patients are reevaluated frequently to establish which procedures are most effective and best tolerated. Patients receiving long term chest physical therapy are reevaluated about every three months.

Turning

Turning from side to side permits lung expansion. Patients who cannot turn themselves are turned by a caregiver. The head of the bed is also elevated to promote drainage if the patient can tolerate this position. Critically ill patients and those dependent on mechanical respiration are turned once every one to two hours around the clock.

Coughing

Coughing helps break up secretions in the lungs so that the mucus can be suctioned out or expectorated. However, for patients with conditions like COPD, it can be painful to cough normally. An important part of chest

A patient with cystic fibrosis receives chest physical therapy after using nebulizer therapy to loosen the mucus in her lungs. (Photograph by Simon Fraser. Science Source/Photo Researchers. Reproduced by permission.)

physical therapy is teaching patients to clear their airways by gentler methods, such as with a controlled cough or by “huffing.”

Before either technique, patients are advised to sit upright and drink a glass of water. For the controlled cough, patients purse their lips and take a deep breath. They hold their breath for several seconds and then make two brief, gentle coughs. Huffing also starts with pursing the lips and taking a deep breath. After holding the breath for several seconds, patients exhale by using the **stomach** muscles to push the air out. The vocal chords remain open so that the cough has almost a whispery sound. Coughing and huffing are repeated several times a day as needed.

Deep breathing exercises

Deep breathing helps expand the lungs and forces better distribution of the air into all areas. The patient may initially need to lie down to do these exercises, but eventually it is done while sitting upright, then while walking.

Patients may find it helpful to monitor their breathing by placing a hand on their abdomen to provide a sense of their regular breathing pattern. The patient then starts by taking a deep breath through the nose, then purses the lips as if to whistle. The patient then exhales the air slowly through pursed lips. The exhalation should take twice as long as the inhalation. A patient may start by inhaling for two seconds and then exhaling for four. After taking several deep breaths, the patient breathes at a normal rhythm and begins another cycle of deep breathing. The patient builds up to taking deeper breaths, following a schedule given by the health care team. Generally, COPD patients practice deep breathing exercises for 20 minutes each day.

Incentive spirometry

The incentive spirometer helps the patient improve lung function. This self-administered therapy involves inhaling into a tube attached to a device. The specific technique and goal depends on the type of spirometer. The patient receives directions from the doctor, nurse, or respiratory therapist.

With a breath flow-oriented device, the patient inhales through a tube to raise a ball inside the plastic spirometer chamber. The drop in pressure causes the ball to rise, and the goal is to keep the ball in the air for as long as possible.

For a volume-oriented device, the patient sets a pointer on the chamber at the desired breath volume level. The patient inhales into the tube and attempts to raise a piston inside the chamber so that the volume marker reaches that level.

Hybrid volume accumulators combine a flow-oriented device with a volume-oriented device. A piston inside a cylinder responds to negative pressure from the patient’s inhalation.

Some devices have a component designed for exhalation. If the model does not include an exhaling function, the patient breathes out air naturally.

At the end of the session, the patient takes a deep breath and then coughs. The length of therapy and the number of exercises done depend on the patient’s condition and is determined by a respiratory therapist or other health professional.

Postural drainage

Postural drainage uses gravity to assist in draining secretions from the lungs and into the central airway where they can either be coughed up or suctioned out. This therapy generally lasts a maximum of 30 minutes. If various positions are tried to induce a cough, the patient may remain in one position for from five to 15 minutes. The health care team guides the patient in determining the amount of time needed. Each position reaches a specific area of the lungs. Chest drainage positions include:

- the patient seated with head back
- the patient seated with head bent forward
- the patient lying face up with feet higher than the head
- the patient lying face down with feet higher than the head
- the patient lying first on one side, then the other, with feet higher than the head

Critical care patients and those depending on mechanical ventilation receive postural drainage therapy

four to six times daily. Patients at home are given schedules set by their doctor or respiratory therapist. Percussion and vibration may be performed in conjunction with postural drainage.

Percussion

Percussion, also called cupping or clapping, involves rhythmically striking the chest wall with cupped hands. Mechanical devices can also be used. Percussion results in breaking up thick secretions in the lungs so that they can be more easily removed. Percussion is performed on each lung segment for one to two minutes at a time.

Vibration

Vibration therapy is done for one minute after percussion therapy or may be used instead of percussion therapy for patients who may be too sore or frail to tolerate percussion. The purpose is also to help break up lung secretions. Vibration can be performed either mechanically or manually. When done manually, the person performing the vibration places his or her hands against the patient's chest and creates vibrations by quickly contracting and relaxing arm and shoulder muscles while the patient exhales. The procedure is repeated several times each day for about five exhalations.

Preparation

Preparation for chest physical therapy starts with an evaluation of the patient's condition to determine which chest physical therapy techniques would be most beneficial. Since most therapies are done at home, **patient education** is extremely important. The doctor, nurse, physical therapist, or respiratory therapist instructs the patient or caregiver in chest physical therapy techniques. The therapy should be explained and demonstrated by the health professional. Then the patient or caregiver should try the therapy. This will demonstrate whether the patient understands the therapy or if more instruction is needed.

Aftercare

Patients should be advised to practice **oral hygiene** procedures to lessen the bad taste and odor of the secretions that they spit out.

Complications

Risks and complications associated with chest physical therapy depend on the health of the patient. Although chest physical therapy usually poses few problems, the health care team should be aware that in some patients it may cause:

- oxygen deficiency if the head is kept lowered for drainage
- increased intracranial pressure
- temporary low blood pressure
- bleeding in the lungs
- pain or injury to the ribs, muscles, or spine
- vomiting
- inhaling secretions into the lungs
- heart irregularities

Results

The health care team should tell patients that CPT is often an ongoing treatment, with some or all therapies done daily. A positive response to treatment can be assessed by:

- increased volume of sputum secretions
- ease in breathing
- changes in breath sounds
- improved vital signs
- improved chest x ray
- increased oxygen in the blood as measured by arterial blood gas values

Health care team roles

The doctor typically orders chest physical therapy for a patient. A nurse or respiratory therapist provides therapy when a patient is hospitalized. For people seen on an outpatient basis, the emphasis is generally on patient education.

Patient education

Effective patient education is vital because chest physical therapy is often performed at home. A doctor, nurse, or respiratory therapist explains and demonstrates techniques such as breathing, percussion, and incentive spirometry. The patient or caregiver performs the therapy under the health professional's observation to be sure it can be done correctly independently.

Nurses and respiratory therapists also participate in public awareness education, such as anti-smoking campaigns.

Training

Chest physical therapy is part of training for physicians and nurses specializing in cardiopulmonary treatment, and for respiratory therapists (also known as respi-

ratory care practitioners). Therapists must have at least an associate degree, which is earned after completion of a two-year program. There are also four-year bachelor degree programs for this profession. Graduates with both types of degrees are certified after passing the examination given by the National Board for Respiratory Care.

Chest tube maintenance

Definition

A chest tube is a drain placed into the pleural space to restore intrapleural pressure and reinflate the lung after it has collapsed. It also acts to prevent fluid and air from returning to the chest. Chest tube maintenance includes the actions performed by the nurse or other health care professional to keep the tube functioning properly.

Purpose

Under normal circumstances, intrapleural pressure is below atmospheric pressure. When this pressure changes because of excess air and/or fluid, the lung may collapse. If this occurs, a chest tube is inserted into the intrapleural space. This lets excess fluids drain, restores normal pressure, reinflates the lung, and allows adequate **gas exchange**. Persons experiencing a pleural effusion (accumulation of fluid in the spaces of the pleura), hemothorax (accumulation of **blood** in the pleural cavity), pneumothorax (collapsed lung), and empyema (accumulation of pus in the pleural cavity) may all require the insertion of a chest tube.

Precautions

The patient requiring a chest tube is acutely ill because any change in the intrapleural pressure compromises the patient's ability to breathe. An oxygen source, suction, and emergency equipment must be nearby when this procedure is performed.

Description

Depending on the patient's condition, the chest tube insertion may occur at the bedside, in the emergency room, or in the operating room. In any case, the insertion of a chest tube is a sterile procedure. Most hospitals have chest tube insertion trays containing all of the necessary supplies. First, the health care provider administers a local anesthetic. The patient is positioned according to the type of lung collapse being treated. After making a small incision, the physician inserts the chest tube. To avoid accidental puncture of the lung or pleura, the patient should be reminded not to cough or move during the procedure. Once the chest tube is in and sutured in place, the tube will be attached to a drainage system. Vaseline gauze may be placed at the chest tube insertion site to make certain an adequate seal has been achieved. Sterile 4 × 4 gauze pads will be placed over the Vaseline gauze, then securely taped. It is wise to tape the far end of the chest tube to the patient's chest to prevent dislodgement.

Preparation

The patient may be anxious about the procedure. Providing privacy and emotional support, along with explaining the procedure may help calm the patient. The nurse should perform a baseline assessment and take **vital signs**. An **informed consent** should be signed if the patient is able to do so. The physician may order pre-

medications, which should be administered by the nurse as prescribed.

Aftercare

After the chest tube has been inserted, it is the nurse's responsibility to maintain a patent (clear) and intact pleural drainage system. The chest tube will be connected to about 6 ft (1.8 m) of rubbery tubing that leads to a collection device several feet below the chest. The patient should be instructed to avoid lying on the tubing, and the nurse must make certain no kinks occur. All tubing connections should be taped to prevent air leaks.

The chest drainage system has a separate water seal that acts as a one-way valve. The nurse adds a specified amount of sterile saline to this water seal chamber and makes sure the end of the tubing stays in the fluid. When air is pushed out of the pleural space and through the tubing, it bubbles into the saline and cannot return to the chest. If necessary, suction may be added to the drainage system. The depth of the saline determines the maximal allowable suctioning for the system.

The nurse should note and document the amount and color of the chest tube drainage, and the level of drainage should be marked at the end of each shift. The patient's respiratory status should be assessed frequently. It is normal to note decreased breath sounds on the side of the chest tube. The patient should be encouraged to perform coughing and deep-breathing exercises.

Complications

Several complications can occur when managing a patient with a chest tube. If the tube accidentally becomes dislodged, the open insertion site should be quickly covered with Vaseline gauze and the physician notified. If the tubing becomes disconnected from the drainage system, the chest tube should be clamped. (Padded clamps should be kept at the bedside at all times.) Both of these situations, if untreated, could allow air to enter the lung. Sometimes clots can form within the tube and prevent free drainage. If this happens, the tube should be milked gently, squeezing it to move the clot, but not handling it so firmly that the tubing becomes occluded.

If the drainage system unit is damaged or cracked, allowing atmospheric pressure into the system, the uncontaminated end of the connective tubing should be placed into sterile saline or water to a depth of 0.79 in (2 cm) until a new system can be obtained. Finally, a patient with a chest tube is at increased risk for **infection**. This risk can be reduced by cleaning the chest tube site and changing the dressing regularly.

KEY TERMS

Atmospheric pressure—The force exerted by air at any point on the earth's surface. Mean atmospheric pressure at sea level is approximately 1,000 millibars (100 kilopascals), give or take 5%.

Empyema—A collection of pus in the pleural space.

Hemothorax—Blood in the pleural cavity, usually caused by a chest injury.

Intrapleural—Situated within the pleura or pleural cavity

Pleura—Thin membrane that covers each half of the thorax, surrounding and protecting the lung on that side.

Pleural cavity—The space within each pleura, which contains the lungs.

Pleural effusion—Fluid in the pleural cavity, caused by, among other things, congestive heart failure, cancer, tuberculosis, and lung infections.

Pneumothorax—Air in the pleural cavity, which causes the lung to collapse. Causes include lung disease, penetrating trauma, and certain medical procedures, including ventilation and cardiopulmonary resuscitation.

Valsalva maneuver—Holding the breath while bearing down. This maneuver may be used to interrupt a mild heart arrhythmia or to prevent air from entering the pleural cavity when a chest tube is removed.

Results

The chest tube can be removed when one of the following has happened:

- The lung has fully expanded.
- No air leak has developed during a 24–48 hour period.
- Less than 5.07 oz (150 ml) of fluid has drained in a 24-hour period.

Normally, the physician removes the chest tube while the patient performs a Valsalva maneuver. Vaseline gauze is immediately applied over the insertion point. This prevents any air from entering the pleural space.

Health care team roles

The physician is responsible for inserting the chest tube and is usually responsible for its removal. (Some nurse prac-

tice acts allow nurses to remove chest tubes.) The nurse assists with the insertion procedure, assesses the patient's respiratory status afterwards, and maintains a patent chest tube.

Chest x ray

Definition

A chest x ray is a procedure used to evaluate organs and structures within the chest for symptoms of disease. Chest x rays include views of the **lungs**, **heart**, small portions of the gastrointestinal tract, and the bones of the chest area. X rays are a form of radiation that can penetrate the body and produce an image on an x ray film. Another name for the x ray image is radiograph.

Purpose

Chest x rays are ordered for a wide variety of diagnostic purposes. In fact, this is probably the most frequently performed x ray exam. In some cases, chest x rays are ordered for a single check of an organ's condition, and at other times, serial x rays are ordered to compare to previous studies. Some common reasons for chest x rays include:

Pulmonary disorders

Chest films are frequently ordered to diagnose or rule out **pneumonia**, bronchitis, pleurisy, **tuberculosis**, and other acute illnesses. Other pulmonary disorders such as **emphysema** or pneumothorax (presence of air or gas in the chest cavity outside the lungs) may be detected or evaluated through the use of chest x ray. It might also show vascular damage in the lung, which would require further evaluation.

Cancer

A chest x ray may be ordered by a physician to check for possible tumors of the lungs, thyroid, lymph nodes, or even the displacement of an organ by a tumor, if present. Chest x rays can occasionally be used to check for secondary spread of **cancer** from one organ to another.

Cardiac disorders

Although less sensitive than **echocardiography** to evaluate the heart, chest x ray is preferred to check for disorders such as congestive **heart failure** or pulmonary **edema**. Pericardial effusion (fluid surrounding the heart), if present, and cardiac size will also be noted on the chest x ray.

Other

Chest x rays can be used to see **foreign bodies** that may have been swallowed or inhaled, and to evaluate response to treatment for various diseases. The chest x ray is also used to verify correct placement of chest tubes or catheters in acutely ill patients.

Precautions

Pregnant women, particularly those in the first or second trimester, should not have chest x rays unless absolutely necessary. If the exam is ordered, women who are, or could possibly be, pregnant must wear a protective lead apron, with the full coverage adjusted for the direction of the x-ray beam. Because the procedure involves radiation, care should always be taken to avoid overexposure, particularly for children. However, the amount of radiation from one chest x ray procedure is minimal.

Description

Routine chest x rays consist of two views: the frontal view (referred to as posterior-anterior or PA) and the lateral (side) view, with the left side against the x-ray board. It is preferred that the patient stand for this exam.

The patient must remain motionless, and will be asked to take in a big breath for each x ray. Filling the lungs with air expands the lung fields, and shows the anatomy at its most optimum. In addition, the deep inspiration of air also helps the patient remain motionless, which is critically important in such a short x-ray exposure.

The chest x ray may be performed in a physician's office or referred to an outpatient radiology facility or hospital radiology department. In some cases, particularly for bedridden patients, a portable chest x ray may be taken. Portable films are sometimes of poorer quality than those taken with permanent equipment, but are the

best choice for some patients or situations. Bedridden patients may be placed in as upright a position as possible to get the best possible image.

Preparation

There is no advance preparation necessary for chest x rays. Once the patient arrives at the exam area, the patient will undress to the waist, and wear a gown or drape as provided by the facility. All necklaces will be removed as well.

Aftercare

No aftercare is required by patients who have chest x rays.

Complications

The only risk associated with chest x ray is minimal exposure to radiation, particularly for pregnant women and children. Those patients should use protective lead aprons during the procedure. Technologists are cautioned to carefully check possible dislodging of any tubes or monitors in the chest area from the patient's placement during the exam, if IVs (intravenous lines) or chest tubes are in place.

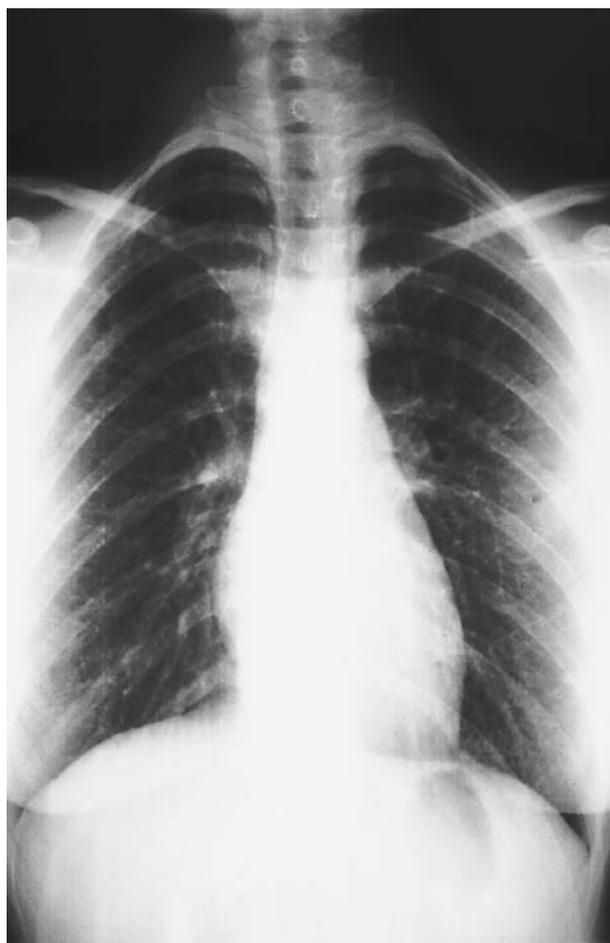

Results

A radiologist, or physician specially trained in the technique and interpretation of x rays, will evaluate the results. A normal chest x ray will show normal structures for the age and medical history or the patient. Findings, whether normal or abnormal, will be provided to the referring physician in the form of a written report.

Abnormal findings on chest x rays are used in conjunction with a physician's physical exam, medical history and other diagnostic tests to reach a final diagnosis. Often a patient can have normal appearing x rays and still have underlying diseases or conditions. Interpretation of chest x rays is most accurate when compared to previous chest studies. The patient may be asked to help the radiology facility in locating previous chest radiographs from other facilities.

Pulmonary disorders

Pneumonia shows up on radiographs as a patchy white area of density, as a result of fluid in the lung(s). If the bronchi, which are usually not visible, can be seen, a diagnosis of bronchial pneumonia may be made. Widening of the spaces between ribs, or very large, dark lung fields, also can be a radiographic sign of emphyse-

A chest x ray of normal, healthy adult lungs. (Photograph by John Smith, Custom Medical Stock Photo. Reproduced by permission.)

ma. Other pulmonary diseases may also be detected or suspected through chest x ray.

Cancer

In nearly all patients with **lung cancer**, some sort of abnormality can be seen on a chest radiograph. Hilar masses (enlargements at that part of the lungs where vessels and nerves enter) are one of the more common signs, as are abnormal masses and fluid buildup on the outside surface of the lungs or surrounding areas. Interstitial lung disease, which is a large category of disorders, many of which are related to exposure to substances (such as asbestos fibers), may be detected on a chest x ray as fiber-like deposits, often in the lower portions of the lungs.

Other

Congestive heart failure and other cardiac diseases may be diagnosed on the view of the heart and lung in a chest radiograph. **Fractures** of the sternum and ribs are

KEY TERMS

Bronchi—Plural of bronchus. The air passages in the lungs through which inhaled air passes on its way to the lungs.

Diaphragm—The large muscle that is located between the abdomen and the chest area. The diaphragm aids in breathing.

Gastrointestinal—The digestive organs and structures, including the stomach and intestines.

Interstitial lung disease—About 180 diseases fall into this category of breathing disorders. Injury or foreign substances in the lungs, (such as asbestos fibers) as well as infections, cancers, or inherited disorders may cause the diseases. They can lead to breathing or heart failure.

Lymphoid—Tissues relating to the lymphatic system. A thin yellowish fluid, called lymph fluid, travels throughout the body. The lymphatic system helps control fluids in the body.

Portable chest x ray—An x ray procedure taken by equipment that can be brought to the patient. The resulting radiographs may not be as high in quality as stationary x ray radiographs, but allow a technologist to come to the bedridden patient.

Pulmonary—Refers to the lungs and the breathing system and function.

Serial x rays—A number of x rays performed over time in the disease progression or treatment intervals. The radiographs will be compared to one another to track changes.

Sternum—Also referred to as the breast bone, this is the long flat bone in the middle of the chest.

Thorax—The chest area, which runs between the abdomen and neck and is encased in the ribs.

X ray—A form of electromagnetic radiation with shorter wavelengths than normal light. X rays can penetrate most structures.

sometimes also detected as breaks in the bone visible on the film. In some instances, the view of the diaphragm may indicate an abdominal problem. Foreign bodies which may have been swallowed or inhaled can usually be located by the radiologist as they will see the object either in the esophagus, or the upper part of the **stomach**, and will look different from any other tissue or structure in the chest. Serial chest x rays may be ordered to track changes in the position of an object over a period of time.

Health care team roles

The technologist performing the chest x ray is a highly trained professional and provides films for the radiologist to interpret. The technologist should be able to be versatile, should the patient have any physical challenges in complying with the x ray. In performing bedside, or portable chest x rays, often the assistance of nursing staff becomes necessary due to the condition of the patient. It should be the goal of both the technologist and/or nurse to ensure patient comfort, while getting the best possible radiograph.

Patient education

The technologist will explain the exam to the patient so that they feel comfortable with the procedure. Most adult patients are familiar with a chest x ray, nevertheless, a brief discussion between technologist and patient is important. Keeping the patient immobile during the exposure will limit having to repeat the x ray.

Child abuse

Definition

Child abuse is a blanket term for four types of child mistreatment: physical abuse, sexual abuse, emotional abuse, and neglect. In many cases children are the victims of more than one type of abuse. The abusers can be parents or other family members, caretakers such as

teachers and babysitters, acquaintances (including other children), and (in rare instances) strangers.

Description

Prevalence of abuse

Child abuse was once viewed as a minor social problem affecting only a handful of children in the United States. In recent years, however, it has received close attention from the media, law enforcement, and the helping professions, and with this has come a sharp rise in the number of reported cases. But because abuse is often hidden from view and its victims too young or fearful to speak out, some experts suggest that its true prevalence may be much greater than the official data indicate. In 1999, Child Protective Service (CPS) agencies investigated 3 million reports that involved the maltreatment of approximately 4 million children.

The CPS ranks neglect as the most common form of child maltreatment, comprising an estimated 54% of investigations in 1997. Physical abuse accounted for 24%; sexual abuse, 13%; emotional maltreatment, 6%; and medical neglect, 2%. Many children suffer more than one type of maltreatment.

Although experts are quick to point out that abuse occurs among all social, ethnic, and income groups, reported cases usually involve poor families with little education. Young mothers, single-parent families, and parental alcohol or drug abuse are also common in reported cases. According to recent statistics, more than 90% of abusing parents have neither psychotic nor criminal personalities. Rather, they tend to be lonely, unhappy, angry, young, single parents who do not plan their pregnancies. About 10%, or perhaps as many as 40%, of abusive parents were themselves physically abused as children, but most abused children do not grow up to be abusive parents.

Additional factors that contribute to child abuse include lack of parenting skills, unrealistic expectations about children's behavior and capabilities, social isolation, and frequent family crises. Child abuse is a symptom that parents are having difficulty coping with their situation.

In 1999, the majority of child abusers (75%) were parents, and another 10% were other relatives of the victim. About 13% of all perpetrators were classified as non-caretakers or unknown. People who were in other caretaking relationships to the victim (e.g., child care providers, foster parents, and facility staff) accounted for only 2% of perpetrators. In many states, perpetrators of child maltreatment by definition must be in a caretaking role.

Types of abuse

PHYSICAL ABUSE. Physical abuse is the nonaccidental infliction of physical injury to a child. The abuser is usually a family member or other caretaker, and is more likely to be male. In 1996, 24% of the confirmed cases of child abuse in the United States involved physical abuse. A rare form of physical abuse is Munchausen syndrome by proxy, in which a caretaker (most often the mother) seeks attention by making the child sick or appear to be sick.

SEXUAL ABUSE. Child sexual abuse is defined as any activity with a child under the age of legal consent that is for the sexual gratification of an adult or a significantly older child. It includes, among other things, sexual touching and penetration, persuading a child to expose his or her sexual organs, and allowing a child to view pornography. In most cases the child is related to or knows the abuser, and about one in five abusers are themselves underage. Sexual abuse was present in 12% of the confirmed 1996 abuse cases. An estimated 20–25% of females and 10–15% of males report that they were sexually abused by age 18.

EMOTIONAL ABUSE. Emotional abuse, according to Richard D. Krugman, director of the Kempe Center in Denver, “has been defined as the rejection, ignoring, criticizing, isolation, or terrorizing of children, all of which have the effect of eroding their self-esteem.” Emotional abuse usually expresses itself in verbal attacks involving rejection, scapegoating, belittlement, and so forth. Because it often accompanies other types of abuse and is difficult to prove, it is rarely reported.

NEGLECT. Neglect—failure to satisfy a child's basic needs—can assume many forms. Physical neglect is the failure (beyond the constraints imposed by poverty) to provide adequate food, clothing, shelter, or supervision for a child. Emotional neglect is the failure to satisfy a child's normal emotional needs, or behavior that damages a child's normal emotional and psychological development (such as permitting drug abuse in the home). Failing to see that a child receives proper schooling or medical care is also considered neglect. Neglect was found in 52% of 1996 abuse cases.

Causes and symptoms

Physical abuse

Physical abuse, which can be triggered by such normal child behavior as crying or dirtying a diaper, often occurs when a parent loses control and lashes out at a child. Unlike nonabusive parents, who may become angry at or upset with their children from time to time but

CHILD ABUSE: SIGNS AND SYMPTOMS

Although these signs do not necessarily indicate that a child has been abused, they may help adults recognize that something is wrong. The possibility of abuse should be investigated if a child shows a number of these symptoms, or any of them to a marked degree:

Sexual Abuse

Being overly affectionate or knowledgeable in a sexual way inappropriate to the child's age
 Medical problems such as chronic itching, pain in the genitals, venereal diseases
 Other extreme reactions, such as depression, self-mutilation, suicide attempts, running away, overdoses, anorexia
 Personality changes such as becoming insecure or clinging
 Regressing to younger behavior patterns such as thumb sucking or bringing out discarded cuddly toys
 Sudden loss of appetite or compulsive eating
 Being isolated or withdrawn
 Inability to concentrate
 Lack of trust or fear someone they know well, such as not wanting to be alone with a babysitter
 Starting to wet again, day or night/nightmares
 Become worried about clothing being removed
 Suddenly drawing sexually explicit pictures
 Trying to be "ultra-good" or perfect; overreacting to criticism

Physical Abuse

Unexplained recurrent injuries or burns
 Improbable excuses or refusal to explain injuries
 Wearing clothes to cover injuries, even in hot weather
 Refusal to undress for gym
 Bald patches
 Chronic running away
 Fear of medical help or examination
 Self-destructive tendencies
 Aggression towards others
 Fear of physical contact—shrinking back if touched
 Admitting that they are punished, but the punishment is excessive (such as a child being beaten every night to "make him/her study")
 Fear of suspected abuser being contacted

Emotional Abuse

Physical, mental, and emotional development lags
 Sudden speech disorders
 Continual self-depreciation ("I'm stupid, ugly, worthless, etc.")
 Overreaction to mistakes
 Extreme fear of any new situation
 Inappropriate response to pain ("I deserve this")
 Neurotic behavior (rocking, hair twisting, self-mutilation)
 Extremes of passivity or aggression

Neglect

Constant hunger	Poor personal hygiene	No social relationships
Constant tiredness	Poor state of clothing	Compulsive scavenging
Emaciation	Untreated medical problems	Destructive tendencies

A child may be subjected to a combination of different kinds of abuse. It is also possible that a child may show no outward signs and hide what is happening from everyone.

Source: Kidscape, <http://www.solnet.co.uk/kidscape/kids5.htm>. Reprinted by permission.

are genuinely loving, abusive parents tend to harbor deep-rooted negative feelings toward their children.

Unexplained or suspicious bruises or other marks on the skin, such as **burns**, are common signs of physical abuse. **Skull** and other bone **fractures** are often seen in young children, and in fact, head injuries are the leading cause of death from abuse. Children less than a year old are particularly vulnerable to injury from shaking. This is called shaken baby syndrome or shaken impact syndrome. Not surprisingly, physical abuse also causes a wide variety of behavioral changes in children.

Sexual abuse

According to psychological experts, the two prerequisites for this form of maltreatment include sexual arousal to children and the willingness to act on this arousal. Factors that may contribute to this willingness include alcohol or drug abuse, poor impulse control, and the mistaken belief that such sexual behaviors are acceptable and not harmful to the child. The chances of abuse are higher if the child is developmentally handicapped or vulnerable in some other way.

Genital or anal injuries or abnormalities (including the presence of sexually transmitted diseases) can be signs of sexual abuse, but often there is no physical evidence. In fact, physical examinations of children in cases of suspected sexual abuse supply grounds for further suspicion only 15–20% of the time. **Anxiety**, poor academic performance, and suicidal tendencies are some behavioral signs of sexual abuse, but these are also found in children suffering other kinds of **stress**. Excessive masturbation and other unusually sexualized kinds of behavior are more closely associated with sexual abuse itself.

Emotional abuse

Emotional abuse can happen in many settings: at home, at school, on sports teams, and so on. Some of the possible symptoms include loss of self-esteem, sleep disturbances, head- or stomachaches, school avoidance, and running away from home.

Neglect

Many cases of neglect occur because the parent experiences strong negative feelings toward the child. At other times, the parent may truly care about the child, but lacks the ability or strength to provide for the child's needs adequately because they are handicapped by depression, drug abuse, mental retardation, or some other problem.

Neglected children often do not receive adequate nourishment or emotional and mental stimulation. As a result, their physical, social, emotional, and mental development is hindered. They may, for instance, be underweight, develop language skills less quickly than other children, and seem emotionally needy.

Diagnosis

Doctors and many other professionals who work with children are required by law to report suspected abuse to their state's CPS agency. Abuse investigations are often a group effort involving medical personnel, social workers, police officers, teachers, and others. Some hospitals and communities maintain child-protection teams that respond to cases of possible abuse. Careful questioning of the parents is crucial, as is interviewing the child (if he or she can speak). The investigators must ensure, however, that their questioning does not further traumatize the child. A **physical examination** for signs of abuse or neglect is, of course, always necessary, and may include x rays, **blood** tests, and other procedures.

Treatment

Notifying the appropriate authorities, treatment of the child's injuries, and protecting the child from further harm are the immediate priorities in abuse cases. If the child does not require hospital treatment, protection often involves placing him or her with relatives or in foster care. Once the immediate concerns are dealt with, it becomes essential to determine how the child's long-term medical, psychological, educational, and other needs can best be met, a process that involves evaluating not only the child's needs but also the family's (such as drug abuse counseling or parental skills training). If the child has brothers or sisters, the authorities must determine whether they have been abused as well. On investigation, signs of physical abuse are discovered in about 20% of the brothers and sisters of abused children.

Prognosis

Child abuse can have lifelong and devastating consequences. Research has shown that abused children and adolescents are more likely, for instance, to do poorly in school, suffer emotional problems, develop an antisocial personality, become promiscuous, abuse drugs and alcohol, and attempt suicide. As adults they may have trouble establishing intimate relationships. Whether professional treatment is able to moderate the long-term psychological effects of abuse is a question that remains unanswered.

KEY TERMS

Child maltreatment—Another name for child abuse or neglect.

Munchausen syndrome by proxy—A rare form of physical abuse wherein a caretaker (most often the mother) seeks attention by making the child sick or appear to be sick.

Perpetrator—Any person who inflicts abuse of any form on a child, including neglect.

Health care team roles

Nursing staff and allied health professionals can assist in the treatment of child abuse by being aware of physical symptoms and emotional reactions caused by abuse or neglect. During the diagnosis and treatment phase, nursing staff and allied health professionals can help patients and perpetrators by providing appropriate educational materials, and referrals to community and individual supportive programs.

Prevention

Government efforts to prevent abuse include home-visitor programs aimed at high-risk families, and school-based efforts to teach children how to respond to attempted sexual abuse.

When children reach age three, parents should begin teaching them about “bad touches” and about confiding in a trusted adult if they are touched or treated in a way that makes them uneasy. Parents also need to **exercise** caution in hiring babysitters and other caretakers. Anyone who suspects abuse should immediately report those suspicions to the police or his or her local CPS agency, which will usually be listed in the blue pages of the telephone book under Rehabilitative Services or Child and Family Services, or in the yellow pages. Round-the-clock crisis counseling for children and adults is offered by the Childhelp USA/IOF Foresters National Child Abuse Hotline. The National Committee to Prevent Child Abuse is an excellent source of information on the many support groups and other organizations that help abused and at-risk children and their families. One of these organizations, National Parents Anonymous, sponsors 2,100 self-help groups throughout the United States, Canada, and Europe. Telephone numbers for its local groups are listed in the white pages of the telephone book under Parents Anonymous or can be obtained by calling the national headquarters.

Childbirth

Definition

Childbirth includes both labor (the process of birth) and delivery (the birth itself); it refers to the entire process as an infant makes its way from the womb down the birth canal to the outside world.

Description

Childbirth usually begins spontaneously, following about 280 days after conception, but it may be started by artificial means if the **pregnancy** continues past 42 weeks gestation, or if complications develop. Labor may also begin prematurely. The average length of labor is about 14 hours for a first pregnancy and about eight hours in subsequent pregnancies. However, many women experience a much longer or shorter labor.

Labor can be described in a series of phases.

First phase of labor

During the first phase of labor, the cervix dilates (opens) from 0–10 cm (0–4 in). This phase has an early, or latent, phase and an active phase. During the latent phase, progress is usually very slow. It may take quite a

while and many contractions before the cervix dilates the first few centimeters. Contractions increase in strength and frequency as labor progresses. Most women are relatively comfortable during the latent phase.

As labor begins, the muscular wall of the uterus contracts and relaxes as the cervix thins and expands. As a portion of the amniotic sac surrounding the baby is pushed into the opening, it bursts under the pressure, releasing amniotic fluid (water breaking). Sometimes the amniotic sac breaks before labor begins.

During this first phase the birth attendant or nurse will do periodic pelvic exams to determine how the labor is progressing. If the contractions aren't forceful enough to open the cervix, a drug called oxytocin (Pitocin) may be given to make the uterus contract.

As **pain** and discomfort increase, women may be tempted to request pain medication or anesthetics. If possible, though, these should be delayed until the active phase of labor begins—at which point the medication will not slow down or stop the labor.

The active stage of labor is faster and more efficient. In this phase, contractions are longer and more regular, usually occurring about every two to three minutes. These stronger contractions are also more painful. Women who use the breathing exercises learned in childbirth classes find that these can help them cope with the pain experienced during this phase. Many women also receive some pain medication at this point—either a short-term narcotic or epidural anesthesia.

As the cervix dilates to 8–9 cm (3.15–3.54 in), the transition phase begins. This refers to the progression from the first phase, during which the cervix dilates, to the second phase, during which the baby is pushed out through the birth canal. As the cervix dilates completely and the baby's head begins to descend, women feel the urge to push or bear down.

Second stage of labor

When the top of the baby's head appears at the opening of the vagina, the birth is nearing completion. First the head passes under the pubic bone. It fills the lower vagina and stretches the perineum. This position is called "crowning," since only the crown of the head is visible. When the entire head is out, the shoulders follow. The attending practitioner may suction the baby's mouth and nose to ease its first breath. The rest of the baby usually slips out easily, and the umbilical cord is cut.

Episiotomy

As the baby's head appears, the perineum may be stretched so tightly that the baby's progress is slowed. If

there is risk of tearing the mother's tissue, the doctor or midwife may make a small incision, called an episiotomy, into the perineum to enlarge the vaginal opening. If the woman has not had an epidural or pudendal block, she will get a local anesthetic to numb the area. Once the episiotomy is made, the baby is born with a few pushes.

Third stage

In the final stage of labor, the placenta is pushed out of the vagina by the continuing uterine contractions. The placenta is pancake shaped and about 10 in (25.4 cm) in diameter. During the pregnancy it was attached to the uterine wall and conveyed nourishment from the mother to the fetus. Continuing uterine contractions release it from the uterus at this point. It is important that all of the placenta be removed from the uterus. If it is not, the uterine bleeding that is normal after delivery may be much heavier, and uterine **infection** may occur.

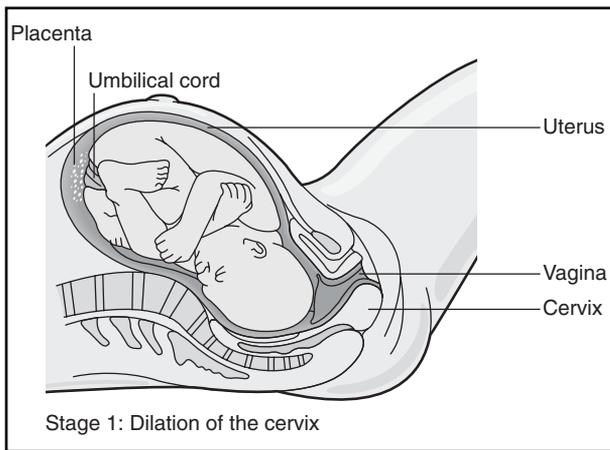

Breech presentation

Approximately 4% of babies are in what is called a "breech" position when labor begins. In breech presentation, the baby's bottom or legs press against the cervix and are positioned to enter the birth canal. An obstetrician may attempt to turn the baby to a head-down position using a technique called version before labor begins. This is only successful approximately half the time.

The risks of vaginal delivery with breech presentation are much higher than with a head-first presentation. In these cases the mother and attending practitioner will need to weigh the risks and decide whether to deliver via cesarean section or attempt a vaginal birth. The extent of the risk depends to a great extent on the type of breech presentation, of which there are three:

- *Frank breech*—the baby's legs are folded up against its body. This is the most common and the safest for vaginal delivery.
- *Complete breech*—the baby's legs are crossed under and in front of the body.
- *Footling breech*—one or both legs are positioned to enter the birth canal. Vaginal delivery with this presentation is considered unsafe.

Several factors should be considered before attempting a vaginal **breech birth**. An ultrasound examination should be done to be sure the baby's head is not unusually large, and that it is flexed (tilted forward) rather than hyperextended (tilted back). Fetal monitoring and close observation of the progress of labor are also important. If labor slows or there is any sign that it will be difficult for the baby to pass through the pelvis it may be safer to consider a cesarean section.

(Illustration by Hans & Cassidy.)

Forceps delivery

If the labor is not progressing as it should, the baby appears to be in distress, or the mother is too exhausted to push, the doctor may opt for a forceps delivery. A forceps is a spoon-shaped device that resembles a set of salad tongs. It is placed around the baby's head so the doctor can pull the baby gently out of the vagina. Forceps can be used after the cervix is fully dilated.

Before placing the forceps around the baby's head, pain medication or anesthesia may be given to the mother. The doctor may use a catheter to empty the her bladder, and may clean the perineal area with soapy water. Often an episiotomy is done before a forceps birth, although tears can still occur.

The obstetrician slides half of the forceps at a time into the vagina and around the side of the baby's head to gently grasp the head. When both halves are in place, the doctor pulls on the forceps to help the baby through the birth canal as the uterus contracts. Sometimes the baby can be delivered this way after the very next contraction.

When used by an experienced physician, forceps can save the life of a baby in distress. Complications from this type of delivery include nerve damage or bruises to the baby's face. The frequency of forceps delivery varies from one hospital to the next, depending on the experience of staff and the types of anesthesia offered at the hospital. Some obstetricians accept the need for a forceps delivery as a way to avoid cesarean birth. Others don't use forceps at all.

Vacuum-assisted birth

This method of helping a baby out of the birth canal was developed as a gentler alternative to forceps. As with forceps, vacuum-assisted birth can only be used after the cervix is fully dilated and the head of the fetus has begun

to descend through the pelvis. In this procedure, the doctor uses a device called a vacuum extractor, placing a large rubber or plastic cup against the baby's head. A pump creates suction that gently pulls on the cup to gently ease the baby down the birth canal. The force of the suction may cause a bruise on the baby's head, but it fades in a day or so.

The vacuum extractor is not as likely as forceps to injure the mother, and it leaves more room for the baby to pass through the pelvis. However, there may be problems in maintaining the suction with this method, and there is the potential for **brain** damage if repeated attempts are made, so forceps may be a better choice if it is important to remove the baby quickly.

Cesarean sections

A cesarean section, also called a C-section, is a surgical procedure in which incisions are made through a woman's abdomen and uterus to deliver her baby. The procedure is used to deliver nearly 25% of babies born in the United States; the rate can be as high as 60% for mothers who have had a previous C-section. Cesarean sections are performed whenever abnormal conditions complicate labor and vaginal delivery, threatening the life or health of the mother or the baby.

Labor complications include: abnormalities in the mother's birth canal; abnormalities in the fetus's position; an unusually large baby; and abnormalities in the labor, including weak or infrequent contractions. Another complication is fetal distress, a condition in which the fetus does not get enough oxygen. This can lead to fetal brain damage. The mother's health can also influence the decision to deliver by C-section, especially if she has vaginal herpes, pregnancy-induced **hypertension**, or diabetes.

Causes and symptoms

One of the earliest signs of approaching labor is loss of the "mucous plug," the thick secretion that covers the cervix during the nine months of pregnancy to protect the fetus from infection. Another is the "bloody show," which is produced by broken capillaries in the cervix. Both the mucous plug and the bloody show appear as the cervix begins to expand and dilate in preparation for labor.

The most common indication that labor has begun is the onset of contractions. Sometimes women have trouble telling the difference between early contractions and false labor pains, but the biggest distinction is that true labor pains develop a regular pattern, with contractions coming closer together.

Another less common sign that labor is beginning is the breaking of the amniotic sac that cushioned the baby during the pregnancy. When it breaks, it releases water in a trickle or a gush. Only about 10% of women actually experience this water flow in the beginning of labor, however. Most of the time, the rupture occurs sometime later in labor. If the amniotic sac doesn't rupture on its own, the birth-attendant may break it during labor.

A few women have **diarrhea** or nausea as labor begins. Others notice a sudden surge of energy and the urge to clean or arrange things right before labor begins; this is known as "nesting."

Diagnosis

The progression of labor can be determined by measuring how much the cervix has dilated. The degree of dilation is estimated by feeling the opening cervix during a pelvic exam. Dilation is measured in centimeters, from 0–10 cm (0–4 in). Contractions that cause the cervix to dilate are the sign of true labor.

Fetal monitoring

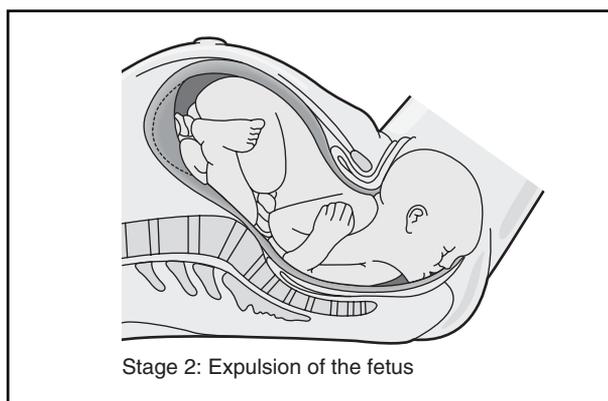

Fetal monitoring is a process in which the baby's **heart** rate is monitored for indicators of **stress** during labor and birth. There are several types of fetal monitoring.

A special **stethoscope** called a fetoscope may be used. This is a simple and noninvasive method.

The Doppler method uses ultrasound; it involves a handheld listening device that transmits the sounds of the heart rate through a speaker or into an attached ear piece. It can usually pick up the heart sounds 12 weeks after gestation. This method offers intermittent monitoring. It allows the mother freedom to move about and is also useful during contractions.

Electronic (external) fetal monitoring, in which a monitor is strapped to the mother's abdomen, uses ultrasound to measure the fetal heartbeat in relation to the mother's contractions. It is often used in high-risk pregnancies, and is not always recommended for low-risk ones because it renders the mother immobile. External monitoring can be done intermittently, as needed.

Internal monitoring provides continuous monitoring for the high-risk mother. It requires the mother's water to be broken and that she be 2–3 cm (0.75–1.25 in) dilated. An electrode is attached to the baby, usually on the head, and a pressure catheter records the strength of uterine contractions. Internal monitoring is more accurate than external fetal monitoring, because external monitors are more likely to slip off. Internal monitoring is continuous.

(Illustration by Hans & Cassidy.)

Telemetry monitoring, the newest type, is similar to electronic monitoring, but uses radio waves beamed from a transmitter worn by the mother to measure the fetal heartbeat. The mother is able to remain mobile while still being monitored continuously.

FETAL MONITORING RESULTS. The results of internal and external fetal monitoring are both displayed and printed. Most interpretations are based on the printed tracing. The top tracing reflects fetal heart rate; the bottom tracing measures contractions. Baseline fetal heart rate is considered normal if it is between 120 and 160 beats per minute (bpm). Monitoring of contractions with an external fetal monitor gives the frequency and duration of the contractions. Internal monitoring of contractions can provide contraction intensity values.

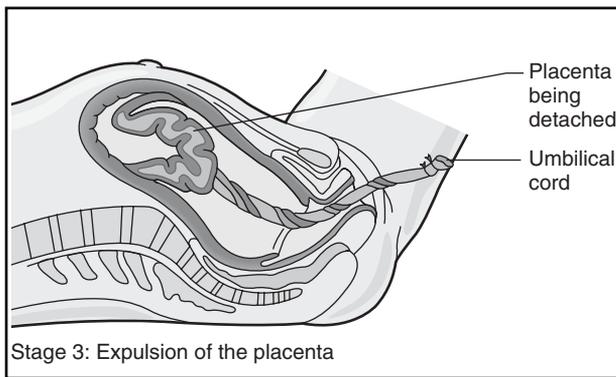

Treatment

Childbirth options

Most women choose some type of pain relief during childbirth, ranging from **relaxation** and imagery to powerful drugs. The specific choice may depend on what's available, the woman's preferences, her doctor or midwife's recommendations, and how the labor is proceeding. All drugs have some risks and some advantages.

REGIONAL ANESTHETICS. Regional anesthetics include epidurals and spinals. Depending on the type of medication used, these types of anesthesia can block nerve signals, causing temporary pain relief, or a loss of sensation from the waist down. An epidural or spinal block can provide complete pain relief during cesarean birth.

An epidural is placed with the woman lying on her side or sitting up in bed with the back rounded to allow more space between the vertebrae. Her back is scrubbed with antiseptic, and a local anesthetic is injected in the skin to numb the site. The needle is inserted between two

(Illustration by Hans & Cassidy.)

vertebrae and through the tough tissue in front of the spinal column. A catheter is threaded through the needle and the needle is then removed. The anesthetic then drips continuously through the catheter.

Epidurals provide complete pain relief and can help conserve a woman's energy, allowing her to relax or even sleep during labor. This method requires an IV and fetal monitoring. It may be harder for a woman to bear down when it comes time to push, although the amount of anesthesia can be adjusted as this stage nears.

Spinal anesthesia is used primarily for C-section delivery. Unlike epidural anesthesia, which is administered continuously in the space around the spinal column, spinal blocks are one-time injections of anesthetic that go directly into the fluid that surrounds the spine. Although this method disables motor nerves, preventing women who use it from pushing during delivery, this is not an issue during a C-section. Spinals provide quick and strong anesthesia and permit major abdominal surgery with minimal pain.

NARCOTICS. Short-acting narcotics can ease pain and do not interfere with a woman's ability to push. However, they can cause sedation, dizziness, nausea, and vomiting. Narcotics cross the placenta and may slow down a baby's breathing. For this reason they can not be given too close to the time of delivery.

METHODS OF PREPARATION. Health care providers often use psychoprophylaxis to help expectant mothers prepare for childbirth. These techniques use relaxation and breathing exercises along with other methods to diminish the discomfort and fear many women experience in childbirth. Although several distinct methods have evolved since the 1930s, when psychoprophylaxis first gained acceptance in the medical community, most doctors, nurses, and midwives today use a combination of approaches to instruct their patients.

The Read method is named for Dr. Grantly Dick-Read, the English obstetrician who developed it in the 1930s. This method aims to decrease the fear and tension surrounding childbirth by educating the mother about the birth process, and using relaxation and deep breathing techniques.

Lamaze, or Lamaze-Pavlov, is probably the best-known method in the United States today, although the pure Lamaze method is rarely used. It first became widely popular in the 1960s. The Lamaze method combines breathing exercises with concentration on a focal point to allow mothers to control pain while maintaining consciousness. This also allows the flow of oxygen to the baby and to the muscles in the uterus to be maintained. A partner coaches the mother throughout the birthing process.

The LeBoyer method stresses a relaxed delivery in a quiet, dim room that prevents overstimulation of the baby. Mother-child bonding is fostered by placing the baby on the mother's abdomen and by having the mother massage the baby immediately after delivery. Then the father washes the baby in a warm bath.

The Bradley method is called father-coached childbirth because it encourages the father to serve as coach throughout the labor. It encourages normal activities during the first stages of labor.

A newer method, called water birthing, allows mothers to labor and sometimes deliver—provided a doctor, nurse, or midwife is at hand—in a pool of warm water. The water supports and relaxes the mother, making labor more comfortable.

Prognosis

National U.S. health goals are to reduce the maternal mortality rate to no more than 3.3 deaths per 100,000 live births. The baseline in 1998 was 7.1 maternal deaths per 100,000 live births. The target for fetal and infant death reduction during the perinatal period (28 weeks of gestation to seven days or more after birth) is no more than 4.5 per 1,000 live births plus fetal deaths. The baseline in 1997 was 7.5 per 1,000.

Health care team roles

The nurse or nurse-midwife caring for the patient during labor and delivery will perform the following:

- Obtain an initial history and perform a **physical examination** upon admission.
- Determine the position of the baby.
- Assess for rupture of membranes.

- Determine the cervical dilation, effacement, and level of descent (station), and confirm presenting part through vaginal exam.
- Monitor vital signs.
- Monitor baby's heartrate and measure frequency and duration of contractions. Apply fetal monitoring apparatus if ordered. Observe tracing and record results in patient's record.
- Encourage involvement of the father and provide explanations to him as requested.
- Insert IV if ordered. Obtain laboratory specimens; evaluate results.
- Provide comfort measures through emotional support, changing pads, giving ice chips if allowed, giving back massages, assisting with breathing during contractions, administering pain medications, and assisting with regional anesthesia administration.
- Implement emergency measures if necessary.
- Assist with vaginal exams, rupturing the membranes (amniotomy) and other procedures as indicated.
- Prepare for delivery by setting up instruments, transporting to delivery room or readying birthing bed, and preparing equipment for initial newborn care.
- Provide coaching during pushing and delivery.
- Receive the baby after delivery and perform initial newborn care.
- Administer medications as ordered.
- Assess the mother and baby frequently after delivery.
- Provide perineal care for the mother.
- Monitor mother's and baby's vital signs.
- Assist mother with breastfeeding.
- Facilitate bonding of baby with mother, father, and other family members.

KEY TERMS

Amniotic sac—The membranous sac that surrounds the embryo and fills with watery fluid as pregnancy advances.

Breech birth—Birth of a baby bottom- or feet-first, instead of the usual head first delivery. This can add to labor and delivery problems because the baby's bottom doesn't mold a passage through the birth canal as well as the head.

Cervix—A small cylindrical organ, about an inch (2.54 cm) or so long and less than an inch around, that makes up the lower part and neck of the uterus. The cervix separates the body and cavity of the uterus from the vagina.

Embryo—The unborn child during the first eight weeks of its development following conception.

Gestation—The period from conception to birth, during which the developing fetus is carried in the uterus.

Perineum—The area between the thighs that lies behind the genital organs and in front of the anus.

Placenta—The organ that develops in the uterus during pregnancy and that links the blood supplies of mother and baby.

Childbirth education

Definition

Childbirth education prepares the mother and usually her partner for labor and birth. It may also include information on cesarian birth, breastfeeding, maternal postpartum issues, and **neonatal care**. Special classes may be available for adolescent mothers, vaginal birth after cesarian birth, siblings, and grandparents. Classes may consist of lectures, slides, videos, demonstration, and practice.

Description

Based on the goals of the facility or instructor, childbirth education classes can vary considerably in terms of content. For example, some classes may focus primarily on the childbirth process, while others provide information on wellness behaviors during the different trimesters of **pregnancy**. Classes offered by some facilities may not include information on postpartum contraceptive choices. Some classes provide information on fetal growth and development and maternal changes during pregnancy. These classes are usually offered earlier in a woman's pregnancy while classes that focus primarily on labor and delivery are offered later. Some obstetric practices may provide gestational-appropriate information at each prenatal visit; others may focus primarily on the mother's questions or concerns. Some practices may offer classes that complement the information given during prenatal visits or they may have on hand a list of classes that pregnant women may want to contact.

Content areas that may be included in childbirth education classes are:

- maternal changes in early pregnancy: physical and emotional
- fetal growth and development
- risks of certain environmental factors on fetal development
- maternal self-care: **nutrition**, rest, **exercise**, work accommodations
- common discomforts in pregnancy and safe/unsafe relief measures
- sexuality and pregnancy
- signs and symptoms of complications of pregnancy
- signs of preterm labor
- signs of the initiation of labor
- symptoms which require a call to the obstetric provider
- what to expect during labor and delivery

A midwife meets with a pregnant patient. (Photograph by Cliff Moore. Science Source/Photo Researchers. Reproduced by permission.)

- labor and delivery analgesia/anesthesia options
- breathing and **relaxation** techniques
- role of certified nurse midwife versus obstetrician
- role of the coach
- making a birth plan; hiring a doula
- episiotomy issues
- breastfeeding versus formula
- breastfeeding techniques, normal/abnormal problems, and relief measures
- neonatal care and safety issues
- postpartum contraception
- tour of labor and delivery area of affiliated health care center

Viewpoints

Childbirth education classes are offered based on the premise that knowledge about what to expect during labor and delivery prepares a woman for the process. For example, fear of the unknown is associated with increased **pain** and muscle tension. Childbirth classes traditionally teach breathing and relaxation techniques for women to use during labor and delivery. It is believed that these techniques enable the mother to better manage the pain of childbirth, feel more in control, have a better birth experience, and bond more readily with her newborn. Some childbirth classes promote a particular method and philosophy, such as the Lamaze and the Bradley methods.

The Lamaze method is supported by the American Society for Psychoprophylaxis in Obstetrics (ASPO) and was popularized by the French physician Ferdinand Lamaze. Classes focus on breathing, movement and posi-

tioning during labor, use of massage and relaxation techniques, the role of labor support, use of heat and cold, and water therapy. The ASPO/Lamaze philosophy is:

- Birth is normal, natural, and healthy.
- The birth experience profoundly affects women and their families.
- Women's inner wisdom guides them through birth.
- Women's confidence and ability to give birth is either enhanced or diminished by the care provider and place of birth.
- Women have the right to give birth free from routine medical interventions.
- Birth can safely take place in birth centers and homes.
- Childbirth education empowers women to make informed choices in health care, to assume responsibility for their health, and to trust their inner wisdom.

The Bradley method was designed by Robert Bradley, an obstetrician. During the 12 sessions, Bradley classes emphasize a special pregnancy diet, maternal changes during pregnancy, the coach's role, special coaching techniques, the importance of natural childbirth, sex during pregnancy, the first, second, and third stages of labor, pushing during labor, making a birth plan, labor rehearsal, postpartum information, breastfeeding, and newborn care. The Bradley method's goals are:

- natural childbirth
- active participation of the husband coach
- excellent nutrition as the foundation of a healthy pregnancy
- avoidance of drugs during pregnancy, birth, and breastfeeding unless absolutely necessary
- relaxation and natural breathing
- tuning in to the body
- responsibility of parents for the safety of the birth place, procedures, attendants, and emergency backup
- immediate and continuous contact with the newborn
- initiation of breastfeeding at birth
- preparation of parents for unexpected situations such as emergency childbirth and cesarian delivery

Childbirth education classes provide information to pregnant women in an environment of their peers, where they meet with other women or couples at the same stage of pregnancy. By educating women about the childbirth process, these classes enable women to focus on their particular issues during prenatal visits, while still receiving general pregnancy and childbirth information. Issues raised during the classes allow women time to reflect on

Questions to consider when making a birth plan

How have you tried to prepare yourself for labor? How has your partner or support person been involved?

What do you think labor will be like?

How much pain do you think you will have in labor? Why do you think it will be like that?

Do you want pain medications, or do you want to avoid them? Which pain medications would you prefer?

How long do you think your labor will last? Why do you think it will be that long?

Which support people will be with you during labor? How is each related to you?

Who is welcome to be at the birth?

What do you want your support person to do for you when you are in labor?

What is most scary to you about being in labor and giving birth?

What is most important to you about this birth?

How do you feel about:

monitoring the baby during labor?

mobility during labor?

positions during labor?

an IV?

having your bag of water broken?

using breathing and relaxation techniques to help you through the contractions?

medication to relieve pain during labor?

an epidural anesthetic to take away the pain of labor?

episiotomy procedure?

If a cesarean becomes necessary, do you have any special requests?

If the birth is planned at home or at a birth center, what are your plans in case of transport?

What are your preferences for baby care, feeding, and rooming?

If you had a baby before, did anything happen that might affect you during labor this time?

SOURCE: Wheeler, L. *Nurse-Midwifery Handbook: A Practical Guide to Prenatal and Postpartum Care*. Philadelphia: Lippincott-Raven Pub., 1997.

the choices they want for their birth experience. In addition, these classes often are a springboard for new groups where mothers get together postpartum with their newborns. Friendships formed during class time can help avoid the isolation sometimes existing in the postpartum period.

Professional implications

While some women benefit from choosing a particular method of childbirth education, many women prefer using a more eclectic approach. The more nurses and other health care professionals are informed of various methods, the better equipped they are to assist women to have the type of childbirth they choose. The various breathing and focusing techniques provide relief from or a decrease in pain through distraction and muscle relaxation. There are many ways to achieve these goals. It is important for nurses to provide options while allowing women to make their own choices. Taking a series of

KEY TERMS

Doula—A doula is someone who undergoes special training to enable them to support women during childbirth and into the postpartum period.

Episiotomy—A surgical incision made to enlarge the perineal area for delivery, to avoid tearing of the tissues, especially with a large neonate or during a difficult birth. Many women request the avoidance of a routine episiotomy. To avoid performing an episiotomy, certified nurse midwives may stretch the perineum with perineal massage.

Perineum—The area encompassing the anus and the vagina.

classes and doing the required homework requires time, effort, and motivation. Many women come into childbirth virtually unprepared. Labor and delivery nurses may choose to select different aspects of a variety of methods and incorporate them into their own practice.

It is helpful for office obstetric nurses to be aware of the various classes in their areas, even classes not listed by their own facility. One may be able to request permission to sit in on some classes or to view the class content list. This enables the provider to know what information, accurate or otherwise, is available to pregnant women and to address issues as needed during prenatal visits. If not provided during the classes, obstetric providers may wish to offer instruction on exercises women can do at home that will facilitate the birth process: abdominal and back exercises for strength and flexibility, Kegel (pelvic floor muscle) exercises to promote perineal healing and to counteract **stress** incontinence, tailor sitting and squatting to stretch perineal and pelvic floor muscles, and pelvic rocking to relieve lower backache.

Nurses also need to be culturally sensitive. While most husbands may wish to participate in the birth process, this may be an uncomfortable practice in some cultures. In addition, some men, regardless of their cultural background, may not want to participate in the birth process. The birthing woman may wish instead to have a female relative or friend as a support person. As long as a practice is medically safe, nurses need to respect the choices of the birthing woman and her family.

Chorionic villus sampling

Definition

Chorionic villus sampling (CVS) is a prenatal procedure for the removal by needle of chorionic villi and culture and examination of the fetal cells obtained. The cells are used in tests for genetic and chromosomal abnormalities of a fetus as early as 10 to 12 weeks of gestation.

Purpose

Women who are at risk of carrying a fetus with a genetic or chromosomal defect may be counseled to have a prenatal screening test such as CVS or **amniocentesis**. CVS, which is performed at 10 to 12 weeks after a woman's last menstrual period, may be offered as an alternative to amniocentesis, the more commonly used test for prenatal diagnosis of genetic disorders, which is performed usually at 15 to 18 weeks. Earlier diagnosis of congenital defects is especially beneficial in cases where the parents' desire to know the results as early in **pregnancy** as possible, for instance, when therapeutic abortion is being considered, as the risks associated with abortion increase with gestational age.

Prenatal screening can diagnose some genetic and virtually all chromosomal disorders and is advised for women who have one or more of the following risk factors:

- Women age 35 and older. The chance of having a child with certain chromosomal birth defects increases with maternal age. The most common chromosomal disorder is **Down syndrome**, a combination of mental and physical abnormalities caused by the presence of an extra copy of chromosome 21. The occurrence of Down syndrome in children born to women in their 20s is approximately 1 in 1,250, but increases to 1 in 400 by age 35, and to 1 in 100 at age 40.
- A child or previous pregnancy with a birth defect, or a history of miscarriages. A woman who has already had a child or pregnancy diagnosed with a genetic birth defect or chromosomal abnormality, or who has had multiple miscarriages, is at increased risk of having a child with a genetic disorder.
- Determination of the sex of a fetus when the mother is known to be a carrier of a sex-linked genetic disease (for example, **hemophilia A**).
- Other family history of genetic disease. Couples who do not have an affected child but who have family medical histories of genetic or chromosomal abnormalities or are known through genetic screening to be carriers of an inherited disease are at increased risk of having an affected child. Prenatal testing is offered only when the suspected condition can be diagnosed before birth.

Precautions

Chorionic villus sampling usually is not recommended for:

- A woman whose pregnancy has progressed further than about 12 weeks, counted from the first day of the last menstrual period.
- A woman who is experiencing bleeding or spotting.
- In the presence of certain vaginal infections.
- When there are uterine abnormalities, such as a bicornuate (double) uterus or uterine fibroids.
- Women who would not consider intervening in a pregnancy where a genetic abnormality is detected.

Women who are concerned about the risk of **miscarriage** associated with CVS can be offered amniocentesis or a noninvasive alternative. One such alternative is a maternal **blood** test called triple marker screening or multiple marker screening, which is performed no sooner than 15 weeks but no later than 20 weeks of pregnancy. A sample of the pregnant woman's blood is analyzed for three substances produced by the fetus and passed into the

mother's blood: alpha fetoprotein (AFP), human chorionic gonadotropin (HCG), and unconjugated estriol (UE3). Elevated AFP may indicate the presence of anencephaly or spina bifida; HCG is increased and AFP and UE3 are decreased in Down syndrome. This screening test, however, does not definitively diagnose a genetic defect and has a relatively high rate of false negatives, but it can help to identify an unborn baby at increased risk for these birth defects. A pregnant woman whose triple marker results are indicative of a fetus at risk would be encouraged to undergo further screening, such as ultrasound and/or amniocentesis (the timing of the triple marker screening rules out CVS) to provide a definitive diagnosis.

Since only cells and not fluid are collected, CVS does not allow evaluation of AFP to indicate the presence of neural tube defects. AFP is then generally measured by a maternal blood test at 15–20 weeks, but with less accuracy than would be obtained with an amniotic fluid sample.

A CVS sample may be obtained either via the vagina and cervix (transcervical CVS) or through the abdomen (transabdominal CVS). Women who have a retroverted (tipped) uterus should be sampled transabdominally, since studies have shown the risk of miscarriage to be lower than when the procedure is done transcervically. In cases where the location of the placenta contraindicates transabdominal CVS, amniocentesis should be offered as an alternative screening test. Amniocentesis, however, is only rarely performed in the first trimester.

Although CVS is over 99% accurate in ruling out certain chromosomal birth defects and specific genetic problems, it is slightly more likely than amniocentesis to give inconclusive results. Amniocentesis, then, may be used as a back-up screening procedure. However, the patient should be cautioned that not all birth defects can be ruled out before birth and no prenatal test can guarantee the birth of a healthy baby. Because it is performed earlier in pregnancy than amniocentesis, CVS sampling is more likely to detect fatal genetic diseases that result in miscarriages after the diagnosis has been established.

Description

Chorionic villus sampling has been in use increasingly since the 1980s. The CVS procedure involves taking a sample of the chorion frondosum—the part of the chorionic membrane that contains the villi, microscopic, finger-like projections that emerge from the chorionic membrane to form the placenta—for laboratory analysis. The chorion is the outermost membrane surrounding the developing fetus; the amnion is the inner membrane that contains the amniotic fluid. The cells that make up the chorionic villi are of fetal origin, and, thus, normally

have the same genetic makeup as the fetus. The sample may be obtained with a catheter, a thin, plastic tube, inserted through the vagina and the cervix (transcervical CVS) or with a needle through the abdominal wall (transabdominal CVS); both sampling methods take about five minutes to perform (not including preparation time), are equally effective, and carry similar risks.

Chorionic villus sampling is best performed between 10 and 12 weeks of pregnancy. **Abdominal ultrasound** is used to determine the position of the uterus, the position of the placenta within the uterus, and the size of the amniotic sack. The woman assumes the lithotomy position (on her back with her feet in stirrups). In transcervical CVS, the vulva, vagina, and cervix are thoroughly cleansed with antiseptic; no anesthetic is required. A speculum is inserted into the vagina and opened, then, using ultrasound as a guide, the doctor inserts a catheter through the cervix and into the uterus. The catheter is carefully advanced to the chorionic villi and suction is applied with the syringe attached to the catheter to obtain a small sample of the villi. The catheter is then carefully withdrawn.

In transabdominal CVS, the appropriate area on the woman's abdomen is cleansed thoroughly with antiseptic and a local anesthetic may be injected to numb the area. With ultrasound guidance to strictly avoid the placenta, a long needle is inserted through the woman's abdominal wall, through the uterine wall and to the chorionic villi. Suction is applied with the syringe attached to the needle to obtain a small sample of the villi, and the needle is then carefully withdrawn.

Most women report that transcervical CVS feels similar to the procedure for a Pap smear. The passage of the catheter through the cervix may cause cramping, and some women experience cramping or pinching sensations when the sample is taken. There is generally little or no discomfort associated with the transabdominal procedure. Occasionally, when insufficient villus material is obtained, a second sampling procedure must be performed.

The chorionic villus sample is immediately placed into a sample dish containing nutrient medium for transport to the cytogenetics laboratory. At the laboratory, the sample is examined under the **microscope** so that any contaminating cells or material may be carefully removed. The villi can be analyzed immediately, or incubated for a day or more to give the cells time to undergo division. When the cells are in the midst of dividing, they are spread onto a slide and examined under a microscope. Cells that have clearly separated chromosomes are photographed to allow analysis of the type and number of chromosomes. The chromosomal images are collected in a report called a karyotype, which shows the number,

shape, size, and arrangement of chromosomal pairs. For biochemical studies, deoxyribonucleic acid (DNA) is extracted from cultured chorionic villus cells. Depending upon which tests are performed, results may be available as early as two days or up to ten days after the procedure.

The chorionic villus sampling procedure costs about \$3,000, including ultrasound, laboratory, and counseling charges. Some insurance plans may provide some level of coverage for this test.

Preparation

Thorough pre-CVS counseling is strongly recommended to give the couple the opportunity to make informed decisions about prenatal diagnosis. The couple should be provided with literature about CVS and genetic screening options to read prior to the counseling conference, so that any questions or concerns they may have can be addressed at that time. Prior to the procedure, the woman will likely be asked to sign a consent form.

For the procedure itself, the woman will be instructed to drink fluids and refrain from urinating so that the bladder is partly filled; excessive and uncomfortable bladder filling is not necessary. A filled bladder can help to properly position the uterus and create a better ultrasound picture for guiding the CVS procedure.

Aftercare

After the sample is taken, the fetal heartbeat is checked by ultrasound before the woman leaves the examination room. A follow-up ultrasound procedure may be scheduled two to four days after CVS to ascertain the health of the fetus.

Most physicians recommend that the woman have someone drive her home after the CVS procedure and that she limit strenuous activity for the remainder of the day. A woman who experiences excessive bleeding, vaginal discharge, **fever**, or abdominal **pain** after the procedure should consult her doctor.

Women with Rh negative blood may receive a Rho (D) immune globulin (RhoGAM) injection to avoid Rh incompatibility.

Advances in prenatal treatment have made it possible to treat some genetic defects diagnosed by prenatal screening before birth. Congenital adrenal hyperplasia (CAH), for example, is an inherited birth defect in which an enzyme deficiency causes a female fetus to develop abnormal external genitalia by the 16th week of pregnancy. Prenatal diagnosis by CVS in pregnancies known to be at risk of CAH allows the fetus to be treated with hormones during the critical period of development from 10 to 16 weeks of gestation and can circum-

vent the need for surgery after birth. For conditions in which prenatal treatment is not available, prenatal diagnosis can allow parents the opportunity to discuss their options with genetic counselors or other health care providers, to plan the delivery, and to prepare emotionally for the birth.

Complications

Of women who undergo transcervical CVS, one third experience minimal vaginal spotting and 7–10% experience vaginal bleeding; bleeding that is heavier than during a normal menstrual period should be reported to the doctor. One out of five women experience cramping following the procedure. Rupture of the amniotic membranes is a rare but serious complication that can lead to **infection** and/or miscarriage. The risk of miscarriage after CVS is 1–3%, compared to 0.5–1% for amniocentesis. A woman with Rh negative blood who is carrying an Rh positive fetus may be at an increased risk for developing Rh incompatibility following CVS and should be treated with Rho immune globulin.

In the early 1990s, there were several reports linking babies born with missing or shortened fingers or toes and abnormalities of the tongue and lower jaw with CVS performed before the tenth week of pregnancy. These reports raised concerns about the safety of CVS, although this type of limb defect is known to occur in approximately 1 out of every 1,700 babies. Subsequent studies of the risk of limb defects following CVS have produced conflicting results, and CVS safety studies continue. A study by the World Health Organization's CVS Registry, which performs ongoing assessment of CVS, reported in 1999 that the risk of these limb defects in babies born to more than 200,000 women who had CVS was not significantly increased compared to the norm. CVS is now generally performed only at ten weeks or later, and all women being offered CVS should be advised of the limited risk of limb defects.

There is risk with CVS of getting a "placental mosaicism" artifact in which the cultured cells contain some abnormal chromosomes that originate in the placenta and are not related to the fetus. Mosaicism occurs when cells have two or more distinct chromosome counts. This occurs when nondisjunction (failure of chromatids to separate) occurs in germ line cells (after fertilization). The fetus may be normal, and the only way to rule out actual mosaicism is to follow up with amniocentesis. There is also a risk that insufficient chorionic villi are collected for analysis, or that the cells collected are contaminated with cells of maternal origin. In this case, a second sampling procedure is performed

about a week later, or amniocentesis may be offered as an alternative.

Results

The chorionic villus cells are cultured and photographed through a microscope during **cell division** to obtain images of the chromosomes. The images are sorted, identified, and reported in a karyotype. Humans have 23 pairs of chromosomes, including the sex chromosomes. The karyotype allows detection of aneuploidies (extra copies of chromosomes), chromosomal deletions, and gross chromosomal translocations. The gender of the fetus is identified from the sex chromosomes, and can be reported to the parents upon request.

DNA studies are performed when indicated by a family history of genetic disorders. DNA is the biochemical molecule that stores genetic information in the chromosomes. The DNA is extracted from the chorionic villus cells, and analysis of the DNA allows prenatal diagnosis of over 200 diseases, including Tay-Sachs disease, **cystic fibrosis**, sickle-cell anemia, and **muscular dystrophy**.

Health care team roles

The genetic counselor, physician, or other health care provider will provide information to the couple considering CVS and explain the procedure and its risks, and alternative procedures. Counselors can also advise parents of their options when they learn that their unborn child has an inherited disorder and/or help them prepare emotionally for the delivery of a child with a birth defect.

The obstetrics team carries out the ultrasound and CVS procedure, and ensures that the chorionic villus cells are properly handled for transport to a cytogenetics laboratory. The team of physician(s) and nurses also provide practical and psychological support for the couple undergoing prenatal diagnosis.

Technologists in the cytogenetics laboratory perform cell culture on the chorionic villus cells, fix a sample of cells during cell division, prepare the cells on a slide for microscopic analysis, and make photographs of the chromosomes of dividing cells to be collated in a karyotype. Cytogenetic technologists are also involved in the extraction of DNA from the cells and the biochemical testing of the DNA.

Training

The obstetrician receives special training in the procedure for collecting the chorionic villus specimen. Cytogenetic laboratory technologists, CLSp(CG) are specially trained in sterile techniques for cell culture,

KEY TERMS

Alpha fetoprotein—A serum protein produced by the fetus during pregnancy and passed to the mother's blood, useful in the prenatal diagnosis of multiple births or birth defects.

Amniocentesis—A prenatal screening procedure in which a sample of amniotic fluid from the amniotic sac in the uterus of a pregnant woman is obtained by inserting a needle through the abdominal wall.

Aneuploidy—An irregular number of chromosomes caused by the loss or addition of one or more chromosomes or parts of chromosomes.

Chromosomes—Tightly compressed rod-like structures that carry DNA; humans have 23 pairs of chromosomes including the sex chromosomes.

Cystic fibrosis—An inherited chronic disease of the exocrine glands, characterized by the production of viscous mucus that obstructs the pancreatic ducts and bronchi, leading to infection and fibrosis.

Down syndrome—Also called trisomy 21, a genetic disorder, associated with the presence of an extra copy or a rearrangement of chromosome 21, characterized by mild to severe mental retardation, weak muscle tone, a low nasal bridge, and epicanthic folds at the eyelids; formerly called mongolism.

Human chorionic gonadotropin—A hormone produced by the developing placenta that stimulates the production of estrogen and progesterone; its presence in maternal blood or urine is used to diagnose pregnancy.

Karyotype—A report in which photographic images of the chromosomes of a cell are displayed as a systematized arrangement of pairs in descending order of size.

Muscular dystrophy—An inherited disease in which muscles become gradually wasted and are replaced by scar tissue and fat, sometimes also affecting the heart.

Neural tube defect—Any of a group of inherited abnormalities of brain and spinal cord development, including spina bifida and anencephaly, caused by failure of the neural tube to close properly during development.

Rh incompatibility—An Rh negative person who is exposed to Rh positive red blood cells. When an Rh negative mother becomes pregnant with an Rh positive fetus, the fetal red blood cells may enter the maternal circulation and stimulate production of Rh antibodies. This process can be prevented by administration of Rho immune globulin prior to or during the pregnancy.

Sickle-cell anemia—An inherited chronic blood disease that occurs primarily among persons of African descent characterized by abnormal hemoglobin that causes red blood cells to become sickle-shaped and nonfunctional, leading to an enlarged spleen, chronic anemia, weakness, joint pain, and formation of blood clots.

Tay-Sachs disease—A rare and fatal inherited disease occurring chiefly in persons of eastern European Jewish origin, characterized by a red spot on the retina, gradual blindness, and paralysis.

Ultrasound—Also called ultrasonography, a diagnostic imaging technique that uses reflected high-frequency sound waves to visualize internal body structures or organs, especially useful as a non-invasive prenatal diagnostic tool.

photomicrography, construction of the karyotype report, and biochemical analysis of DNA.

Chronic kidney failure

Definition

Chronic kidney failure occurs when disease or disorder damages the **kidneys** so that they can no longer adequately remove fluids and wastes from the body or maintain proper levels of kidney-regulated chemicals in the bloodstream.

Description

Chronic kidney failure, also known as chronic renal failure, affects over 250,000 Americans annually. It may be caused by a number of diseases and inherited disorders, but the progression (end result) of chronic kidney failure is always the same. The kidneys, which serve as the body’s natural filtration system, gradually lose their ability to remove fluids and waste products (urea) from the bloodstream. They also fail to regulate certain chemicals in the bloodstream and allow protein to leak into the urine. Chronic kidney failure is irreversible and eventually leads to total kidney failure, known as end-stage renal disease (ESRD). Without treatment and intervention to remove wastes and fluids from the bloodstream, ESRD is inevitably fatal.

Causes and symptoms

Kidney failure is caused by acquired disease or hereditary disorders in the kidneys. The four most common causes of chronic kidney failure include:

- **Diabetes.** **Diabetes mellitus** (DM), both insulin dependant (IDDM) and non-insulin dependant (NIDDM), occurs when the body cannot produce and/or use insulin, the hormone necessary for the body to process glucose. Long-term diabetes may cause the glomeruli, the filtering units located in the nephrons of the kidneys, to gradually lose function.
 - **Hypertension.** High **blood pressure** is both a cause and a result of kidney failure. The kidneys can become stressed and ultimately sustain permanent damage from **blood** pushing through them at excessive pressures over long periods of time.
 - **Glomerulonephritis.** Glomerulonephritis is an inflammation of the glomeruli, or filtering units of the kidney. Certain types of glomerulonephritis are treatable, and may only cause a temporary disruption of kidney functioning.
 - **Polycystic kidney disease.** Polycystic kidney disease is an inherited disorder that causes cysts to form in the kidneys. These cysts impair the regular functioning of the kidney.
- Less common causes of chronic kidney failure include kidney **cancer**, obstructions such as **kidney stones**, pyelonephritis, reflux nephropathy, systemic lupus erythematosus, amyloidosis, sickle cell anemia, Alport syndrome, and oxalosis.
- Initially, symptoms of chronic kidney failure develop slowly. Even individuals with mild to moderate kidney failure may have few symptoms in spite of increased urea in their blood. Among signs and symptoms that may be present at this point are frequent urination during the night and high blood pressure.
- Most symptoms of chronic kidney failure are not apparent until kidney disease has progressed significantly. Common symptoms include:
- **Anemia.** The kidneys are responsible for the production of erythropoietin (EPO), a hormone that stimulates red cell production. If kidney disease causes shrinking of the kidney, this red cell production is hampered.
 - **Bad breath or a bad taste in mouth.** Urea in the saliva may cause an ammonia-like taste in the mouth.
 - **Bone and joint problems.** The kidneys produce **vitamin D**, which aids in the absorption of **calcium** and keeps bones strong. In patients with kidney failure, bones may become brittle, and in children, normal growth may be stunted. Joint **pain** may also occur as a result of unchecked phosphate levels in the blood.
 - **Edema.** Puffiness or swelling around the eyes and legs.
 - **Frequent urination.**
 - **Foamy or bloody urine.** Protein in the urine may cause it to foam significantly. Blood in the urine may indicate bleeding from diseased or obstructed kidneys, bladder, or ureters.
 - **Headaches.** High blood pressure may trigger headaches.

- Hypertension, or high blood pressure. The retention of fluids and sodium causes blood volume to increase, which, in turn, causes blood pressure to rise.
- Increased fatigue. Toxic substances in the blood and the presence of anemia may cause feelings of exhaustion.
- Itching. **Phosphorus**, which is typically eliminated in the urine, accumulates in the blood of patients with kidney failure. This heightened phosphorus level may cause itching of the skin.
- Low back pain. Pain where the kidneys are located, in the small of the back below the ribs.
- Nausea, loss of appetite, and vomiting. Urea in the gastric juices may cause upset **stomach**. This can lead to malnutrition and weight loss.

Diagnosis

Kidney failure is typically diagnosed and treated by a nephrologist, a physician specializing in kidney disease. The patient suspected of having chronic kidney failure will undergo an extensive blood work-up, usually performed by a laboratory technologist or technician. Blood tests will assess the levels of creatinine, blood urea nitrogen (BUN), uric acid, phosphate, sodium, and potassium in the blood. Urine samples will also be collected, usually over a 24-hour period, to assess protein loss.

Uncovering the cause of kidney failure is critical to proper treatment. A full assessment of the kidneys is necessary to determine if the underlying disease is treatable and if the kidney failure is chronic or acute. X ray, MRI, computed tomography scan, ultrasound, renal biopsy, and/or arteriogram of the kidneys may be employed to determine the cause of kidney failure and level of remaining kidney function. X rays and ultrasound of the bladder and/or ureters may also be taken. Most imaging studies are performed by radiology technicians.

Treatment

Chronic kidney failure is an irreversible condition. Hemodialysis, **peritoneal dialysis**, or kidney transplantation must be employed to replace the lost function of the kidneys if the failure progresses to ESRD. In addition, dietary changes and treatment to relieve specific symptoms such as anemia and high blood pressure are critical to the treatment process.

Hemodialysis

Hemodialysis is the most frequently prescribed type of dialysis treatment in the United States. Most hemodialysis patients require treatment three times a week, for an average of three to four hours per dialysis

“run” depending on the type of dialyzer used and their current physical condition. The treatment involves circulating the patient’s blood outside of the body through an extracorporeal circuit (ECC), or dialysis circuit. The dialysis circuit consists of plastic blood tubing, a two-compartment filter known as a dialyzer, or artificial kidney, and a dialysis machine that monitors and maintains blood flow and administers dialysate, a chemical bath used to draw waste products out of the blood. The patient’s blood leaves and enters the body through two needles inserted into the patient’s vein, called an access site, and is pushed through the blood compartment of the dialyzer. Once the patient’s blood is inside the dialyzer, excess fluids and toxins are pulled out of the bloodstream and into the dialysate compartment, where they are carried out of the body. At the same time, electrolytes and other chemicals in the dialysate solution move from the dialysate into the bloodstream. The purified, chemically balanced blood is then returned to the body. Specially trained nurses and dialysis technicians supervise and monitor patients during treatment.

Peritoneal dialysis

In peritoneal dialysis (PD), the peritoneum, (lining of the abdomen) acts as a blood filter. A catheter is surgically inserted into the patient’s abdomen. During treatment, the catheter is used to fill the abdominal cavity with liquid dialysate. Waste products and excess fluids move from the patient’s bloodstream into the dialysate solution. After a waiting period of 6 to 24 hours, depending on the treatment method used, the waste-filled dialysate is drained from the abdomen, and replaced with clean dialysate. There are three types of peritoneal dialysis, which vary by treatment time and administration method: continuous ambulatory peritoneal dialysis (CAPD), continuous cyclic peritoneal dialysis (CCPD), and intermittent peritoneal dialysis (IPD).

Kidney transplantation

Kidney transplantation involves surgically implanting a functioning kidney, known as a graft, from a **brain** dead organ donor (a cadaver transplant), or from a living donor, to a patient with ESRD. Patients with chronic renal disease who need a transplant and do not have a living donor register with UNOS (United Network for Organ Sharing), the federal organ procurement agency. UNOS places patients on a waiting list for a cadaver kidney transplant. Kidney availability is based on the patient’s health status. When the new kidney is transplanted, the patient’s diseased kidneys may or may not be removed, depending on the circumstances surrounding the kidney failure. A regimen of immunosuppressive

(anti-rejection) medication is required after transplantation surgery.

Dietary management

A diet low in sodium, potassium, and phosphorous, three substances that healthy kidneys excrete, is critical in managing kidney disease. Other dietary restrictions, such as a reduction in protein, may be prescribed depending on the cause of kidney failure and the type of dialysis treatment employed. Patients with chronic kidney failure also need to limit their fluid intake. Patients may receive instruction about appropriate dietary measures from registered dietitians, nutritionists, nurses, or health educators.

Medications and dietary supplements

Kidney failure patients with hypertension typically take medication to control their high blood pressure. Epoetin alfa, or EPO (Epogen), a hormone therapy, and intravenous or oral **iron** supplements are used to manage anemia, especially if the kidneys have been surgically removed. A multivitamin may be prescribed to replace **vitamins** lost during dialysis treatments. Vitamin D, which promotes the absorption of calcium, along with calcium supplements, may also be prescribed.

Since 1973, **Medicare** has reimbursed up to 80% of ESRD treatment costs, including the costs of dialysis and transplantation as well as the costs of some medications. To qualify for benefits, a patient must be insured or eligible for benefits under Social Security, or be a spouse or child of an eligible American. Private insurance and state **Medicaid** programs often cover the remaining 20% of treatment costs.

Prognosis

Early diagnosis and treatment of kidney failure is critical to improving length and quality of life in chronic kidney failure patients. Patient outcome varies; it depends on the cause of chronic kidney failure and the method chosen to treat it. Overall, patients with chronic kidney disease leading to ESRD have a shortened life span. According to the United States Renal Data System (USRDS), the life span of an ESRD patient is 18-47% of the life span of the age-sex-race matched general population. ESRD patients on dialysis have a life span that is 16-37% of the general population.

The demand for kidneys to transplant continues to exceed supply. Cadaver kidney transplants have a 50% chance of functioning nine years, and living donor kidneys that are well-matched (have two matching antigen pairs) have a 50% chance of functioning for 24 years.

KEY TERMS

End-stage renal disease (ESRD)—Total kidney failure; chronic kidney failure is diagnosed as ESRD when kidney function falls to 5-10% of capacity.

Nephrotic syndrome—Characterized by protein loss in the urine, low protein levels in the blood, and fluid retention.

Ureters—The two ducts that pass urine from each kidney to the bladder.

However, some transplant grafts have functioned for more than 30 years.

Health care team roles

Patients with chronic kidney failure are treated by a team that includes nephrologists, dialysis technicians, nurses, radiology technicians, and laboratory technicians. Patients undergoing kidney transplant are cared for by a transplant team headed by a transplant surgeon. Registered dietitians, nutritionists, and nurses instruct patients about dietary changes to manage their disease.

Classification of teeth

Definition

Classification of teeth refers to the position of the first molars, and how they bite together.

Description

In 1844 J.F. Cravens, a dentist from Indianapolis, discussed the first dental deformities. He studied the first molar biting relationship and how the molars should line up with each other on the upper and lower jaws. Cravens called the first molar the “patriarch of the mouth,” meaning the first molar determined the bite relationship for the entire mouth. J.N. Farrar, a leading dentist, in 1880 discussed the teeth relationship as an irregularity in his book “A Treatise on the Irregularities of the Teeth and Their Corrections.”

In 1905 at the 4th Annual Meeting of American Society of Orthodontics the subject was again broached, but this time by Edward H. Angle, a dentist who dis-

agreed with the other leading dentists and their terms and names of bite relationships. Angle had devised a simple and logical classification system for the teeth irregularities and deformities, which he didn’t believe were irregularities or deformities at all, but rather malocclusions. He felt the first molar was “king of the mouth” and the basis for the classification of **malocclusion** of the teeth. Angle had studied Cravens’s work and knew he could prove the theories.

Angle’s classification system refers to the position of first molars and how they bite together and is broken into three main categories: Class I, II, III.

- Class I: The normal biting relationship between the upper and lower teeth and jaw, also known as a balanced bite. The front teeth may be spaced apart or crowding of the anterior teeth may be seen, but the biting relationship of the first molars is balanced.
- Class II: The lower first molar is posterior or more towards the back of the mouth than the upper first molar. In this abnormal biting relationship the upper front teeth of the jaw protrude further than the lower jaw, commonly called “buck teeth.” There is a convex appearance in the profile of the patient with a receding chin and lower lip. Class II problems can be due to insufficient growth of the lower jaw or an over growth of the upper jaw, or a combination of the two. Class II cases are commonly genetically inherited and can be aggravated by environmental factors such as thumb sucking.
- Class III: The lower first molar is anterior or more towards the front of the mouth than the upper first molar. In this abnormal relationship the lower teeth and jaw project further forward than the upper teeth and jaws. There is a concave appearance in the profile with a prominent chin. Class III problems are commonly due to an overgrowth in the lower jaw or undergrowth of the upper jaw or a combination of the two. Like Class II, Class III is genetically inherited. Orthodontia may help relieve the class III biting relationship, but often surgery is required to shorten the lower jaw.

Viewpoints

The classification system founded by Angle represented a milestone in the dental profession, because for the first time the concept of diagnostic arrangement based on science was discussed and it opened the way to etiological research of malocclusions. Angle was firmly persuaded that the upper first molars always erupted in a fixed, constant position on the facial bulk, “Upper first molar as basis of diagnosis in orthodontia,” thereby making a set classification system that could be used univer-

KEY TERMS

Anterior—Towards the front.

Etiology—The study of the origin.

Malocclusion—The relationship of the molars is not right, known as a “bad bite.”

Orthodontia—The science of studying malocclusions of the mouth.

Posterior—Towards the back.

sally. This viewpoint was not accepted by a few other dentists, primarily J.N. Farrar, who refused to think this system was correct or would work in dentistry. Many other American dentists grasped this new idea of classification and a new age in orthodontia began.

It took some years for other nations of the world to grasp this system, but American universities began teaching it soon after it was introduced, with the first school of orthodontics established in 1905 by Edward Angle. Many Italian universities have yet to employ this basic system. Japan, England, and many other countries use this method of classification of the teeth, making it an international system for malocclusion in dentistry.

Professional implications

The classification of the teeth for malocclusion has given dentists and orthodontists a much simpler way to diagnose malocclusions. Using this classification system of the teeth universally keeps dentists and orthodontists from getting confused about bite relationships and malocclusion, and facilitates the sharing of information concerning these subjects.

Clinical nurse specialist

Definition

Clinical nurse specialists (CNSs) are licensed registered nurses with additional master's or doctorate level training in CNS. These **advanced practice nurses** are clinical experts in theory-based or research-based nursing, focusing on specific specialty areas.

Description

A CNS is an advanced practice nurse. There are four categories of advanced practice nurses: nurse practitioners, certified nurse-midwives (CNMs), clinical nurse specialists, and certified **registered nurse** anesthetists. Advanced practice nurses typically are registered nurses (RNs) who have gone on to complete master's degree programs. CNSs have broadened patient care roles because of their advanced training and often provide direct patient care without supervision by a doctor. Sometimes, they have the authority to prescribe medications. This authority is granted on the state level and varies from state to state.

CNSs assume many roles within the health care delivery system. While many are in the clinical setting, others also work as educators, administrators, consultants, researchers, change agents, and case managers. CNSs can become specialized in the areas of adult psychiatry, child psychology, community health, home health, gerontology, and medical-surgical, as well as oncology, perinatal critical care, critical care, and rehab. Some in areas of specialty certification classify themselves as CNSs, and others use the umbrella term of advanced practice nursing. There are all kinds of other

KEY TERMS

Certified nurse-midwives (CNMs)—Advanced practice nurses who provide prenatal and gynecological care to healthy women. These nurses deliver babies in all types of settings and offer postpartum care.

Certified registered nurse anesthetists—An advanced practice nurse who administers anesthesia as sole providers or as part of health care teams.

Charge agents—Nurses who work to make changes within systems to improve the delivery of clinical care.

Nurse practitioner—An advanced practice nurse delivering front-line primary and acute care.

certifications, including those of **wound care** nurses, case managers, and administrators, that CNSs might earn in addition to the certification as CNS.

In March 2000, the number of RNs prepared to practice in at least one advanced practice role was estimated to be 196,279, which is about 7.3% of the total RN population. The largest group among the advanced practice nurses was the nurse practitioners, followed by the CNSs. These two groups together made up about 80% of all advanced practice nurses. There were about 54,374 CNSs (up from 53,500 in 1996), which does not include those who were certified as both nurse practitioners and CNSs. While about 36.9% of the CNSs were employed in nursing, only about 24% were practicing under the position title of CNS. Nearly a quarter of CNSs reported working in **nursing education** positions.

Work settings

The work settings of CNSs include all those settings where one would find nurses and other health care providers. CNSs work in the acute care, long-term care, and intermediate care settings. They work in clinical education within health care facilities, as well as in nursing education programs as faculty teaching nursing. Other settings in which CNSs work include outpatient and ambulatory care, private practice, home health, physician office practice, subacute care, government or military service, community health centers, health care administration, private industry (working for drug companies or manufacturers, in managed care, and other areas of the private sector), and nurse-managed centers, which are health centers completely run by nurses. Within these

categories, CNSs work in assisted living facilities; specialized hospital areas, such as **cardiac catheterization** labs; correctional facilities; dialysis units; parish nursing; and psychiatric hospitals.

Education and training

First of all, nurses must have a baccalaureate degree, or its equivalent, to enroll in a CNS program. To use the title of CNS, the nurse must have a minimum of a master's degree from an education program that prepares CNSs. The training is graduate-level education. Some universities have a fast track program whereby they will accept individuals who do not have a baccalaureate and move them into a master's program. CNSs also take a certification exam in a specialty, offered by one of the nationally recognized certification entities.

CNS students go through advanced theory and practice training, revolving around the three areas of influence, that impact on direct patient care, others supervising direct patient care, and patient care systems. The general areas of learning that are included in this graduate education are theoretical foundations; phenomena of concern; assessment and intervention/design and development; clinical inquiry; technology, products, and devices; teaching and coaching; change, persuasion, influence, and negotiation; systems thinking, consultation theory; measurement; and evaluation methodologies. Under the umbrella of theory, CNSs learn to understand health, illness, and wellness as subjective experiences. They also learn to understand health behavior and health behavior change, as well as the theories of learning, **stress**, consultation, and organizational development. On the clinical side, CNSs focus on awareness, knowledge, and skill in cognitive work in the three spheres of influence. They learn about technology, products, and devices, as well as how to teach and coach patients and other health care providers.

The American Nurses Credentialing Center certifies CNSs as adult psychiatric, child psychology, community health, home health, gerontology, and medical-surgical CNSs. There also are other certifying bodies, including the rehabilitation nursing certification board, oncology nursing certification corporation, and American association of critical care nurses certification.

Advanced education and training

The master's-prepared clinical specialist can go on to get a doctorate. Each certifying body has its own requirements for recertification. State licensing boards may also have continuing education requirements.

The CNS at the doctoral level typically focuses on research. Although there is a research component to the masters, the doctorate training, more often than not, is a research degree.

Future outlook

The outlook is good for all types of nurses, especially those at the RN level or higher. It is projected that if current trends continue, demand will exceed supply of RNs by about 2010. It is possible that as many as 114,000 jobs for full-time-equivalent RNs are going to go unfilled nationwide by 2015. This is due to a growing elderly population with mounting health care needs, an aging RN workforce, the expansion of primary care, and technological advances that require more highly trained nurses.

Coagulation tests

Definition

Hemostasis has been described as “a process by which the body spontaneously stops bleeding and maintains **blood** in the fluid state within the vascular compartment.” There are at least four major systems that are involved in this complex process: the vasculature system, the platelets, the fibrin-forming system, and the fibrin-lysing system. Hemostasis has also been further segregated into stages or steps. These are primary hemostasis, which is the interaction of the injured blood vessel and platelets; secondary hemostasis, which is referred to historically as the **blood coagulation** process; and tertiary hemostasis, which is the process of fibrinolysis (clot destruction). The first two stages are assessed by blood coagulation tests that evaluate platelets, circulating coagulation factors, and **blood vessels**.

Purpose

Coagulation tests are performed to aid in the diagnosis of **bleeding disorders**, monitor the effectiveness of anticoagulant therapy, and confirm a patient’s blood clotting status prior to surgery.

Precautions

Before administering the test, the patient should be asked to list the medications he or she is taking, and whether or not he or she has recently experienced active bleeding, acute **infection** or illness, or undergone a blood transfusion, as these factors could adversely affect their coagulation test results. Some of the medications that can affect coagulation results include **antacids**, **antibiotics**, anticoagulants, **antihistamines**, aspirin, diuretics, nicotine, **nonsteroidal anti-inflammatory drugs**, oral contraceptives, steroids, tranquilizers, and **vitamins C** and **K**. If a patient is currently being medicated, the testing facility should be contacted to determine the acceptability of the blood sample. From the moment the blood specimen is drawn until the test is completed, the handling of the specimen is critical in coagulation studies. Assuming that the specimen is drawn correctly, the following procedures should be followed.

Collection of blood for coagulation tests

There is a generally held belief that the first tube in a case where multiple specimens are drawn should never be used for any hemostasis assay, because tissue thromboplastin from the initial venipuncture may affect coagulation test results. In addition, the tube(s) for coagulation

testing should be filled before any tubes containing EDTA. If coagulation tests are the only studies ordered, a discard tube should be drawn before filling the blue-stoppered citrate tube used for the tests.

Anticoagulant for coagulation tests

The anticoagulant of choice for coagulation testing is sodium citrate, which reversibly chelates **calcium**. Evacuated blue-top tubes containing sodium citrate are available commercially with a 3.8% (129 mmol/L) or 3.2% (109 mmol/L) citrate concentration. Blue-stoppered tubes are manufactured to draw nine parts of whole blood to one part of liquid sodium citrate already present in the tube. Thus, when using an evacuated system, blood must be allowed to flow into the tube until it stops automatically. This provides for the 90% fill ratio required for coagulation testing. Ideally the plasma specimen is tested within four hours of collection. If this is not possible then the samples should be frozen until testing. Gross hemolysis is usually a criterion for sample rejection.

Description

The first or primary event that stops bleeding from a very small wound is the formation of a platelet plug, which seals the hole in the vessel wall. This is followed by arteriolar vasoconstriction. The plug in turn is strengthened by fibrin strands. Exposure to collagen and subendothelial components is thought to be the trigger that causes the platelets to aggregate and form the primary plug. Aggregation has been proven to be dependent on the Von Willebrand factor and other plasma factors, such as ADP release from lysed red cells or platelets after exposure to collagen. A defect in one of these plasma factors, a qualitative defect in platelets, a reduced number of platelets (thrombocytopenia), or a defect in the blood vessel wall can result in failure of the primary hemostatic stage, causing spontaneous bleeding or purpura.

The blood clotting or coagulation system is a proteolytic cascade. Each enzyme of the pathway is present in plasma in an inactive (zymogen) form, which, when activated, releases the active factor from the precursor molecule. An active factor then “switches on” the next factor. The mechanism functions as a series of positive and negative feedback loops to effectively control the process. The main aim of this process is to produce thrombin, which can convert soluble fibrinogen into insoluble fibrin, thus forming the clot.

There are three phases of coagulation, the intrinsic and extrinsic (tissue factor) pathways that provide alternative routes for the generation of factor X and the final common pathway that results in thrombin formation. The distinction between the intrinsic and extrinsic pathways

is important for understanding the laboratory tests of coagulation. It is not relevant for the real-life process of blood clotting in the body, which may involve both pathways to different extents. Experts are unclear as to which pathway is involved in venous thromboembolic diseases such as deep vein thrombosis and pulmonary embolism.

Bleeding disorders

According to the cascade theory, each coagulation factor is converted to its active form by the preceding factor in a series of biochemical chain reactions. If there is a deficiency of any one of the factors, coagulation cannot proceed at a normal rate, initiation of the next reaction is delayed, and the time required for clotting is prolonged, resulting in bleeding from injured vessels for a longer time. Bleeding disorders can be either acquired or inherited (congenital). Von Willebrand’s disease is the most common hereditary coagulation disorder; it results in problems with platelet quality and can cause mild to moderately severe bleeding. Inherited disorders also include **hemophilia** A and B, which are associated with a decrease in factor VIII or IX activity, respectively. Because the **liver** produces many of the coagulation factors, diseases that affect the liver may be associated with clotting abnormalities. Disseminated intravascular coagulation (DIC), anticoagulant therapy, and thrombocytopenia also increase bleeding tendencies.

There are several tests available to aid in the diagnosis of bleeding disorders and monitor anticoagulation therapy, and the most common are listed below.

Platelet count

Platelets are disk-shaped structures formed by the detachment of cytoplasm from megakaryocytes. They aid in the coagulation process by attaching or adhering to the walls of injured blood vessels, where they stick together to form the initial platelet plug. A low platelet count may occur in patients with **AIDS**, viral infections, lymphoma, and lupus erythematosus, or in patients taking certain drugs, most notably quinine and quinidine. Decreased platelet production is also a cause of thrombocytopenia, and may be due to aplastic anemia, leukemia, lymphoma, or bone marrow fibrosis.

When collecting a specimen for a platelet count, EDTA is the anticoagulant of choice. The test is most commonly performed on an automated instrument which employs impedance measurement to count platelets, red blood cells, and white blood cells. Impedance counting is also known as the Coulter principle. According to Beckman Coulter, a major manufacturer of cell counters, the methodology works as follows: “A small opening (aperture) between electrodes is the sensing zone through

which suspended particles pass. In the sensing zone each particle displaces its own volume of electrolyte. Volume displaced is measured as a voltage pulse; the height of each pulse being proportional to the volume of the particle. Several thousand particles per second are individually counted and sized with great accuracy.” Automated cell counters also report the Mean Platelet Volume (MPV) or Platelet Distribution Width (PDW), two indices used to determine the relative size of the platelets being counted. Since a variety of factors can affect results (e.g., fibrin clots in EDTA blood, platelet clumping in capillary samples), a platelet estimate can also be performed to verify count accuracy. This is done by counting the platelets seen on a blood film by microscopic examination. Each platelet seen per field is estimated to be equivalent to 20,000 platelets/ μL . This means 10 platelets per field would correspond to a platelet count of 200,000/ μL . When results are questionable, manual platelet counts may be performed using light or phase contrast microscopy. The procedure is as follows: the sample is first treated with 1% ammonium oxalate counting fluid, then charged into a Neubauer hemacytometer chamber. The chamber is placed in a moist Petri dish for 10 minutes to allow the cells to settle. The chamber is then placed on the **microscope** platform and the platelets in the 25 small center squares of the chamber grid are systematically counted. The number obtained is multiplied by 1,000 to give the platelet count per microliter of blood.

Thrombin time

This test is used to screen for abnormalities in the conversion of fibrinogen to fibrin. These may be caused by qualitative or quantitative abnormalities of fibrinogen or by inhibitors, such as heparin or fibrin/fibrinogen split products. The principle of the thrombin time test is that the exogenous addition of thrombin to plasma converts fibrinogen to fibrin and bypasses both the intrinsic and extrinsic pathways. The time it takes for the patient’s plasma to clot on addition of thrombin, referred to as the thrombin time, is a function of fibrinogen concentration. The test procedure involves adding one part of a known concentration of thrombin to one part of the patient’s citrated plasma and the clotting time is recorded. A reference range should be established by each testing facility, but a range of 14.0 to 20.0 seconds is considered normal.

Prothrombin time (PT)

The PT measures the function of the extrinsic and common pathways of the coagulation cascade. A reagent containing tissue thromboplastin (factor III) of rabbit **brain** origin and calcium is commonly used as an activating substance. Factor III (thromboplastin) initiates the

extrinsic pathway by forming a complex with factor VII. Calcium is needed to replace the plasma calcium that was chelated by the citrate in the blood collection tube. The PT is timed from the moment that the reagent is added to the plasma until the sample clots. As the factor VII-tissue thromboplastin complex activates factor X, the coagulation cascade proceeds into the common pathway. After formation of thrombin, fibrin will form at a normal rate only if factors involved in the extrinsic pathway (VII) and common pathway (X, V, II, I) are present in adequate amounts. If the PT is normal, then the sample contains adequate levels of factors VII, X, V, II, and I.

The PT test is used to (1) screen for hereditary or acquired factor deficiencies in the extrinsic/common pathway (i.e., VII, X, V, II, I), (2) screen for specific factor or non-specific inhibitors (such as the lupus anticoagulant), (3) monitor anticoagulant therapy with **vitamin K** antagonists such as Coumadin and warfarin, and (4) assess the effect of vitamin K deficiency, which is an index of liver damage in patients with chronic liver disease.

The results of the PT depend on the source and preparation of the thromboplastin reagent used, the instrumentation selected to perform the test, and the handling of the patient’s sample. The PT may be reported as the clotting time in seconds or as the INR (international normalized ratio). The INR is preferred to the clotting time measured in seconds because different thromboplastin reagents have different sensitivities to warfarin-induced changes in levels of clotting factors. Since the potency of different commercially prepared calcium-thromboplastin reagents varies, the International Sensitivity Index (ISI) was developed to describe the relative strength of each reagent. This index is a measure of the sensitivity of the thromboplastin used in PT assays. The higher the ISI, the less sensitive the thromboplastin. The INR is calculated by dividing the patient PT value by the established mean PT value of the normal population in each testing facility. This value is then raised to the power of the ISI. Use of the INR eliminates the interlaboratory variation seen with prothrombin times measured in seconds.

Activated partial thromboplastin time (aPTT)

The aPTT measures the function of the intrinsic and common pathways of the coagulation cascade. To begin the test, a reagent containing a contact activator (cephalin) and a phospholipid substitute for platelet factor III is incubated with the patient’s platelet-poor plasma. During this incubation period, the intrinsic pathway is initiated by conversion of XII to XIIa, which then converts XI to XIa. The cascade does not proceed any further, since the subsequent conversion of IX to IXa

requires calcium ions. At this point, calcium is added as a second reagent. After recalcification, fibrin will form at a normal rate only if the factors involved in the intrinsic pathway (prekallikrein, high molecular weight kininogen [HMWK], XII, XI, IX, VIII) and common pathway (V, X, II, I) are present in adequate amounts. This rate of clotting measures the overall coagulant activity. The term “partial” in aPTT is used because platelet substitutes (the phospholipid emulsion) are not capable of activating the extrinsic pathway. This requires “complete” thromboplastin (tissue factor). Thus, the aPTT bypasses the extrinsic pathway and is unaffected by any abnormalities of factor VII. The aPTT is used to (1) screen for hereditary or acquired deficiencies of factors in the intrinsic/common pathway (i.e., all factors except VII and XIII), (2) screen for specific factor or non-specific inhibitors (such as the lupus anticoagulant), and (3) monitor anticoagulant therapy with parenteral heparin. Intrinsic coagulation disorders are apparent when the aPTT is prolonged and the prothrombin time is normal. For screening purposes, the aPTT is usually done in combination with other tests, such as the prothrombin time, which evaluates the factors of the extrinsic pathway. The combination of tests narrows the list of possible missing or defective factors. Results of the aPTT are prolonged by factor VIII deficiency (Hemophilia A) and factor IX deficiency (Hemophilia B). When the aPTT test is being used to monitor the effect of heparin, the test is done before the first dose of heparin and then as necessary to monitor therapeutic dosage. The activated clotting test (ACT) may be used in place of the aPTT to monitor heparin therapy. This test is performed by adding kaolin, (a clay that activates factor XII), or other clotting activator to the patient’s plasma and measuring the time required for clot formation.

Bleeding time test

The bleeding time (BT) is defined as the time between making a small incision through a skin capillary and the moment the bleeding stops. It is an *in vivo* measurement of platelet participation in small blood vessel hemostasis, and is one of the simplest and best tests of overall platelet function. This test is used to determine how well platelets interact with the blood vessel wall to form a blood clot. The test is usually performed on patients who have a history of prolonged bleeding after cuts, or who have a family history of bleeding disorders, or as a preoperative test to determine a patient’s likely bleeding response during and after surgery. There are four methods used: the Ivy method, template, modified template, and Duke method. With all methods the skin is cut in an area void of visible veins. The time from when the incision is made until all bleeding has stopped is

measured and recorded as the bleeding time. Every 30 seconds, filter paper or a paper towel is used to draw off the blood. The test is finished when bleeding has stopped completely.

Fibrinogen

The fibrinogen test aids in the diagnosis of suspected clotting or bleeding disorders caused by fibrinogen abnormalities which include the absence of fibrinogen, low fibrinogen concentration, or functionally abnormal fibrinogen. Reduced fibrinogen levels can be found in liver disease, **prostate cancer**, lung disease, bone marrow lesions, malnutrition, and certain bleeding disorders. Obstetric complications or trauma may also cause low levels. Patients who have received multiple blood transfusions may exhibit low fibrinogen levels because banked blood does not contain fibrinogen. Fibrinogen levels are also decreased in approximately 50% of patients with disseminated intravascular coagulation (DIC). In this condition the coagulation process is triggered by malignancy, severe injury, sepsis (and other conditions) and continues unabated, causing systemic clots to form until coagulation factors and platelets are depleted. This process is followed by internal hemorrhage. The fibrinogen test is performed by adding thrombin to specific dilutions of the patient’s plasma and measuring the amount of time it takes for the sample to clot.

Anticoagulation therapy with low molecular weight heparin (LMWH)

The anticoagulating effects of LMWH (heparin of smaller chain length) are easier to predict than standard heparin, and LMWH is associated with a lower risk of excessive bleeding and heparin induced thrombocytopenia. However, the effects of LMWH cannot be measured using the aPTT or activated clotting test (ACT). LMWH therapy is monitored by the anti-factor Xa assay. The antifactor Xa activity of heparin has been considered important because it is relatively unaffected by the molecular weight of heparin and therefore less influenced by the effect of potent heparin antagonists which can be released from platelets. The anti-factor Xa assay measures the anti-Xa effect of LMWH whereby heparin in a citrated plasma sample combines with antithrombin, forming a complex that inhibits an excess of purified factor Xa. Measurement of the clotting activity of residual factor Xa is done by the addition of phospholipids and calcium in the presence of a substrate plasma. This substrate plasma brings to the assay an excess of AT-III and other coagulation factors, thus eliminating interferences by the factors that are already present in the plasma being tested.

KEY TERMS

Anticoagulant—A substance that suppresses or counteracts coagulation of the blood.

Coagulation—The process of blood clotting.

Coagulation cascade—The sequence of biochemical activities, involving clotting factors, that stops bleeding by forming a clot.

Coagulation factors—Substances in the blood that act in sequence to stop bleeding by forming a clot.

Coumadin—An anticoagulant taken to prevent blood clots.

Fibrin—The insoluble protein formed by the action of thrombin on fibrinogen and stabilized by the action of factor XIIIa. Fibrin forms strands that add bulk to a forming blood clot to hold it in place and help “plug” an injured blood vessel wall.

Fibrinogen—A type of blood protein called a globulin that interacts with thrombin to form fibrin.

Fibrinolytic (thrombolytic) therapy—The intravenous administration of a drug to break up a blood clot.

Hemostasis—The process the body uses to stop the flow of blood when the vascular system is damaged.

Heparin—A medication that prevents blood clots by enhancing the activity of antithrombin. The heparin-antithrombin complex inhibits the activity of factor Xa, thrombin, and other clotting factors.

International Normalized Ratio (INR)—A measurement system that standardizes the prothrombin time to help monitor anticoagulant activity for clients receiving warfarin (Coumadin) therapy. It is recommended by the World Health Organization (WHO) for more consistent reporting of prothrombin time results, as it eliminates variation in PT results between laboratories caused by differences in the sensitivity of thromboplastin reagents.

Partial thromboplastin time—A test that measures the function of the clotting factors of the intrinsic pathway.

Platelet—An irregularly shaped cell-like particle in the blood that is an important part of blood clotting. Platelets are activated when an injury causes a blood vessel to break. They change shape from round to spiny, “sticking” to the broken vessel wall and to each other to begin the clotting process.

Prothrombin—A protein in blood plasma that is converted to thrombin during the clotting process.

Thrombin—An enzyme in blood plasma that converts fibrinogen to fibrin during the last stage of the clotting process.

Thromboplastin—A tissue substance that initiates the intrinsic coagulation pathway.

Thrombus—A solid mass of blood constituents (blood clot) formed in the heart or vessels.

Complications

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with this test.

Results

The absolute numbers that are considered normal vary from one laboratory to another. Any results reported should come with information regarding the testing facility’s normal range. The values listed below are representative of normal values. The patient’s physician is the best person to consult about a specific test level.

- Platelets: A normal platelet count ranges between 150,000 and 400,000/ μL . Platelet counts under 50,000/ μL put a patient at risk for severe bleeding, while counts below 30,000/ μL are considered critical.

- Thrombin time: Reference values for the thrombin time are 14 to 15 seconds or within five seconds of the control.
- Prothrombin time: PT results are reported in seconds and/or the International Normalized Ratio (INR). The normal range for the prothrombin time reported in seconds is between 11 and 13 seconds. Therapeutic levels for patient receiving Coumadin therapy generally are between 1.5 and 2-fold normal, or in terms of the INR, between 2.0 and 3.0.
- Activated partial thromboplastin time: The normal range is between 20 and 36 seconds. If a patient is being anticoagulated with heparin, a result approximately 1.5 to 2.5 times the normal control value is usually a therapeutic goal.
- Bleeding time: A normal bleeding time for the Ivy method is less than five minutes from the time of the incision until all bleeding from the wound has stopped.

Some texts extend the normal range to eight minutes. The normal value for the template method is eight minutes or less, while for the modified template method, up to 10 minutes is considered normal. Normal for the Duke method is three minutes or less.

- Fibrinogen: Normal reference values for fibrinogen are 200 mg/dL-400 mg/dL for adults and 125 mg/dL-300 mg/dL for newborns.

Health care team roles

Coagulation tests are ordered and interpreted by physicians (in some cases pharmacists). The samples may be collected by a nurse, physician assistant, phlebotomist, or technician. Testing is preformed by a clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) or by a clinical laboratory technician, CLT(NCA)/medical laboratory technician, MLT(ASCP).

Code of ethics for nurses

Definition

A code of ethics is a guide for an individual or group to follow in making decisions regarding ethical issues.

Description

In the broadest sense, ethics are the principles that guide an individual, group, or profession in conduct. Although nurses do make independent decisions regarding patient care, they are still responsible to the profession as a whole in how those decisions are made. From the earliest concept of nursing, the proper behavior and conduct of a nurse was closely scrutinized. Florence Nightingale wrote of specific issues of conduct and moral behavior. The Nightingale pledge that was composed in 1893 by nursing instructor Lystra Gretter includes the vow "to abstain from whatever is deleterious and mischievous and will not take or knowingly administer any harmful drug."

Over the last 100 years, nursing has evolved into a very complex professional field. Nurses are now faced with life and death decisions, sometimes on an hourly basis. Medical care has advanced to the point that new technology with its potential benefit or harm to a patient changes constantly. Although the private conduct of a nurse is no longer controlled by the employer, the effects of that lifestyle on the nurse's ability to think and respond to patients while on duty falls under the code of ethics.

Viewpoints

The study of ethics is actually a branch of philosophy. The word ethics is derived from the Greek term *ethos* which means customs, habitual usage, conduct, and character. The study of ethics has led to the identification of basic concepts including rights, autonomy, beneficence, nonmaleficence, justice, and fidelity. Understanding these concepts assists the nurse with making decisions during difficult situations.

Rights

Webster defines a right as "something to which one has a just claim or the power or privilege to which one is justly entitled." **Patient rights** have evolved to the point that federal legislation has been passed in the United States to protect a patient's individual rights. A Patient's Bill of Rights was initially developed by the American Hospital Association in 1973 and revised in 1992. All hospitals are now required by law to inform patients of these rights upon admission to the hospital.

Autonomy

Autonomy comes from the latin *auto* meaning “self” and *nomy* which means “control.” Individuals must be given the rights to assist in their own decision making. This ethical concept has led to the need for **informed consent**. Sometimes patients’ religious or cultural beliefs lead them to make decisions regarding their own care that may seem controversial or even dangerous. However, the concept of autonomy gives them the right to make those decisions unless they are mentally impaired.

Beneficence and nonmaleficence

Beneficence means to do good, not harm, to other people. Nonmaleficence is the concept of preventing intentional harm. Both of these ethical concepts relate directly to patient care. In the American Nurses Association Code for Nurses, there is a specific charge to protect patients by specifying that nurses should report unsafe, illegal, or unethical practices by any person. Nurses are often faced with making decisions about extending life with technology, which might not be in the best interest of the patient. Often the concept of weighing potential benefit to the patient against potential harm is used in making these difficult decisions, along with the patient’s own stated wishes.

Justice

The word justice is closely tied with the legal system. However, the word refers to the obligation to be fair to all people. In 2001, healthcare economics have hospitals and other providers stretching their resources to their limits. Economic decisions about healthcare resources have to be made based on the number of patients who would benefit. The potential of rationing care to the frail elderly, poor, and disabled creates an ethical dilemma that is sure to become even more complicated in the future.

Fidelity

Fidelity refers to the concept of keeping a commitment. Although the word is more closely used to describe a marital relationship, fidelity is the concept of accountability. What is the nurse’s responsibility to his or her patient, employer, society, or government? Privacy and confidentiality are concepts that could be challenged under the concept of fidelity. If a nurse is aware of another healthcare giver who is impaired, but the circumstances are private or confidential, how is the conflict resolved?

Professional implications

As a general rule, nurses are employed by a hospital, clinic, or private practice. Decisions that are made about patient care are not totally independent. Every decision creates a ripple effect and touches someone else in the health care field. One of the purposes of a code of ethics is to help nurses keep perspective and a balanced view regarding decisions. One way to study a code of ethics is to look at a case study.

J. L. presents herself to the emergency room with lower right abdominal **pain**. J. L. is a 17-year-old white female and is accompanied by her mother. J. L.’s mother is a nurse and works in another department of the hospital. The mother signed all of J. L.’s admission paperwork and received the Patient Bill of Rights. Although J. L.’s pain does not seem severe enough for **appendicitis**, she does have a history of **fever** for 24 hours and her temperature in the hospital is 100.8°F (38°C). An ultrasound that did not show appendicitis had been done earlier in the day. She was told to report to emergency room if the fever rose. After J. L. reports her symptoms to both a nurse and a physician assistant, she is examined briefly by emergency department physician. The staff assumes that J. L.’s mother wants to stay in the room and does not seek the patient’s permission. As a part of her history, J. L. informs them she is not sexually active and is on the second day of her menstrual cycle. The mother can tell by the tone of questioning that the staff does not believe J. L. is still a virgin. After a two-hour delay, including having to repeat the **urinalysis** because of a lost specimen, the emergency physician decides a pelvic exam needs to be done. The pelvic exam is traumatic for the patient, despite her mother’s best efforts to calm her. J. L. is told in a condescending tone that the exam hurts because of her failure to relax. Following the exam, the physician tells J. L. and mother that her **blood** count is normal, the urinalysis was inconclusive because of menstrual blood, and the patient was uncooperative in giving a catheterized specimen.

J. L. and her mother were informed a **pregnancy test** was done, because the staff have experienced “immaculate conceptions” in their department. The only time that J. L. and her mother had contact with an RN during this time was when she was initially triaged and when the discharge instructions were handed to her mother. J. L. and her mother were sent home with instructions. Her pain subsided without treatment.

Although this case study is not one of life and death decision making, there were numerous violations of the patient’s rights and of the nursing code of ethics. The patient’s right to privacy was violated. It is questionable whether the patient (J. L.) ever saw the Patient’s Bill of

KEY TERMS

Beneficence—The obligation to do good, not harm, to other people.

Ethics—A specific area of study of morality, which concentrates on conduct and human values.

Maleficence—The act of intentionally doing harm or evil. Nonmaleficence is the principle of purposefully not doing harm.

Rights, since it was given to her mother. J. L. was sexually inactive and a virgin, so the question of nonmaleficence is raised by the traumatic pelvic exam. The question of abandonment is also raised due to lack of nursing attention. If J. L. had asked her mother to leave during the exams, could confidentiality have been breached by the mother the next day by checking the hospital computer for reports? The answer to all of the above questions is *yes*; areas of nursing code of ethics could have been broken. No one died, but there must be constant re-education of staff regarding the importance of these issues.

In an attempt to keep the concept of ethical care in the forefront of nurses, physicians, and other healthcare worker's minds, hospitals have ethics committees or even an ethicist on staff. Special educational seminars may be offered or actual case studies reviewed. Some hospitals have protocols for requesting an ethics consult at the bedside. These type of consults are usually seen in ICU or trauma situations where ceasing life support is being discussed.

A new area of potential ethical dilemma was discussed in the July 2, 1999, *Online Journal of Issues in Nursing*. Silva and Ludwick discussed the pros and cons of interstate practice laws. As new laws are passed that allow more fluid movement of nurses between states, new issues of ethical behavior may arise. The initial reaction of most people in the health care field is that a nurse practices the same way everywhere, but there are subtle differences in the laws between states. For example, there are different definitions of minors and when minors can be emancipated to make their own decisions. Are there differences in state laws regarding patients with impaired decision-making capabilities? What if the nurse is not aware of the subtle differences in each state's law?

Communication technology such as the Internet is also complicating ethical issues. Do web sites that encourage patients to describe symptoms to on-line nurses expose too great a risk? What backup mechanisms are

in place if a patient talking to a triage nurse gets disconnected or loses consciousness? How can there be assurances of confidentiality in a telenursing setting? Silva and Ludwick encouraged their readers to "be proactive and stimulate critical thinking about ethics and interstate practice."

A nursing code of ethics cannot remain a stagnant document. As new issues arise in nursing and healthcare practice, they must be addressed and possibly included in a formal statement. The American Nurses Association (ANA) Code for Nurses with Interpretive Statements was approved in 1985 and was still being used in mid-2001. A task force met in 1996 and began the process of reviewing and revising the code. A draft of the new code is anticipated to be approved and released in 2001. The new code is more comprehensive than the 1985 code. It is the responsibility of all professional nurses to be aware of the Code for Nurses and any changes that may be made in the future. It is also the responsibility of each individual nurse to practice ethical care on a daily basis.

Cognitive-perceptual rehabilitation

Definition

Cognitive-perceptual rehabilitation addresses the impairments, functional limitations, and disabilities that result from a deficit in cognition or perception. Cognition

refers to the mental processes of comprehension, judgment, **memory**, and reasoning. Perception is part of the cognitive process, and is characterized by the conscious recognition and interpretation of sensory stimuli for knowledge or motivation of action.

Purpose

Individuals who have neurological insult (trauma to the **brain**), whether mild or severe, may experience cognitive and perceptual difficulties. Researchers have found that 75–90% of children with learning disabilities present with motor difficulties, which often are accompanied by perceptual deficits. In one study, over half of patients admitted for cognitive rehabilitation due to **head injury** also presented with visual perceptual impairments. In addition, individuals who have experienced strokes or inflammatory or infectious brain diseases, such as **meningitis** or encephalitis, are at risk for perceptual and cognitive disorders.

Cognitive and perceptual rehabilitation is indicated when a patient or client presents with deficits in these areas during the medical, **physical therapy**, or **occupational therapy** assessment. Difficulties may appear in equilibrium and vestibular functions, automatic postural reactions, fine and visual motor performance, motor planning abilities, and/or sensory integration. The individual may remember events incorrectly and have difficulty perceiving new information. In addition, he or she may have inappropriate responses to sensory input due to deficits in sensory processing.

Unilateral spatial inattention, a visual perceptual dysfunction occurring most frequently in patients who have had a stroke, traumatic brain injury, or tumor, may be detected by asymmetries in performance. For example, in drawing a clock, the individual may place all of the numbers on the right half of the clock only. When an individual has visual, auditory, or tactile agnosia, he or she is unable to recognize and name a common object using one of the senses of sight, **hearing**, or touch, respectively. Visuospatial disorders are manifested by the inability to discern spatial relationships. Visuoconstructive disabilities occur when an individual is unable to synthesize parts into a whole, such as building a tower from blocks or copying a line drawing. Vestibular impairments may present as dizziness or imbalance with certain movements or head positions. Many standardized tests exist to assess perceptual performance in children or adults.

Description

Intervention is found in either direct therapy or indirect therapy. Direct therapy usually focuses on the par-

ticular tasks or skills to be learned, with compensatory behaviors filling in for abilities that are missing. In contrast, indirect therapy focuses on rehabilitating the underlying dysfunction of the **central nervous system** (CNS), in hopes that improvement of the dysfunction will transfer to skill attainment.

Sensory integration and motor control approaches are considered indirect therapies. Sensory integration is an approach, used often with children, in which sensory input is provided within the context of a meaningful activity, usually play-related. The goal is that the child will display appropriate responses and gain experience in organization of sensory input. When using the motor control approach, task-oriented behavior is practiced to enhance perceptual information from the feedback and feedforward mechanisms in the CNS. Verbal and visual cues, in addition to varying the practice situation, are all used to assist in facilitating appropriate performance that can be applied to a variety of situations.

An example of direct therapy is functionally relevant motor skill training. Balance, locomotion, body awareness, and eye-hand coordination tasks are practiced in the context of activities of daily living, e.g., tying a shoe. Tasks are broken down into simple parts, then as a whole, and practiced in a variety of ways for carryover to different situations. Visual perceptual rehabilitation usually takes the form of direct therapy as well. Clients are trained to use eye and head movements along with visual markers to scan their environment, compensating for unilateral spatial inattention. Clients with visuospatial and visuoconstructive disorders are trained by progressing from simple to more complex tasks, using verbal, proprioceptive, and vestibular input to aid in performing the tasks. Treatment of vestibular impairments takes place in a similar fashion. The patient is habituated to certain head movements through practice, then is progressed to more complex ones as tolerance increases.

Cognitive **prosthetics**, another form of direct therapy, may be used in the rehabilitation of an individual with impairments in brain processes. Prosthetics, in the form of computer technology, are used to compensate for the individual's impairments by altering the environment for optimum function. Highly individualized computer software is used to provide an individual with the support necessary to successfully perform tasks of daily living. For example, it may sequence steps of a task, or convert written words to pictures or speech.

Regardless of the interventions selected, the underlying strategies for working with an individual who has cognitive-perceptual dysfunction are similar. Goals should be clear and relevant to the patient to reduce con-

KEY TERMS

Feedback—Peripheral sensory input which indicates a need for correction of errors.

Feedforward—The use of previous motor learning to anticipate errors in movement planning, allowing for advance correction.

Proprioceptive—Pertaining to sensations of body movements and position.

Sensory integration—The processing and organization of sensory input.

Unilateral spatial inattention—Perceptual unawareness of stimuli on one side of the body, associated with a cortical or subcortical lesion in the opposite side of the brain.

Vestibular—Pertaining to the inner ear structures associated with balance and position sense.

fusion and increase motivation. In the beginning, the complex should be broken down into simple parts with verbal, visual, tactile, or other cues provided as necessary. Distractions in the environment should be decreased at first. As progress is made, tasks then move toward more complexity.

Results

Progress may be slow, depending upon the severity of disability, individual motivation, family support, etc. The desired outcome, however, is that the individual learns to better modulate and discriminate sensory input in order to process it and respond to it appropriately. This may occur as an actual change in neural function, or through the use of compensatory measures. An increase in functional ability and reduction in disability are the ultimate goals.

Health care team roles

Cognitive-perceptual rehabilitation truly requires a transdisciplinary approach. Any or all of the following individuals may be involved, depending upon the specific needs of the individual: family physician, neurologist, psychiatrist, ophthalmologist, otologist, psychologist, occupational therapist, physical therapist, speech and language pathologist, recreational therapist, and vocational education specialist.

Cold injuries

Definition

Cold injuries include frostbite and frostnip. Frostbite is the term for damage to skin and other tissues caused by freezing. Frostnip is a milder form of cold injury.

Description

In North America, frostbite is largely confined to Alaska, Canada, and the northern states. However, it can occur whenever people are exposed to sustained cold temperatures without proper protection. Recent years have witnessed a substantial decline in the number of cold injury cases, probably for several reasons, including better winter clothing and footwear and greater public understanding of how to avoid cold-weather dangers. At the same time, the nature of the at-risk population has changed. Increased numbers of homeless people have made frostbite an urban as well as a rural **public health** concern. The growing popularity of outdoor winter activities has also expanded the at-risk population.

Causes and symptoms

Frostbite

Skin exposed to temperatures slightly below the freezing mark can take hours to freeze, but very cold temperatures can freeze skin in minutes or seconds. Air temperature, wind speed, and moisture all affect how rapidly skin becomes cold. A strong wind can lower skin temperature considerably by dispersing the thin protective layer of warm air that surrounds human bodies. Wet clothing readily draws heat away from skin because water is a potent conductor of heat. The evaporation of moisture from the surface of skin also produces cooling. For these reasons,

wet skin or clothing on a windy day can lead to frostbite even if the air temperature is above the freezing mark.

The extent of any permanent injury, however, is determined not by how cold skin and underlying tissues become but by how long they remain frozen. Consequently, homeless people and others whose self-preservation instincts may be clouded by alcohol or psychiatric illness face a greater risk of frostbite-related health effects because they are more likely to stay out in the cold when prudence dictates seeking shelter or medical attention. Alcohol and smoking also affect **blood** circulation in the extremities in a way that can increase the severity of injury. A review of 125 Saskatchewan frostbite cases found a tie to alcohol in 46% and to psychiatric illness in 17%. Other risk factors identified by researchers include inadequate clothing, previous cold injury, fatigue, wound **infection**, atherosclerosis, and diabetes. Driving in poor weather can also be dangerous. Vehicular failure was a predisposing factor in 15% of the Saskatchewan cases.

Three nearly simultaneous physiological processes underlie frostbite injury: tissue freezing, tissue hypoxia, and the release of inflammatory mediators. Tissue freezing causes the formation of ice crystals and other changes that damage and eventually kill cells. Much of this harm occurs because the ice produces pressure changes that cause water (crucial for cell survival) to flow out of cells. Tissue hypoxia (oxygen deficiency) occurs when **blood vessels** in the hands, feet, and other extremities narrow in response to cold. Among its many tasks, blood transfers body heat to skin, which then dissipates the heat into the environment. Blood vessel narrowing is the body's way of protecting vital internal organs at the expense of the extremities by reducing heat flow away from the core or center portions of the body. However, blood also carries life-sustaining oxygen to skin and other tissues, and narrowed vessels result in oxygen starvation. Narrowing also causes acidosis (an increase in tissue acidity) and increases blood viscosity (thickness). Ultimately, blood stops flowing through capillaries (tiny blood vessels that connect arteries and veins), and blood clots form in the arterioles and venules (the smallest arteries and veins). Damage also occurs to endothelial cells that line blood vessels. Hypoxia, blood clots, and endothelial damage lead, in turn, to the release of inflammatory mediators (substances that act as links in the inflammatory process), which promote further endothelial damage, hypoxia, and cell destruction.

Frostbite is classified by degree of injury (first, second, third, or fourth), or simply divided into two types, superficial (corresponding to first- or second-degree injury) and deep (corresponding to third- or fourth-degree injury). Most frostbite injuries affect the feet or

hands. The remaining 10% of cases typically involve ears, nose, cheeks, or penis. Once frostbite sets in, an affected part begins to feel cold and usually becomes numb. This is followed by a feeling of clumsiness. Skin turns a white or yellowish color. Many individuals experience severe **pain** in the affected part during rewarming treatment. This is often followed by an intense throbbing pain that arises two or three days later and can last for days or weeks. As skin begins to thaw during treatment, **edema** (excess tissue fluid) often accumulates, causing swelling. In second- and higher-degree frostbite, blisters appear. Third-degree frostbite cases produce deep, blood-filled blisters and, during the second week, a hard black eschar (scab). Fourth-degree frostbite penetrates below the skin to the muscles, tendons, nerves, and bones. In severe cases of frostbite the dead tissue can mummify and drop off. Infection is also a possibility.

Frostnip

Like frostbite, frostnip is associated with ice crystal formation in tissues, but no tissue destruction occurs and any crystals dissolve as soon as the skin is warmed. Frostnip affects areas such as the earlobes, cheeks, nose, fingers, and toes. The skin turns pale and one experiences numbness or tingling in the affected part until warming begins.

Diagnosis

Frostbite diagnosis relies on a **physical examination** and may also include conventional radiography (x rays), **angiography** (x-ray examination of the blood vessels using an injected dye to provide contrast), thermography (use of a heat-sensitive device for measuring blood flow), and other techniques for predicting the course of injury and identifying tissue that requires surgical removal. During the initial treatment period, however, a physician cannot judge how a case will progress. Diagnostic tests only become useful between three and five days after rewarming, once the blood vessels have stabilized.

Treatment

Frostbite

Emergency medical help should always be summoned whenever frostbite is suspected. While waiting for help to arrive, one should, if possible, remove wet or tight clothing and put on dry, loose clothing or wraps. A splint and padding are used to protect an injured area. Rubbing an injured area with snow or anything else is dangerous. The key to prehospital treatment is to avoid partial thawing and refreezing, which releases more

Human hand with frostbite. (Photo Researchers, Inc. Reproduced by permission.)

inflammatory mediators and makes an injury substantially worse. For this reason, the affected part must be kept away from heat sources such as campfires and car heaters. Experts advise rewarming in the field only when emergency help will take more than two hours to arrive and refreezing can be prevented.

Because the outcome of a frostbite injury cannot be initially predicted, all hospital treatment follows the same protocol. Treatment begins by rewarming the affected part for 15–30 minutes in water at a temperature of 104–108°F (40–42.2°C). This rapid rewarming halts ice crystal formation and dilates narrowed blood vessels. Aloe vera (which acts against inflammatory mediators) is applied to the affected part, which is then splinted, elevated, and wrapped in a dressing. Depending on the extent of injury, blisters may be debrided (cleaned by removing foreign material) or simply covered with aloe vera. A tetanus shot and possibly penicillin are used to prevent infection, and the injured person is given ibuprofen to combat inflammation. Narcotics are needed in most cases to reduce the excruciating pain that occurs as sensation returns during rewarming. Except when injury is minimal, treatment generally requires a hospital stay of several days, during which **hydrotherapy** and **physical therapy** are used to restore health to the affected body parts. Experts recommend a cautious approach to tissue removal, and advise that 22–45 days must pass before a decision on amputation can safely be made.

Alternative practitioners suggest several kinds of treatment to speed recovery from frostbite after leaving a hospital. Bathing the affected part in warm water or using contrast hydrotherapy may help enhance circulation. Contrast hydrotherapy involves a series of hot and cold water applications. A hot compress (as hot as the patient can stand) is applied to the affected area for three minutes followed by an ice cold compress for 30 seconds. These

applications are repeated three times each, ending with the cold compress. Nutritional therapy to promote tissue growth in damaged areas may also be helpful. Homeopathic and botanical therapies may also assist recovery from frostbite. Homeopathic *Hypericum* (*Hypericum perforatum*) is recommended when nerve endings are affected (especially in the fingers and toes) and *Arnica* (*Arnica montana*) is prescribed for **shock**. Cayenne pepper (*Capsicum frutescens*) can enhance circulation and relieve pain. Drinking hot ginger (*Zingiber officinale*) tea also aids circulation. Other possible approaches include acupuncture to avoid permanent nerve damage and **oxygen therapy**.

Frostnip

Frostnipped fingers are helped by blowing warm air on them or holding them under one's armpits. Other frostnipped areas can be covered with warm hands. The injured areas should never be rubbed.

Prognosis

The rapid rewarming approach to frostbite treatment, pioneered in the 1980s, has proved to be much more effective than older methods in preventing tissue loss and amputation. A study of 56 first-, second-, and third-degree frostbite patients treated with rapid rewarming in 1982–85 found that 68% recovered without tissue loss, 25% experienced some tissue loss, and only 7% needed amputation. In a comparison group of 98 patients, treatment using older methods resulted in a tissue loss rate of 35% and an amputation rate of nearly 33%. Although the comparison group included a higher proportion of second- and third-degree cases, the difference in treatment results was determined to be statistically significant.

The extreme throbbing pain that many frostbite sufferers endure for days or weeks after rewarming is not the only prolonged symptom of frostbite. During the first weeks or months after a cold injury, people often experience tingling, a burning sensation, or a sensation resembling shocks from an electric current. Other possible consequences of frostbite include skin-color changes, nail deformation or loss, joint stiffness and pain, hyperhidrosis (excessive sweating), and heightened sensitivity to cold. For everyone, a degree of sensory loss lasting at least four years—and sometimes a lifetime—is inevitable.

Health care team roles

The head of most health care teams is a physician. A physician determines a plan for treatment, provides guidance, assigns tasks for other members of the team, and monitors progress. Paramedics or other persons render-

ing **first aid** are also members of the team by providing immediate or early assistance to persons with frostbite or frostnip. Nurses may provide treatment alongside physicians. Physical therapists may become involved with rehabilitation of serious cases of frostbite. Occasionally, surgeons are called upon to amputate (remove) portions of bodies that have become too severely damaged to recover from frostbite.

Prevention

With appropriate knowledge and precautions, frostbite can be prevented even in the coldest and most challenging environments. Appropriate clothing and footwear are essential. To prevent heat loss and keep blood circulating properly, clothing should be worn loosely and in layers. Covering the hands, feet, and head is also crucial for preventing heat loss. Outer garments need to be wind and water resistant, and wet clothing and footwear must be removed and replaced as quickly as possible. Alcohol and drugs should be avoided because of their harmful effects on judgment and reasoning. Experts also warn against alcohol use and smoking in the cold because of the circulatory changes they produce. Paying close attention to weather reports before venturing outdoors and avoiding unnecessary risks such as driving in isolated areas during a blizzard are also important.

Cold sore

Definition

A cold sore is a clear, fluid-filled blister, which often appears on the lips or nose. Cold sores, also referred to as **fever** blisters, are caused by a viral **infection**, herpes simplex virus Type 1 (HSV-1).

Description

Cold sores are painful, unsightly, and often recurrent. HSV-1 often occurs on the lower face but can occur on the genitals or buttocks. Though rarely fatal, HSV-1 can be serious if cold sores occur in newborns, the chronically ill, or the elderly.

Other names for cold sores are oral herpes, labial herpes, herpes labialis, and herpes febrilis. They are different from common canker sores because they usually are on the lips, whereas canker sores usually occur inside the mouth, on the tongue, or inside the cheeks. Cold sores rarely occur inside the mouth except during the initial episode.

While there are eight types of herpes **viruses**, cold sores are only caused by HSV-1 or herpes simplex virus Type 2 (HSV-2). It is commonly believed that herpes simplex virus type 1 infects above the waist and herpes simplex virus type 2 infects below the waist. This is not completely true. HSV-1 does appear on the genitals and sometimes on other areas of the body. Nurses and other health care workers have been known to get herpetic sores after the virus has entered a break in the skin of their fingers.

Oral herpes is very common. About 50-80% (some estimates are as high as 90%) of Americans are thought to carry antibodies for HSV-1. Most people who are exposed to HSV-1 become infected but only 10% of

those people have symptoms, such as sores, and experience recurring outbreaks of the infection. Of the 50 million Americans thought to be infected with HSV-1, most acquired the virus when they were children and only about 5% are bothered enough by HSV-1 to consider it a medical problem.

Anyone can become infected by the herpes virus, and once a person is infected the virus remains latent for life. Herpes viruses are spread from person to person by direct skin-to-skin contact and, sometimes, by respiratory transmission (coughing or sneezing). The highest risk for spreading the virus is the time period beginning with the appearance of blisters and ending with scab formation. However, infected persons need not have visible blisters to spread the infection to others, since the virus may be present in the saliva without obvious oral lesions.

Viruses are different from **bacteria**. While bacteria are independent and can reproduce on their own, viruses enter human cells and force the cells to make more of the virus. The infected human cell is usually killed and releases thousands of new viruses. The cell death and resulting tissue damage causes the actual cold sores. In addition, the herpes virus can infect a cell and instead of making the cell produce new viruses, it hides inside the cells of the nervous system. This is called “latency.” A latent virus can wait inside the nervous system for days, months, or even years. At some future time, the virus “awakens” and causes the cell to produce thousands of new viruses which cause an active infection.

This process of latency and active infection is best understood by considering the cold sore cycle. An active infection is obvious because cold sores are present. The first infection is called the “primary” infection. This active infection is then controlled by the body’s **immune system** and the sores heal. In between active infections the virus is latent. At some point in the future, latent viruses become activated and once again cause sores. These are called “recurrent” infections. Although it is not known what triggers the latent virus to activate, several conditions seem to bring on infections. These include **stress**, illness, tiredness, exposure to sunlight, menstruation, fever, and diet.

Causes and symptoms

While anyone can be infected by the herpes virus, not everyone will show symptoms. The first symptoms of herpes occur within 2-20 days after contact with an infected person. Symptoms of the primary infection are usually more severe than those of recurrent infections. The primary infection can cause symptoms like other viral infections, including tiredness, headache, fever, and swollen lymph nodes in the neck.

People who experience outbreaks might have one or several blisters. Typically, 50-80% of persons who have outbreaks experience prodrome symptoms of oncoming disease of **pain**, burning, itching, or tingling at the site where blisters will form. This prodrome stage may last from a few hours, to one or two days. The herpes infection prodrome occurs in both the primary infection and recurrent infections.

In 95% of people with cold sores, the blisters occur at the outer edge of the lips, which is called the “vermillion border.” Less often, blisters form on the nose, chin, or cheek. Following the prodrome, the disease process is rapid. First, small red bumps appear which quickly form fluid-filled blisters. The painful blisters may either burst and form a scab or dry up and form a scab. Within two days of the first red bumps, all the blisters have formed scabs. The skin heals completely and without scarring within six to ten days. The virus then moves to nerve cells and remains in its resting state until the next outbreak, which can occur in the same or a nearby site.

Some children have a very serious primary (first episode) herpes infection called “gingivostomatitis.” This causes fever, swollen lymph glands, and numerous blisters inside the mouth, lips, and tongue that may form large, open sores. These painful sores may last up to three weeks and can make eating and drinking difficult. Because of this, young children with gingivostomatitis are at risk from **dehydration** (excessive loss of water from the body).

Most people experience fewer than two recurrent outbreaks of cold sores each year. Some people never experience outbreaks, while some have very frequent outbreaks, as often as every few weeks. In most people, the blisters form in the same area each time and are triggered by the same factors (such as stress, sun exposure, etc.).

Diagnosis

The typical appearance of HSV-1 often makes it an easy visual diagnosis. Health care professionals who are uncertain of the diagnosis can swab the infected area and send it to a lab for analysis. HSV-1 can be diagnosed and treated by family doctors, dermatologists (doctors who specialize in skin diseases), and infectious disease specialists. Sometimes, dentists or nurses are the first to see the signs of HSV-1. Other laboratory tests, including scrapings and **blood** tests, might be performed to look for the virus. These tests produce valid results only in the early stages of an outbreak and, sometimes, more than one test is needed.

Oral herpes may resemble a bacterial infection called “impetigo.” This skin infection is most commonly seen in

children and causes herpes-like blisters around the mouth and nose. Also, because oral herpes can occur inside the mouth, the blisters could be mistaken for common canker sores. Therefore, the doctor would need to determine whether the blisters are oral herpes, canker sores, or impetigo. The diagnosis and treatment of herpes infections should be covered by most insurance providers.

Treatment

There is no cure for herpes virus infections. There are **antiviral drugs** available, which have some effect in lessening the symptoms and decreasing the length of herpes outbreaks. There is evidence that some may also prevent future outbreaks. These antiviral drugs work by interfering with the replication of the viruses and are most effective when taken as early in the infection process as possible. For the best results, drug treatment should begin during the prodrome stage before blisters are visible. Depending on the length of the outbreak, drug treatment could continue for up to ten days or be used on an on-going basis as a method of prevention.

Acyclovir, famciclovir, and valacyclovir are oral antiviral medications developed to effectively treat herpes infections. In June 2000, the United States Food and Drug Administration approved the first over-the-counter ointment, called docosanol 10% cream, as a topical treatment for cold sores.

During an outbreak of cold sores, salty foods, citrus fruits (oranges, etc.), and other foods which irritate the sores should be avoided. The sores should be washed once or twice a day with warm, soapy water and patted gently dry. Over-the-counter lip products which contain the chemical phenol (such as Blistex Medicated Lip Ointment) and numbing ointments (Anbesol) help to relieve cold sores. Sometimes applying ice at the first sign of a cold sore diminishes the outbreak. A band-aid may be placed over the sores to protect them and prevent spreading the virus to other sites on the lips or face. Acetaminophen (Tylenol) or ibuprofen (Motrin, Advil) may be taken if necessary to reduce pain and fever.

Alternative treatment

Vitamin and mineral supplements and diet may have an effect on the recurrence and duration of cold sores. In general, cold sore sufferers should eat a healthy diet of unprocessed foods such as vegetables, fruits, and whole grains. Alcohol, **caffeine**, and sugar should be avoided.

An imbalance in the amino acids lysine and arginine is thought to be one contributing factor in herpes virus outbreaks. A diet that is rich in the amino acid lysine may help prevent recurrence of cold sores. Foods which con-

tain high levels of lysine include most vegetables, legumes, fish, turkey, and chicken. In one study, patients taking lysine supplements had milder symptoms during an outbreak, a faster healing time, and had fewer outbreaks than patients who did not take lysine. Patients should take 1,000 mg of lysine three times a day during a cold sore outbreak and 500 mg daily on an ongoing basis to prevent recurrences. Intake of the amino acid arginine should be reduced. Foods rich in arginine that should be avoided are chocolate, peanuts, almonds, and other nuts and seeds.

Vitamin C and bioflavonoids (a substance in fruits that helps the body to absorb and use vitamin C) have been shown to reduce the duration of a coldsore outbreak and reduce the number of sores. The **vitamin B complex** includes important **vitamins** that support the nervous system where viruses can hide out. B complex vitamins also can help manage stress, an important contributing factor to the outbreak of herpes viruses. Applying the oil in **vitamin E** capsules directly to cold sores may provide relief. **Zinc** lozenges appear to affect the reproduction of viruses and also enhance the immune system. Ointments containing lemon balm (*Melissa officinalis*) or licorice (*Glycyrrhiza glabra*) and peppermint (*Menthapiperita*) have been shown to help heal cold sores.

Prognosis

Oral herpes can be painful and embarrassing but it is not a serious condition. There is no cure for oral herpes but outbreaks usually occur less frequently with time. The spread of the herpes virus to the eyes is very serious. Herpes virus can infect the cells in the cornea and cause scarring which may impair **vision**. Those who are seriously ill, with compromised immune systems, are vulnerable to more severe and dangerous outbreaks.

Health care team roles

Registered nurses are often involved in helping to identify oral herpes. It is important that nurses then educate patients that cold sores caused by herpes simplex are highly contagious. Nurses need to teach patients not to touch their mouths and then other parts of their bodies, such as the eyes, because they can spread the virus to other parts of their bodies. Nurses should also inform patients that if the sore is indeed herpetic, patients might experience intense symptoms when the infection first appears and the sores and symptoms could last up to two weeks. Normally, subsequent outbreaks, if they occur, are shorter because people generally build up some immunity to the virus. Nurses should let patients know about factors, such as sun exposure, that can stimulate outbreaks, and educate them about over-the-counter and

KEY TERMS

Latent—A non-active virus that is in a dormant state within a cell. Herpes virus is latent in the nervous system.

Prodrome—Symptoms that warn of the beginning of disease. The herpes prodrome consists of pain, burning, tingling, or itching at a site before blisters are visible.

Recurrence—The return of an active infection following a period of latency.

prescription options, as well as things patients can do to alleviate their symptoms, such as applying ice at the first signs of an outbreak. While RNs educate patients about cold sores, nurse practitioners often diagnose and treat them just as a physician would.

Nurses can direct patients to many sites on the Internet that can help to answer their questions. For example, the American Academy of Dermatology at www.aad.org, www.herpes.org and www.herpeszone.com. The Herpes Resource Center, a public service of the American Social Health Association, provides educational pamphlets and a counseling line at 919-361-8488.

Prevention

The only way to prevent oral herpes is to avoid contact with those who are infected. This is not an easy solution because as many as 60% of those who are infected don't realize or admit that they may have herpes. As of 2001, there are no herpes vaccines available, although herpes vaccines, which will function to prevent infection in new patients, are being tested. The belief is that an effective vaccine is about three to five years away. Researchers are also attempting to reduce the rate of asymptomatic viral shedding to prevent transmission of the virus. Many say that a cure for herpes won't come for another seven to 10 years.

Several practices can reduce the occurrence of cold sores and the spread of virus to other body locations or people. These practices are:

- Avoidance of sun exposure to the face. Before getting prolonged exposure to the sun, apply sunscreen to the face and especially to the lips. Wearing a hat with a large brim is also helpful.
- Avoid touching cold sores. Squeezing, picking, or pinching blisters can allow the virus to spread to other parts of the lips or face, and infect those sites.
- Herpes can be transmitted via respiratory secretions, such as coughing or sneezing, so avoiding these situations is advised.
- Washing hands frequently. Persons with oral herpes should wash their hands carefully before touching others. An infected person can spread the virus to others, even when he or she has no obvious blisters.
- Avoid contact with others during active infection. Infected persons should avoid kissing and sexual contact with others until after the cold sores have healed.
- Wear gloves when applying ointment to a child's sore.
- Be especially careful with infants. Never kiss the eyes or lips of a baby who is under six months old.
- Be watchful of infected children. Do not allow infected children to share toys that may be put into the mouth. Toys that have been mouthed should be disinfected before other children play with them.
- Maintain good general health. A healthy diet, plenty of sleep, and **exercise** help to minimize the chance of getting a cold or the flu, which are known to bring on cold sores. Also, good general health keeps the immune system strong, which helps to keep the virus in check and prevents outbreaks.

Colonoscopy

Definition

Colonoscopy is an endoscopic (to visualize a hollow organ’s interior) medical procedure that uses a long, flexible, tubular instrument called a colonoscope to view the rectum and the entire inner lining of the colon (**large intestine**).

Purpose

A colonoscopy is generally recommended when the patient complains of rectal bleeding or has a change in bowel habits and other unexplained abdominal symptoms. The test is frequently used to look for **colorectal cancer**, especially when polyps or tumor-like growths have been detected by a **barium enema** examination and other diagnostic imaging tests. Polyps can be removed through the colonoscope, and samples of tissue (biopsies) can be taken to detect the presence of cancerous cells. In addition, colonoscopy can also be used to remove **foreign bodies**, control hemorrhaging, and excise tumors.

The test also enables physicians to check for bowel diseases such as ulcerative colitis and **Crohn’s disease** and is an essential tool for monitoring patients who have a past history of polyps or colon **cancer**. Colonoscopy is being used increasingly as a screening tool in both asymptomatic patients and patients at risk for colon cancer. It has been recommended as a screening test in all people 50 years or older.

Precautions

Patients who regularly take aspirin, **nonsteroidal anti-inflammatory drugs** (NSAIDs), **blood** thinners, or insulin should be sure to inform the physician prior to the colonoscopy. Patients with severe active colitis, extremely dilated colon (toxic megacolon), or severely inflamed bowel may not be candidates for colonoscopy. Patients requiring continuous ambulatory **peritoneal dialysis** are generally not candidates for colonoscopy due to a higher risk of developing intraperitoneal bleeding.

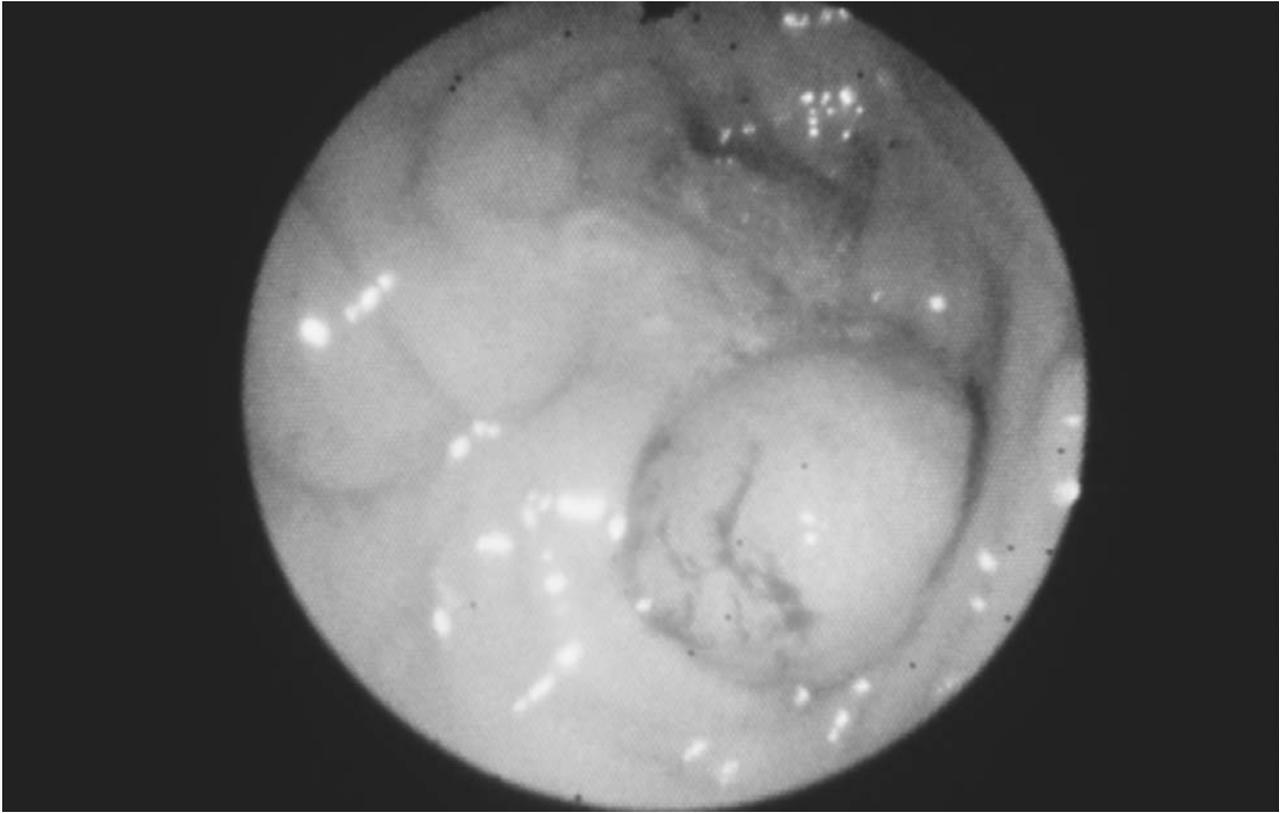

Description

Colonoscopy can be performed either in a physician’s office or in an endoscopic procedure room of a hospital. An intravenous (IV) line is inserted into a vein in the patient’s arm to administer, in most cases, a sedative and a pain-killer.

During the colonoscopy, patients are asked to lie on their sides with their knees drawn up towards the abdomen. The doctor begins the procedure by inserting a lubricated, gloved finger into the anus to check for any abnormal masses or blockage. A thin, well-lubricated colonoscope is then inserted into the anus and gently advanced through the colon. The lining of the intestine is examined through the colonoscope. Images are viewed by the physician on a television monitor, and the procedure can be documented using a video recorder. Still images can be recorded and saved on a computer disk or printed out. Occasionally air may be pumped through the colonoscope to help clear the path or open the colon. If excessive secretions, stool, or blood obstructs the viewing, they are suctioned out through the scope. The doctor may press on the abdomen or ask the patient to change position in order to advance the scope through the colon.

The entire length of the large intestine can be examined in this manner. If suspicious growths are observed, tiny biopsy forceps or brushes can be inserted through the colon and tissue samples can be obtained. Small polyps can also be removed through the colonoscope. For excising tumors or performing other types of surgery on the colon during colonoscopy, an electrosurgical device or laser system may be used in conjunction with the colonoscope. After the procedure, the colonoscope is slowly withdrawn and the instilled air is allowed to escape. The anal area is then cleansed with tissues.

The procedure may take anywhere from 30 minutes to two hours depending on how easy it is to advance the scope through the colon. Colonoscopy can be a long and uncomfortable procedure, and the bowel cleansing preparation may be tiring and can produce **diarrhea** and

Endoscopic view of a colonic polyp. (G-I Associates/Custom Medical Stock Photo. Reproduced by permission.)

cramping. During the colonoscopy, the sedative and the **pain** medications will keep the patient drowsy and relaxed. Some patients complain of minor discomfort and pressure from the colonoscope. However, the sedative and pain medication usually causes most patients to dose off during the procedure.

Preparation

The physician should be notified if the patient has **allergies** to any medications or anesthetics, bleeding problems, or is pregnant. The doctor should also be informed of all the medications that the person is currently taking and if the patient has had a barium enema x-ray examination recently. If the patient has had **heart** valves replaced, the doctor should be informed so that appropriate **antibiotics** can be administered to prevent **infection**. The risks are explained to the patient beforehand, and the patient is asked to sign a consent form.

The colon must be thoroughly cleansed before performing colonoscopy. Hence, for two or more days before the procedure, considerable preparation is necessary to clear the colon of all stool. The patient is asked to refrain from eating any solid food for 24 to 48 hours before the test. Only clear liquid such as juices, broth,

and Jello are allowed. Red or purple juices should be avoided, since they can cause coloring of the colon that may be misinterpreted during the colonoscopy. The patient is advised to drink plenty of water to avoid **dehydration**. A day or two before the colonoscopy, the patient is prescribed liquid, tablet, and/or suppository **laxatives** by the physician. In addition, commercial **enemas** may be prescribed. The patient is given specific instructions on how and when to use the laxatives and/or enemas.

On the morning of the colonoscopy, the patient is not to eat or drink anything. Unless otherwise instructed by the physician, the patient should continue to take all current medications. However, **vitamins** with **iron**, iron supplements, or iron preparations should be discontinued for a few weeks prior to the colonoscopy because iron residues in the colon can inhibit viewing during the procedure. These preparatory procedures are extremely important to ensure a thoroughly clean colon for examination.

After the procedure, the patient is kept under observation until the medications' effects wear off. The patient has to be driven home and can generally resume a normal diet and usual activities unless otherwise instructed. The

patient is advised to drink lots of fluids to replace those lost by laxatives and fasting.

For a few hours after the procedure, the patient may feel groggy. There may be some abdominal cramping and considerable amount of gas may be passed. If a biopsy was performed or a polyp was removed, there may be small amounts of blood in the stool for a few days. If the patient experiences severe abdominal pain or has persistent and heavy bleeding, it should be brought to the physician's attention immediately.

For patients with abnormal results, such as polyps, the gastroenterologist will recommend another colonoscopy, usually in another year or so.

Complications

The procedure is virtually free of any complications and risks. Rarely (two in 1000 cases) a perforation (a hole) may occur in the intestinal wall. Heavy bleeding due to the removal of the polyp or from the biopsy site occurs infrequently (one in 1000 cases). Some patients may have adverse reactions to the sedatives administered during the colonoscopy, but severe reactions are very rare. Infections due to a colonoscopy are also extremely rare. Patients with artificial or abnormal heart valves are usually given antibiotics before and after the procedure to prevent an infection.

Results

The results are normal if the lining of the colon is a pale reddish pink and there are no masses that appear abnormal in the lining.

Abnormal results indicate polyps or other suspicious masses in the lining of the intestine. Polyps can be removed during the procedure, and tissue samples can be biopsied. If cancerous cells are detected in the tissue samples, then a diagnosis of colon cancer is made. A pathologist analyzes the tumor cells further to estimate the tumor's aggressiveness and the extent of the disease. This is crucial before deciding on the mode of treatment for the disease. Abnormal findings could also be due to inflammatory bowel diseases such as ulcerative colitis or Crohn's disease. A condition called diverticulosis, which causes many small fingerlike pouches to protrude from the colon wall, may also contribute to an abnormal result in the colonoscopy.

Health care team roles

For otherwise healthy patients, colonoscopy is generally performed by a gastroenterologist in an office setting. It may also be performed in the endoscopy depart-

KEY TERMS

Barium enema—An x-ray test of the bowel after giving the patient an enema of a white chalky substance that outlines the colon and the rectum.

Biopsy—Removal of a tissue sample for examination under the microscope to check for cancer cells.

Colonoscope—A thin, flexible, hollow, lighted tube that is inserted through the anus and into the rectum and into the colon to enable the doctor to view the entire lining of the colon.

Crohn's disease—A chronic inflammatory disease that generally starts in the gastrointestinal tract and causes the immune system to attack one's own body.

Diverticulosis—A condition that involves the development of sacs that bulge through the large intestine's muscular walls but are not inflamed. It may cause bleeding, stomach distress, and excess gas.

Electrosurgical device—A medical device that uses electrical current to cauterize or coagulate tissue during surgical procedures. Often used in conjunction with laparoscopy.

Pathologist—A doctor who specializes in the diagnosis of disease by studying cells and tissues under a microscope.

Polyps—An abnormal growth that develops on the inside of a hollow organ such as the colon.

Ulcerative colitis—A chronic condition where recurrent ulcers are found in the colon. It is manifested clinically by abdominal cramping and rectal bleeding.

ment of a hospital, where patients with other medical conditions requiring hospitalization, more intensive physiologic monitoring, or **general anesthesia** can be better examined. Depending on the patient's condition, the colonoscopy may also be performed by a colorectal surgeon. In the gastroenterologist's office, a nurse and/or **nurse anesthetist** are necessary to provide patient sedation and analgesic medication, monitor the patient during the procedure, and assist the physician during the colonoscopy. In the hospital, colonoscopy performed under general anesthesia requires an anesthesiologist. Biopsied tissue samples are sent to a clinical laboratory, where they are analyzed by a pathologist.

Color blindness

Definition

The term color blindness describes a deficiency in discriminating various colors. It is a misnomer because most color-blind people do, in fact, see colors. The deficiency is a lack of perceptual sensitivity to certain colors. A rare few may not see colors at all.

Description

Normal color **vision** requires the use of special cells, called cones. They are wavelength receptors located at

the back of the eye on the retina. Most of us are trichromats, which means that we have three types of cones, commonly called red, green, and blue cones. They are long, medium, and short wavelength receptors, respectively. The interplay among these cones enables us to see a large spectrum of colors. A defect in any of these types of cones will result in deficient color vision. Most color-deficient individuals are dichromats. They are not entirely blind to color, rather they get some colors confused with each other. For example, they may see certain colors (like red and green) as very similar, whereas people without the deficiency would easily be able to differentiate these colors.

The following are three basic types of color deficiency:

- Protanopia and deuteranopia (commonly called red/green color blindness). Red/green color blindness is the most common deficiency, affecting about 10% of Caucasian males and 0.5% of females. People with protanopia have fewer red cones; blue-green and red-purple appear gray to them. Deuteranopes have fewer green cones; green and purple-red appear gray to them.
- Tritanopia (commonly called Blue color blindness). People with tritanopia have fewer blue cones; blue and yellow appear as white or gray to them. Such people are very rare and have poor blue and/or yellow perception. As many females as males have this deficiency. It usually appears in people who have physical disorders, such as **liver** disease or **diabetes mellitus**.
- Achromatopsia (commonly called total color blindness). Total color blindness—vision only in black, white, and shades of gray—can be caused by monochromacy (a retina that has only one type of receptor) or from acquired **brain** damage. Monochromacy is a very rare hereditary disorder. It affects one person in 33,000 in the United States, males and females equally. They usually have poor visual acuity and extreme sensitivity to light. Their vision is significantly impaired and they protect their light-sensitive eyes by squinting in even ordinary light.

Causes and symptoms

The key symptom of color blindness is the long-term inability to distinguish colors or notice some colors entirely. Most cases of color blindness (in particular red/green) are inherited, and affect males almost exclusively.

Color blindness can be acquired by the following:

- Chronic illness. Illnesses that can lead to color blindness are: **Alzheimer's disease**, diabetes, **glaucoma**, leukemia, liver diseases, chronic **alcoholism**, **macular**

degeneration, multiple sclerosis, Parkinson's disease, sickle cell anemia, and retinitis pigmentosa.

- Trauma. Accidents or strokes that damage the eye can lead to color blindness.
- Medications. Some frequently used medications may cause color blindness. Some **antibiotics**, barbiturates, anti-tubercular drugs, high **blood pressure** medications, and a number of medications used to treat nervous disorders and psychological problems may lead to color blindness.
- Industrial toxins. Strong chemicals can cause color vision loss. Some include carbon monoxide, carbon disulfide, fertilizers, styrene, and lead-based chemicals.
- Aging. After age 60, changes occur in people's capacity to discriminate colors.

Diagnosis

Some of the tests available to detect color vision in the general public include:

- American Optical/Hardy, Rand, and Ritter (AO/H.R.R.) Pseudoisochromatic test. This is the test used most often to detect color blindness. A person with full color vision looking at a sample plate from this test would see a number, composed of blobs of one color, clearly located somewhere in the center of a circle of blobs of another color. A colorblind person is not able to distinguish the number.
- Ishihara test. The Ishihara test is made up of eight test plates similar to the AO/H.R.R. pseudoisochromatic test plates. The person being tested looks for numbers made up of various colored dots on each test plate.
- Titmus II Vision Tester Color Perception test. During this test, a person looks into a stereoscopic machine. The chin rests on a base, and the image comes on only when the forehead touches a pad on the top of the unit. Either a series of plates, or only one plate, can be used to test for color vision. The one most often used in doctors' offices is one that has six samples on it. Six different designs or numbers are on a black background, framed in a yellow border. While Titmus II can test one eye at a time, its value is limited because it only tests for red/green deficiencies and is not highly accurate.

Treatment

There is no treatment or cure for color blindness. Most color deficient persons compensate well for their defect and may even discover instances in which they can discern details and images that would escape normal-sighted persons. Colorblind people tend to look for outlines, not colors. Consequently, they are not easily confused by camou-

KEY TERMS

Acuity—Acuity is the clarity or sharpness of vision.

Cone cells—Cone cells are special cells in the retina and are responsible for color vision and fine visual discrimination.

Retina—The retina is the innermost lining of the eye, containing light sensitive nerve tissue composed of rod and cone cells.

Stereoscopic—Stereoscopic refers to vision in which things have a three-dimensional appearance.

flage. (Some colorblind people were used in World War II spy planes to spot camouflaged German camps.) Also, their night vision may be much better than average.

Health care team roles

Color blindness can be tested for and diagnosed by a general physician, ophthalmologist, or optometrist. Questions about color blindness may be addressed by nurses or **optometry** assistants.

Prognosis

Color blindness that is hereditary is present in both eyes and remains constant over time. Some cases of acquired color vision loss are not severe and last for only a short time. Other cases tend to be progressive, becoming worse over time.

Prevention

Hereditary color blindness cannot be prevented. In the case of acquired color blindness, if the cause of the problem is removed, the condition may improve with time. If not, damage may become permanent.

Colorectal cancer

Definition

The **digestive system** is made up of the esophagus (food pipe), **stomach**, and the small and large intestines. The upper 5–6 feet (1.5–1.8 m) of the **large intestine** is the colon, and the last 6–8 inches (15–20 cm) of the colon is the rectum. Colorectal **cancer** is a disease in which the cells of the tissues lining the colon and the rectum start to grow uncontrollably and form tumors.

Description

Colorectal cancer is the second most common cancer for both men and women, and the second leading cause of cancer deaths. There are 150,000 new cases each year, with more than 55,000 people dying annually. The average age at first diagnosis is between 60 and 65 and appears to be a disease that affects the latter years of life. Since it is slow growing, it may take years before the disease manifests.

The primary function of the colon is to absorb water and the nutrients from the food that is already digested by the stomach and the **small intestine**. The waste material that remains moves into the rectum. From there, it is excreted out of the body through the anus. The colon has four sections. The ascending colon moves upward to the hepatic flexure. It then becomes the transverse colon, moving across to the **liver**. When it reaches the spleen, the colon continues as the descending colon and moves down to the pelvic area. It is then called the sigmoid colon and extends to the rectum. Cancer can develop in any of the four sections or in the rectum. Cancers beginning in the different sections have different symptoms.

Colorectal cancers have a very high cure rate if found early. Unfortunately, most colorectal cancers are silent tumors, which means they grow slowly and often do not produce symptoms until they reach a large size. Therefore, diagnosis is often delayed. The cancer usual-

ly begins as a benign growth (polyp) in the lining of the intestine. Although most polyps are not cancerous, virtually every colorectal cancer case begins with these polyps. There are two kinds of polyps: hyperplastic polyps, which are small, completely benign, and never develop into cancers, and adenomas, which are polyps that do have the potential to become cancerous.

Causes and symptoms

Causes

The current consensus among the medical community is that most colorectal cancers have a genetic link. Abnormal genes have been found in all inherited colorectal cancers and in most sporadic colon cancers. Dietary and environmental factors also seem to play a role in colorectal incidence.

Several risk factors may make a person more susceptible to colorectal cancer. They include:

- **Family history:** Some conditions such as familial adenomatous polyps (FAP) and Lynch syndrome (a genetic condition that predisposes certain families to colon cancer, even when polyps are not present) occur in certain families and may make an individual more likely to develop cancer of the colon or the rectum.
- **History of colorectal cancer:** Even when colorectal cancer has been completely removed, new cancers may still develop in other areas of the colon and the rectum. The incidence of recurrence is every 10 years.
- **Recurrent intestinal polyps:** These are polyps that increase the risk of colorectal cancer, especially if they are large and there are many of them.
- **Inflammatory bowel disease:** Chronic ulcerative colitis, a condition in which the colon is inflamed over a long period of time and causes ulcers in the lining, can increase the risk of colon cancer.
- **Age:** About 90% of colorectal cancers are found in people over the age of 50.
- **Diet:** Eating foods that are high in fat and low in fiber may increase the risk of colorectal cancer. It is estimated that diet accounts for 35%–45% of disease incidence.
- **Physical inactivity:** A sedentary lifestyle and not enough physical activity has been reported to be associated with a higher risk of colorectal cancer.
- **Gender factors:** Women have a 38% higher risk of having upper-colon cancer than men.
- **Smoking:** There is strong evidence that smoking increases the risk of colorectal cancer, possibly causing 12% of all colorectal cancer deaths. The frequency,

amount, and duration of smoking over a lifetime are positively correlated with colon cancer. The more a person smokes over a long period of time, the greater the incidence of colon cancer.

- **Ethnicity:** Black, non-Hispanic people may have as much as a 24% increased risk in upper-colon cancer than other groups.
- **Co-morbid illnesses:** The presence of serious, life-threatening diseases like congestive **heart failure**, peptic ulcer, and **diabetes mellitus** may contribute up to a 28% increase in risk of colorectal cancer.

Symptoms

The earliest sign of colon cancer may be bleeding, though the amount is usually quite small. **Blood** can be detected by the **fecal occult blood test** (FOBT), which is a chemical testing of the feces for hidden (occult) blood.

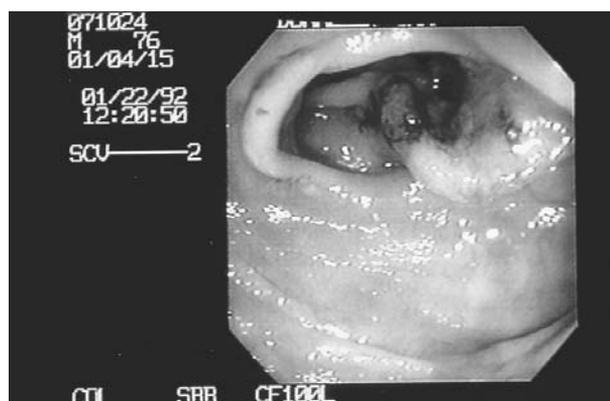

When tumors grow to a large size, they may cause a change in bowel habits. Stools may be very narrow in diameter, and there may be **diarrhea** or constipation. Other symptoms of general stomach discomfort may be present, such as a feeling of fullness or bloating, stomach cramps, or gas pains. Sometimes, the patient complains of a feeling that the bowel does not empty completely. Constant tiredness and weight loss with no known reason may be other warning signs. Even though many of these symptoms can be caused by conditions other than cancer, they must be evaluated by a doctor without delay.

Usually, there are no signs of colorectal cancer at all. That is why screening is essential. Polyps may be detected before they develop into cancers, and are easily removed.

Diagnosis

Regular screenings can identify colorectal cancer before symptoms manifest. Routinely, depending on the screening method used, this is done every one to five years, beginning at age 50. With higher risk populations (a family history of colorectal cancer or polyps, previous ulcerative colitis, or a specific ethnicity), screening may be initiated at an earlier age and conducted more often. Screening methods include a digital rectal examination, fecal occult blood testing (FOBT), a **sigmoidoscopy**, a **colonoscopy**, and a double-contrast **barium enema**.

If the physician suspects colon cancer, then a thorough **physical examination** will be conducted to check all symptoms and a complete medical history will be taken to assess any risk factors. A digital rectal examination will be done during the physical. In this procedure,

An endoscopic view of a colorectal tumor. (Custom Medical Stock Photo. Reproduced by permission.)

the physician inserts a gloved finger into the rectum to feel for anything abnormal. This simple test can help to detect many rectal cancers.

A fecal occult blood test may be ordered, in which a sample of stool is examined for blood. The test kit can be purchased at any local pharmacy. The test involves taking a sample of stool and smearing it on a slide. This is then sent to the laboratory or to the doctor's office to be chemically examined for the presence of red blood cells.

A sigmoidoscopy may be done to enable the physician to look inside the rectum and the lower half of the colon. In this procedure, a thin, flexible, hollow, lighted tube (sigmoidoscope) is inserted into the rectum. The physician then looks inside the scope for polyps. Since they may become cancerous, they are usually removed with the sigmoidoscope and examined for cancer cells. About half of all colon and rectal cancers are found using this procedure.

A colonoscopy will be ordered if the doctor wishes to examine the entire colon lining. A colonoscope is longer than a sigmoidoscope and is inserted through the rectum into the colon. It is connected to a video camera and a video display unit so that the physician can look at the inside of the colon. If a suspicious mass is detected, then the physician may cut out a small piece to examine it under a **microscope** for cancer cells. This procedure is called a biopsy.

Another test that is used to diagnose colon cancer is known as a double-contrast barium enema. The patient is given a barium sulfate enema through the anus. This is a chalky substance that partially fills and opens the colon. When the colon is about half full of barium, the patient is turned on the x-ray table so that the barium spreads throughout the colon. Air is then inserted into the colon to make it expand and x-ray films are taken. Usually, this procedure is done if the patient cannot tolerate a sigmoido-

doscopy, or a suspected mass prevents the penetration of the sigmoidoscope or the colonoscope.

Treatment

Treatment for colon and rectal cancers depends on the stage of the cancer, which refers to the extent to which it has spread (metastasized). The standard modes of treatment are surgery, radiation therapy, and **chemotherapy**.

Surgery is the primary treatment for colon cancer. If the cancer is found at a very early stage, the physician may be able to remove the cancer without cutting into the abdomen. Instead, the physician may insert a tube through the rectum into the colon and cut the tumor out. This procedure is called a local excision. If the cancer is found in a polyp, however, the operation is called a polypectomy. When the cancer is large but confined to a portion of the colon, the abdomen is opened up and the cancerous growth and a small piece of normal tissue from either side of the cancer are removed. This procedure is called segmental resection. If there is any likelihood of the cancer having metastasized to the nearby lymph nodes, they may be removed as well. The remaining sections of the colon are then reattached.

When the physician is unable to reattach the colon, an opening called a stoma will be surgically created on the outside of the body for the waste material to pass from the body. This procedure is called a **colostomy**. Sometimes, the colostomy is temporary, lasting until the colon is healed, and then the colostomy can be reversed. However, if the surgery involves taking out the entire lower colon, a permanent colostomy is required. The patient will need to wear a special bag to collect body wastes. The disposable bag attaches to the body around the opening (stoma). Hospital personnel will teach patients how to take care of the stoma and maintain colostomy bags.

In the case of rectal cancer, different surgical methods are used. When the cancer is found in polyps, a polypectomy is performed. Local excision is a procedure that can be used to remove small superficial cancers. A small amount of adjoining tissue is also removed from the inner layer of the rectum. If the cancer is in the deeper layers of the rectum, local full thickness resection is used. A cut is made through all the layers of the rectum to remove the invasive cancer as well as some surrounding normal rectal tissue. Electrofulguration is a procedure in which the cancer is burned away by passing an electric current through it. All of these methods may be done without cutting through the abdomen. However, a colostomy may still be necessary if the cancer is too

close to the anus, necessitating the removal of the sphincter muscles.

Radiation therapy involves the use of high-energy radiation to kill cancer cells. It can be applied to both colon and rectal cancers. External-beam radiation uses radiation from an external source that is focused on the tumor. Internal radiation therapy uses a small pellet of radioactive material that is implanted directly into the cancer. Radiation therapy is generally used as adjuvant therapy, that is, it is used after the surgery to destroy any cancerous material that may not have been removed during surgery. If the tumor is in a place that makes surgery difficult, then radiation may be used before surgery to shrink the tumor. In advanced cancers, in which surgery is not an option, radiation may be used to ease the symptoms such as **pain**, blockage, or bleeding.

In colorectal cancers, chemotherapy is generally used after surgery to destroy any cancerous cells that may have migrated from the original site and spread to other parts. The anti-cancer drugs are either given intravenously (through a vein) in the arm or orally in the form of pills. In the case of advanced cancers, chemotherapy may be given to alleviate symptoms.

Prognosis

The death rate from colorectal cancer has been going down for the past 20 years. This is due to advanced methods of early detection and improved treatment modes. If colorectal cancer is detected at an early stage and is treated appropriately, 92% of patients will survive five years or more. However, only a third of colorectal cancers are found at that early stage. Once the cancer has metastasized to nearby organs or lymph nodes, the five-year survival rate plummets to 64%. If the disease has metastasized to distant sites such as the liver or the lung, the outlook is bleak, with only 7% of the patients surviving five years after initial diagnosis. The American Cancer Society also notes that once colorectal cancer is detected and removed, another occurrence is highly probable in 10 years.

Health care team roles

Physicians, nurse practitioners, nurses, lab technicians, and radiology technicians all participate in the screening, diagnosing, and treating of colorectal cancers. Physicians and their nursing staff must educate patients in the necessity and urgency of complying with colorectal screening guidelines. Colorectal cancer, for many people, is a totally preventable disease. By exercising regularly, eating a high-fiber diet, and avoiding smoking many colorectal cancers can be prevented. For those with

a family history of polyps or colorectal cancer, participation in a screening program can detect polyps, and they can have them removed before they turn into cancerous growths.

Subsequently, all members of the medical health team will need to educate patients about early screening, the procedures involved, and any possible side effects. They will also need to provide information about diet and **exercise** and anti-smoking support groups. Physicians may need to prescribe medications to cope with nicotine withdrawal.

When cancer is detected, the entire medical team will need to educate the patient about treatment options and procedures, outcomes, and aftercare. Physicians and radiology technicians will perform additional tests. The gastroenterologist and surgeon will prepare the patient physically and psychologically for surgery. The surgeon will remove the cancer and prepare a stoma, if necessary. The gastroenterologist will recommend radiation and/or chemotherapy as a preventative. The nursing staff will educate the patient on the care of the stoma and the colostomy equipment.

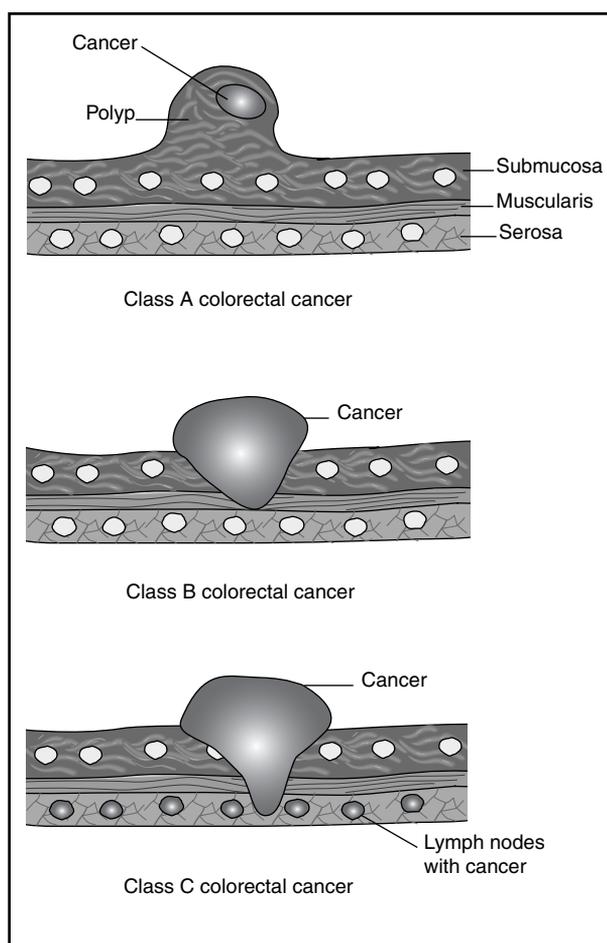

Prevention

Many colon and rectal cancers may be prevented by avoiding risk factors and following screening guidelines. The number of colorectal cancer cases can be lowered and, by detecting the disease at an earlier stage, the death rate can be reduced.

The American Cancer Society recommends that, beginning at age 50, both men and women follow a screening schedule for the early detection of colorectal cancer. One or more of the following tests should be performed: a yearly fecal occult blood test and a digital rectal examination, a flexible sigmoidoscopy every five years, a colonoscopy every five to 10 years (depending on the patient's risk factors), or a barium enema x ray every five to 10 years.

Proper diet and exercise go a long way in preventing colorectal cancer. The American Cancer Society recommends eating at least five servings of fruits and vegetables every day and six servings of food from plant sources that contain fiber, such as breads, cereals, grain products, rice, pasta, or beans. Reducing the consumption of high-fat, low-fiber foods such as red meat and processed foods is also advised. Achieving and maintaining an ideal body weight are recommended, and participating in at least 30 minutes of physical activity every day is advocated.

The addition of mineral supplements may also be helpful in preventing colorectal cancer. **Copper**, selenium,

Classes of colorectal cancer: class A, class B, and class C. (Delmar Publishers, Inc. Reproduced by permission.)

and **calcium** seem to be factors in colorectal cancer prevention. Eating foods rich in these **minerals** is recommended.

It is also recommended that individuals over 50 quit smoking as soon as possible. Besides the risks of other forms of cancer, there seems to be a correlation between the incidence of colorectal cancer and the amount of tobacco smoked and for how long.

It may not be possible to control risk factors such as a strong family history of colorectal cancer. However, by getting information about prevention and early detection, one can still beat the odds. People with a family history of colorectal cancer should start screening at a younger age, and the tests should be done more frequently. Certain genetic tests are now available that can help determine which members of certain families have inherited a high risk for developing colorectal cancer.

KEY TERMS

Adenomas—Polyp-like growths in the colon or the rectum that have the potential to turn cancerous.

Barium enema—An x-ray test of the bowel after receiving an enema of a white chalky substance that outlines the colon and the rectum, making them more visible in an x ray.

Benign—Tested tissue that is not cancerous and does not invade surrounding tissue or spread to other parts of the body.

Biopsy—Removal of a tissue sample for examination under the microscope to check for cancer cells.

Chemotherapy—Treatment with drugs that destroy cancerous tissue.

Colonoscopy—A medical procedure in which the physician looks at the colon through a flexible lighted instrument called a colonoscope.

Colostomy—An opening is created to provide a path for waste material to leave the body after the colon has been removed.

Crohn's disease—A chronic inflammatory disease in which the immune system starts attacking one's own body. The disease generally starts in the gastrointestinal tract.

Digital rectal examination—An exam to detect rectal cancer.

Familial adenomatous polypos (FAP)—An inherited condition in which hundreds of polyps develop in the colon and rectum.

Fecal occult blood test (FOBT)—A test in which the stool sample is chemically tested for hidden blood.

Flexible sigmoidoscopy—An examination in which the physician looks at the lower half of the colon.

Hyperplastic polyps—Benign polyps found in the colon or the rectum.

Lynch syndrome—A genetic condition that predisposes certain families to colon cancer, even when polyps are not present.

Polyp—An abnormal growth that develops on the inside of a hollow organ such as the colon.

Polypectomy—A surgical procedure that involves removal of the polyp.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Segmental resection—Surgical removal of a portion of the colon.

Stoma—The opening established in the abdominal wall by the colostomy procedure.

Ulcerative colitis—A chronic condition in which recurrent ulcers are found in the colon.

Colostomy

Definition

A colostomy is a surgical procedure that brings a portion of the **large intestine** through the abdominal wall to carry feces out of the body.

Purpose

A colostomy is created as a means to treat various disorders of the large intestine, including **cancer**, obstruction, inflammatory bowel disease, ruptured diverticulum, ischemia (compromised **blood** supply), or traumatic injury. Temporary colostomies are created to divert stool from injured or diseased portions of the large intestine, allowing rest and healing. Permanent colostomies are performed when the distal bowel (bowel at the farthest distance) must be removed or is blocked and inoperable. Although **colorectal cancer** is the most common indication for a permanent colostomy, only about 10–15% of patients with this diagnosis require a colostomy.

Description

Surgery will result in one of three types of colostomies:

- **End colostomy:** The functioning end of the intestine, the section of bowel that remains connected to the upper gastrointestinal tract, is brought out onto the surface of the abdomen to form a stoma (an artificial opening) by cuffing the intestine back on itself and suturing the end to the skin. The surface of the stoma is actually the lining of the intestine, usually appearing moist and pink. The distal portion of bowel (now connected only to the rectum) may be removed or sutured closed and left in the abdomen. An end colostomy is usually a permanent colostomy, resulting from trauma, cancer, or another pathological condition.

- **Double-barrel colostomy:** This colostomy involves the creation of two separate stomas on the abdominal wall. The proximal (nearest) stoma is the functional end that is connected to the upper gastrointestinal tract, and will drain stool. The distal stoma, connected to the rectum, drains small amounts of mucus material. This is most often a temporary colostomy, performed to rest an area of bowel and to be later closed.
- **Loop colostomy:** This colostomy is created by bringing a loop of bowel through an incision in the abdominal wall. The loop is held in place outside the abdomen by a plastic rod placed beneath it. An incision is made in the bowel to allow the passage of stool through the loop colostomy. The supporting rod is removed approximately seven to 10 days after surgery, after healing has occurred that will prevent the loop of bowel from retracting into the abdomen. A loop colostomy is most often performed for the creation of a temporary stoma to divert stool away from an area of intestine that has been blocked or ruptured.

Preparation

The physician will outline the procedure, possible side effects, and what the patient may experience after surgery. The physician or an enterostomal therapist will explain the general aftercare to the patient before surgery, so the patient has all of the information necessary to make an informed decision about surgery and medical care.

Blood and urine studies, along with various x rays and an electrocardiograph (EKG), may be ordered as necessary. If possible, the patient should visit an enterostomal therapist, who makes the decision about the appropriate place on the abdomen for the stoma and who offers pre-operative education on colostomy management.

To empty and cleanse the bowel, the patient may be placed on a low-residue diet for several days prior to surgery. A liquid diet may be ordered for at least the day before surgery. A series of **enemas** and/or oral preparations (GoLytely or Colyte) may be ordered to empty the bowel of stool. Oral anti-infectives (neomycin, erythromycin, or kanamycin sulfate) may be prescribed to decrease **bacteria** in the intestine and help prevent post-operative **infection**. On the day of surgery or during surgery, a nasogastric tube is inserted into the nose to connect it to the **stomach** to remove gastric secretions and prevent nausea and vomiting. A urinary catheter may also be placed to keep the bladder empty during surgery, giving more space in the surgical area and decreasing the risk of accidental injury.

KEY TERMS

Diverticulum—Pouches that project off the wall of the intestine.

Embolism—Blockage of a blood vessel by any small piece of material traveling in the blood.

Enema—Insertion of a tube into the rectum to infuse fluid into the bowel and encourage a bowel movement.

Intestine—Commonly called the bowels, divided into the small and large intestine, they extend from the stomach to the anus. The small intestine is about 20 feet (6 m) long; the large intestine is about 5 feet (1.5 m) long.

Ischemia—A compromise in blood supply delivered to body tissues that causes tissue damage or death.

Ostomy—A surgically created opening in the abdomen for elimination of waste products (urine or stool).

Preparation

Post-operative care for the patient with a new colostomy involves monitoring of **blood pressure**, pulse, respirations, and temperature. The patient is instructed how to support the operative site during deep breathing and coughing, and given **pain** medication as necessary. Fluid intake and output is measured, and the operative site is observed for color and amount of wound drainage. The nasogastric tube will remain in place, attached to low-intermittent suction until bowel activity resumes. For the first 24 to 48 hours after surgery, the colostomy will drain bloody mucus. Fluids and electrolytes are infused intravenously until the patient's diet can gradually be resumed, beginning with liquids. Usually within 72 hours, passage of gas and stool through the stoma begins. Initially the stool is liquid, gradually thickening as the patient begins to take solid foods. The patient is usually out of bed in eight to 24 hours after surgery and discharged in two to four days.

A colostomy pouch or bag will generally have been placed on the patient's abdomen, around the stoma, during surgery. During the hospital stay, the patient and the caregivers will be educated on how to care for the stoma and the colostomy bag. Determination of appropriate pouching supplies and a schedule of how often to change the pouch should be established. Regular assessment and meticulous care of the skin surrounding the stoma is important to maintain an adequate surface on which to

apply the pouch. Patients will be instructed in daily irrigation of the stoma about seven to 10 days after surgery. This results in the regulation of bowel function. Some patients with colostomies may need only a dressing or cap over the stoma and do not wear a colostomy pouch. Often, an enterostomal therapist will visit the patient at home after discharge to help with the patient's resumption of normal daily activities.

Complications

Potential complications of colostomy surgery include:

- excessive bleeding
- surgical wound infection
- thrombophlebitis (inflammation and blood clot in veins in the legs)
- pneumonia
- pulmonary embolism (blood clot or air bubble in the lungs' blood supply)
- cardiac **stress** due to allergic reaction to the general anaesthetic
- if the colostomy becomes blocked
- if the stoma extends too far out from the abdomen, presenting the potential for physical damage or infection

The physician should be made aware of any of the following problems after surgery:

- increased pain, swelling, redness, drainage, or bleeding in the surgical area
- flu-like symptoms such as headache, muscle aches, dizziness, or fever
- increased abdominal pain or swelling, constipation, nausea or vomiting, or black, tarry stools

Stomal complications to be monitored include:

- Necrosis (death) of stomal tissue. Caused by inadequate blood supply, this complication is usually visible 12 to 24 hours after the operation and may require additional surgery.
- Retraction (stoma is flush with the abdomen surface or has moved below it). Caused by insufficient stomal length, this complication may be managed by the use of special pouching supplies. Elective revision of the stoma is also an option.
- Prolapse (stoma increases length above the surface of the abdomen). Most often, this results from an overly large opening in the abdominal wall or inadequate fixation of the bowel to the abdominal wall. Surgical correction is required when blood supply is compromised.

- Stenosis (narrowing at the opening of the stoma). Often, this is associated with infection around the stoma or scarring. Mild stenosis can be removed under **local anesthesia**, while severe stenosis may require surgery for reshaping the stoma.
- Parastomal hernia (bowel-causing bulge in the abdominal wall next to the stoma). Usually, this is due to placement of the stoma where the abdominal wall is weak or the creation of an overly large opening in the abdominal wall. The use of a colostomy support belt and special pouching supplies may be adequate. If severe, the defect in the abdominal wall should be repaired surgically, and the stoma moved to another location.

Psychological complications may result from colostomy surgery because of the fear of the social stigma attached to wearing a colostomy bag. Patients also may be depressed and have feelings of low self-worth because of the change in their lifestyle and their appearance. Some patients may feel sexually unattractive and may worry that their spouse or significant other will no longer find them desirable. Counseling and education regarding surgery and the inherent lifestyle changes are often necessary.

Results

Complete healing is expected without complications. The period of time required for recovery from the surgery may vary, depending on the patient's overall health prior to surgery. The colostomy patient, without other medical complications, should be able to resume all daily activities once recovered from the surgery.

Health care team roles

A team of doctors, surgeons, specialists, technicians, and nurses are involved in the care of a patient who has a colostomy. While the skills of each health care provider are necessary, it is education and support that may be the most critical in affecting a successful outcome for the patient. Understanding what is involved in the procedure, what the results will be, and the ramifications of the surgery outcome are all considerations for the patient in order to make informed decisions. A thorough understanding of the implications of the surgical procedure and trust in the medical team enable the patient to face the change in lifestyle in a more positive fashion.

Colostomy care

Definition

A **colostomy** is a surgically created opening in the abdominal wall through which digested food passes. It may be temporary or permanent. The opening is called a stoma from the Greek word meaning mouth. Stool passes through the stoma into a pouch attached to the stoma on the outside of the abdomen. The pouch, stoma, and skin surrounding the stoma require care and maintenance by the patient or caregiver.

Purpose

A pouch is worn over a colostomy to collect the stool passed through the stoma. There are a variety of pouches available for use with a colostomy. Over time the patient can determine which pouch type best suits his or her needs. A colostomy pouch is normally emptied one or more times daily. The pouch itself usually needs to be changed every four to six days. The stoma and surrounding skin need to be kept clean and sanitary.

Colostomy care and colostomy pouch replacement in a hospital. (Delmar Publishers, Inc. Reproduced by permission.)

Precautions

The nurse attending to a colostomy should wash his or her hands before and after the procedure, as well as wear latex gloves while performing care.

Description

A pouching system is normally worn over a colostomy stoma. Pouches can be obtained from several different manufacturers in both disposable and reusable varieties. The enterostomal therapy ET nurse can be an invaluable resource when helping patients select a pouch system.

Colostomy pouches may be either open ended or closed. Open-ended pouches require a clamp for closure. They can be drained simply and reused after they are emptied. Closed pouches are sealed at the bottom and are usually used by patients who irrigate their colostomies or who have a regular bowel elimination pattern. Two-piece pouch systems consist of a separate flange and pouch. The pouch has a closing ring that attaches to a matching piece on the flange. One-piece systems have a connected wafer and pouch that do not separate. The portion of the pouch that is applied to the abdomen is called a skin barrier wafer. Both two-piece and one-piece systems can be either closed or open ended.

Some patients with colostomies can irrigate their stomas using a procedure similar to an enema. This cleans the stool out of the colon through the stoma. A special irrigation system is used. Sometimes a special lubricant is used to prepare for the irrigation. Irrigating often leads to increased control over the timing of bowel movements.

Removing the colostomy appliance requires gently pushing away the skin surrounding the stoma and pulling the appliance downwards. Adhesive remover wipes are available to help in the removal of the wafer. The bag is then discarded in an appropriate waste container. The stoma should be cleaned with lukewarm water and dried with a soft towel. The stoma and surrounding skin should be assessed. The stoma should be pink or red and moist-looking, and may bleed slightly when cleansed. The stoma normally decreases in size slightly during the first weeks after surgery.

The opening in the wafer should fit snugly around the stoma. An opening that is too large will allow intestinal contents to leak onto the skin. Measuring guides come with the colostomy wafers so that the hole can be cut to the proper size. Skin barrier paste can be used to help create a better seal between the wafer and the patient's abdomen. Various skin preparation products are

A colostomy creates a stoma (opening) in the abdominal wall to which a section of the large intestine is attached. The surface of the stoma is the inside lining of the intestine, so it appears moist and pink or red. (Custom Medical Stock Photo. Reproduced by permission.)

also available to help protect the skin under the wafer and around the stoma. They also aid in the adhesion of the wafer. Using the fingertips, gentle pressure should be applied to put the wafer in place.

After the application of the barrier, the bag should be applied (if it is a two-piece system). If it is an open system, apply a clamp to the bottom of the new pouch.

Preparation

The nurse should instruct the patient and caregiver(s) about the procedure before it is performed. Many people feel anxious and nervous when first dealing with an ostomy. Encourage the patient to ask questions, and explain all steps as they are performed.

Aftercare

The nurse should assess the patient's tolerance of the procedure and response to teaching or education about the appliance.

Health care team roles

Although most members of the health care team will come into contact with patients having ostomies, it is the nurse who has the responsibility for providing ostomy care and instructing the patient and/or caregiver how to provide care independently. An enterostomal therapy (ET) nurse is specially educated in all aspects of ostomy care.

Colposcopy

Definition

Colposcopy is a procedure that allows a physician to examine a woman's cervix and vagina using a special **microscope** called a colposcope. It is used to check for precancerous or abnormal areas.

Purpose

Colposcopy is used to identify or rule out the existence of any precancerous conditions in the cervical tissue. If a **PAP test** shows abnormal cell growth, a colposcopy is usually the first follow-up test performed. The physician will attempt to find the area that produced the abnormal cells and remove it for further study (biopsy) and diagnosis.

Colposcopy may also be performed if the cervix looks abnormal during a routine examination. It may also be suggested for women with genital warts and for DES daughters (women whose mothers took DES when pregnant with them). Colposcopy is also used in the emergency department to examine victims of sexual assault and abuse and document any physical evidence of vaginal injury.

Precautions

Women who are pregnant, or who suspect that they are pregnant, must tell their doctor before the procedure begins. Pregnant women can, and should, have a col-

poscopy if they have an abnormal PAP test. However, special precautions must be taken during biopsy of the cervix.

Description

A colposcopy is usually performed in a physician's office and is similar to a regular gynecologic exam. An instrument called a speculum is used to hold the vagina open, and the gynecologist looks at the cervix and vagina using a colposcope, a low-power microscope designed to magnify the cervix 10–40 times its normal size. Most colposcopes are connected to a video monitor, which displays the area of interest. Photographs are taken during the examination to document abnormal areas.

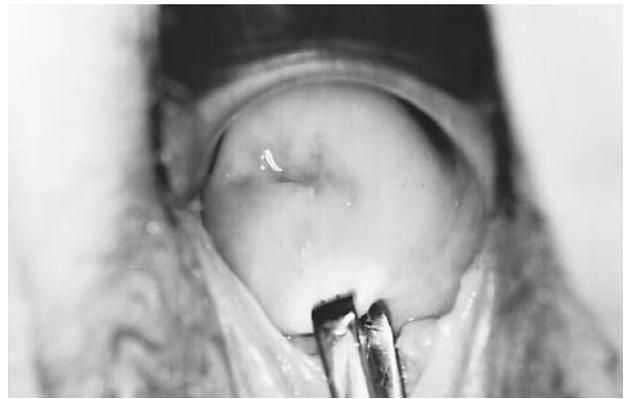

The colposcope is placed outside the patient's body and never touches the skin. The cervix and vagina are swabbed with dilute acetic acid (vinegar). The solution highlights abnormal areas by turning them white (instead of a normal pink color). Abnormal areas can also be identified by looking for a characteristic pattern made by abnormal **blood vessels**.

If any abnormal areas are seen, the doctor will take a biopsy of the tissue, a common procedure that takes about 15 minutes. Several samples might be taken, depending on the size of the abnormal area. A biopsy may cause temporary discomfort and cramping, which usually go away within a few minutes. If the abnormal area appears to extend inside the cervical canal, a scraping of the canal may be done. The biopsy results are usually available within a week.

If the tissue sample indicates abnormal growth (dysplasia) or is precancerous, and if the entire abnormal area can be seen, the doctor can destroy the tissue using one of several procedures, including ones that use high heat (diathermy), extreme cold (cryosurgery), or lasers. Another procedure, called a loop electrosurgical excision (LEEP), uses low-voltage, high-frequency radio waves to excise tissue. If any of the abnormal tissue is within the cervical canal, a cone biopsy (removal of a conical section of the cervix for inspection) will be needed.

Preparation

Patients should be instructed not to douche or have sexual intercourse for 24 hours before the colposcopy. Patients should empty their bladder and bowels before colposcopy for comfort. Colposcopy does not require any anesthetic medication because **pain** is minimal. If a biopsy is done, there may be mild cramps or a sharp pinching when the tissue is removed. To lessen this pain the doctor may recommend 800 mg of ibuprofen (Motrin) taken

A colposcopy makes it possible for a physician to view this healthy cervix without surgery. (Photograph by Dr. P. Marazzi, Custom Medical Stock Photo. Reproduced by permission.)

the night before and the morning of the procedure (no later than 30 minutes before the appointment). Patients who are pregnant or allergic to aspirin or ibuprofen can take two tablets of acetaminophen (Tylenol) instead.

Aftercare

If a biopsy was done, there may be a dark vaginal discharge afterwards. After the sample is removed, the doctor applies Monsel's solution to the area to stop the bleeding. When this mixes with **blood** it creates a black fluid that looks like coffee grounds. This fluid may be present for a couple of days after the procedure. It is also normal to have some spotting after a colposcopy. Pain-relieving medication can be taken to lessen any postprocedural cramping.

Patients should not use tampons or put anything else in the vagina for at least a week after the procedure, or until the doctor says it's safe. In addition, women should not douche or have sex for at least a week after the procedure because of the risk of **infection**.

Complications

Occasionally, patients may have bleeding or infection after biopsy. Bleeding is usually controlled with a topical medication prescribed by the physician or health care provider.

A patient should call her doctor right away if she notices any of the following symptoms:

- heavy vaginal bleeding (more than one sanitary pad an hour)
- fever, chills, or an unpleasant vaginal odor
- lower abdominal pain

Health care team roles

The colposcopy may be performed by a gynecologist or other qualified health care provider. Such examinations will normally be performed in the presence of a female nurse. In cases of sexual assault, a nurse practitioner or **registered nurse** may perform the procedure. If a biopsy is performed, a pathologist examines the tissue samples under a powerful microscope in the laboratory and sends the results to the health care provider who, in turn, informs the patient of the results.

Results

If visual inspection shows that the surface of the cervix is smooth and pink, this is considered normal. Areas that look abnormal may be normal variations; a biopsy will indicate whether the tissue is normal or abnormal.

Abnormal conditions that can be detected using colposcopy and biopsy include precancerous tissue changes (cervical dysplasia), **cancer**, and cervical warts (human papilloma virus).

Jennifer E. Sisk, M.A.

KEY TERMS

Biopsy—Removal of sample of abnormal tissue for more extensive examination under a microscope.

Cervix—The neck of the uterus.

Cryosurgery—Freezing and destroying abnormal cells.

DES—The abbreviation for diethylstilbestrol, a synthetic form of estrogen that was widely prescribed to women from 1940 to 1970 to prevent complications during pregnancy. It was linked to several serious birth defects and disorders of the reproductive system in daughters of women who took DES. In 1971 the FDA suggested it not be used during pregnancy and banned its use in 1979 as a growth promoter in livestock.

Diathermy—Also called electrocautery, this is a procedure that heats and destroys abnormal cells. It is gradually being replaced by cryosurgery, lasers, or LEEP.

Dysplasia—Development of abnormal tissue.

Human papilloma virus (HPV)—A virus that causes common warts of the hands and feet, as well as lesions in the genital and vaginal area. More than 50 types of HPV have been identified, some of which are linked to cancerous and precancerous conditions, including cancer of the cervix.

Loop electrosurgical excision (LEEP)—A procedure that can help diagnose and treat cervical abnormalities using a thin wire loop that emits a low-voltage high-frequency radio wave that can excise tissue. It is considered better than either lasers or electrocautery because it can both diagnose and treat precancerous cells or early stage cancer at the same time.

Monsel's solution—An aqueous solution of Monsel's salts with valuable styptic properties.

PAP test—The common term for the Papanicolaou test, a simple smear method of examining stained cells to detect cancer of the cervix.

Speculum—A retractor used to separate the walls of the vagina to make visual examination easier.

Coma

Definition

Coma, from the Greek word *koma*, meaning deep sleep, is a state of extreme unresponsiveness, in which an individual exhibits no voluntary movement or behavior. Furthermore, in a deep coma, even painful stimuli (actions which, when performed on a healthy individual, result in reactions) are unable to cause any response, and normal **reflexes** may be lost.

Description

The important characteristics of the conscious state is defined by two fundamental elements: awareness and arousal.

Awareness allows one to receive and process all the information communicated by the five senses. Awareness has both psychological and physiological components. The psychological component refers to an individual's mind and mental processes. The physiological component refers to the functioning of an individual's **brain**, and the physical and chemical condition of the brain. Awareness is regulated by cortical areas within the cerebral hemispheres, the outermost layer of the brain.

Arousal is regulated solely by physiological functioning and consists of more primitive responsiveness to the world, as demonstrated by predictable reflex (involuntary) responses to stimuli. Arousal is maintained by the reticular activating system (RAS), a network of brain structures, including the brainstem, the medulla, and the thalamus, and nerve pathways that function together to produce and maintain arousal.

Causes and symptoms

Coma is the result of something that interferes with the functioning of the cerebral cortex and/or the functioning of the structures that comprise the RAS. Several conditions can result in coma. Anatomic causes of coma are those conditions that disrupt the brain structures responsible for consciousness, either at the level of the cerebral cortex or the brainstem, while metabolic causes of coma consist of those conditions that change the chemical environment of the brain, thereby adversely affecting function.

There are many metabolic causes of coma, including:

- a decrease in the delivery to the brain of substances necessary for appropriate brain functioning, such as oxygen, glucose (sugar), and sodium

- the presence of certain substances such as drugs, alcohol, carbon dioxide, and ketones that disrupt the functioning of neurons
- changes in chemical levels in the brain caused by seizures

Diagnosis

History and examination form the cornerstone of diagnosis when an individual is in a coma. However, history must be obtained from family, friends, or emergency medical service personnel.

The Glasgow Coma Scale is a system of examining a comatose person. It evaluates the depth of the coma, tracks the person's progress, and predicts the ultimate outcome of the coma. The Glasgow Coma Scale assigns a different number of points for exam results in three different categories: opening the eyes, verbal response, and motor response (moving a part of the body). Fifteen is the largest possible number of total points, indicating the highest level of functioning, which would be demonstrated by individuals who spontaneously open their eyes, give appropriate answers to questions about their situations, and can carry out a command such as moving a specific limb when ordered. Three is the least possible number of total points, and would be given to a person for whom not even a painful stimulus is sufficient to provoke a response. In the middle are those people who may be able to respond, but who require an intense or painful stimulus, and whose response may demonstrate some degree of brain malfunctioning. When performed as part of the admission examination, a Glasgow score of three to five points often suggests that an individual has likely suffered fatal brain damage, while eight or more points indicates that the person's chances for recovery are good.

Expansion of the pupils and respiratory pattern are also important. Metabolic causes of coma are diagnosed from **blood** work and **urinalysis** to evaluate blood chemistry, drug screen, and blood cell abnormalities that may indicate **infection**. Anatomic causes of coma are diagnosed from computed tomography (CT) or **magnetic resonance imaging** (MRI) scans.

Treatment

Coma is a medical emergency, and attention must first be directed to maintaining an individual's respiration and circulation, using intubation and ventilation, administration of intravenous fluids or blood as needed, and other supportive care. If head trauma has not been excluded, the neck should be stabilized in the event of fracture. It is extremely important for a physician to quickly determine

the cause of a coma, so that potentially reversible conditions are immediately treated. These conditions may include an infection that can be treated with **antibiotics**, a **brain tumor** that can be removed, or brain swelling that can be reduced with certain medications.

Various metabolic disorders can be addressed by supplying an individual with the correct amount of oxygen, glucose, or sodium, by treating the underlying problem in **liver** disease, **asthma**, or diabetes, and by halting seizures with medication. Because of their low incidence of side effects and potential for prompt reversal of coma in certain conditions, glucose, the B-vitamin **thiamine**, and Narcan (to counteract any narcotic-type drugs) are routinely given.

Prognosis

Some conditions that cause coma can be completely reversed, restoring an individual to an original level of functioning. However, if areas of the brain have been sufficiently damaged due to the severity or duration of the condition that led to the coma, an individual may recover with permanent disabilities, either physical or mental, or may never regain consciousness. Short of death, the most severe types of brain injury result in states in which an individual loses all ability to function and remains deeply unresponsive. An individual who has suffered such a severe brain injury may remain in a coma indefinitely. This condition is termed a persistent vegetative state.

Outcome from a coma is therefore quite variable and depends a great deal on the cause and duration of the coma. In the case of drug poisonings, extremely high rates of recovery can be expected following prompt medical attention. Persons who have suffered head injuries tend to do better than do those whose coma was caused by medical illness. Besides those people whose coma results from drug **poisoning**, only about 15% of individuals who remain in a coma for more than just a few hours make a good recovery. Adult patients who remain in a coma for more than four weeks have almost no chance of eventually regaining their previous level of functioning. On the other hand, children and young adults have regained functioning after two months in a coma.

Health care team roles

Emergency medical team members are often first on the scene to provide a preliminary assessment of unconsciousness. In the hospital, a physician makes the diagnosis of coma, often with assistance from radiologists and laboratory technicians. Nurses provide supportive

KEY TERMS

Anatomic—Related to the physical structure of an organ or organism.

Metabolic—Refers to the chemical processes of an organ or organism.

Narcan—A drug that reverses the effects of narcotics.

Neuron—The cells within the body which comprise the nervous system.

Reticular activating system (RAS)—A network of structures, including the brainstem, medulla, and thalamus, and nerve pathways, which function together to produce and maintain arousal.

Stimulus—Action performed on an individual that predictably provokes a reaction.

care throughout the duration of a coma. Physical therapists provide range of motion and other therapeutic movements designed to preserve normal muscular functioning.

Prevention

Medical conditions known to cause comas should be monitored and promptly treated. Applicable safety precautions and rules should be followed when engaging in any activity that has the potential for serious **head injury**.

Common cold

Definition

The common cold is a viral **infection** of the upper **respiratory system**, including the nose, throat, sinuses, eustachian tubes, trachea, larynx, and bronchial tubes. Although over 200 different **viruses** can cause a cold, 30–50% are caused by a group of viruses known as rhinoviruses. Almost all colds clear up in less than two weeks without complications.

Description

Colds, sometimes called rhinovirus or coronavirus infections, are common, frequently occurring illnesses. It is estimated that the average person has more than 50 colds during a lifetime. Anyone can get a cold, although preschool and grade school children catch them more frequently than adolescents and adults because they have not been exposed to the cold viruses and developed immunity. Repeated exposure to the viruses that cause colds creates partial immunity.

Although most colds resolve on their own without complications, they are a leading cause of visits to the doctor and of time lost from work and school. Treating symptoms of the common cold has given rise to a multi-million dollar industry in over-the-counter medications.

Cold season in the United States begins in early autumn and extends through early spring. Colds occur more frequently during this period because people tend to spend more time indoors where it is easier for viruses to spread from one person to another. Although it is not true that getting wet or being in a draft causes a cold (a person has to come in contact with the virus to catch a cold), certain conditions may lead to increased susceptibility. These include:

- fatigue and overwork
- emotional **stress**
- poor nutrition
- smoking
- living or working in crowded conditions

Colds make the upper respiratory system less resistant to bacterial infection. Secondary bacterial infection may lead to otitis media (middle ear infection), bronchitis, **pneumonia**, sinus infection, or **strep throat**. Patients with chronic lung disease, **asthma**, diabetes, or a weakened **immune system** are more likely to develop these complications.

Causes and symptoms

Colds are caused by more than 200 different viruses. The most common groups are rhinoviruses and coronaviruses. Different viruses are more infectious at different seasons of the year, but determining the exact virus causing the cold is not important for purposes of treatment.

People with colds are contagious during the first two to four days of the infection. Colds pass from person to person in several ways. When an infected person coughs, sneezes, or speaks, tiny fluid droplets containing the virus are expelled. If these are inhaled by others, the virus may establish itself in their noses and airways.

Colds can also be passed through direct contact. If a person with a cold touches his runny nose or watery eyes, then shakes hands with another person, the virus is transferred to the uninfected person. When the uninfected person touches his mouth, nose, or eyes, the virus is transported to an environment where it can reproduce and produce symptoms of illness.

Finally, cold viruses can be spread through inanimate objects such as doorknobs, telephones, or toys that become contaminated with the virus. This is a common method of viral transmission in childcare centers. When a child with a cold touches his runny nose, then plays with a toy, the virus may be transferred to the toy. When another child plays with the toy a short time later, he may pick up the virus on his hands. When the second child touches his contaminated hands to his eyes, nose, or mouth the virus is once again in an environment conducive to replication.

Once acquired, the cold virus attaches itself to the mucosal lining of the nasal passages and sinuses. This causes the infected cells to release a chemical called histamine. Histamine increases **blood** flow to the infected cells, causing swelling, congestion, and increased mucus production. One to three days following infection, the affected individual begins to experience cold symptoms.

The first cold symptoms are **sore throat**, runny nose, and sneezing. The initial discharge from the nose is clear and thin. Later it changes to a thick yellow or greenish discharge. Most adults do not develop a **fever** when they contract a cold. Young children may develop fevers to 102°F (38.9°C).

Along with a runny nose and fever, symptoms of a cold include coughing, sneezing, nasal congestion, headache, myalgias (muscle aches), chills, sore throat, hoarseness, watery eyes, fatigue, and loss of appetite. The cough that accompanies a cold is usually intermittent and nonproductive (dry).

Most people begin to feel better four to five days after cold symptoms become noticeable. All symptoms are generally gone within ten days, except for a dry cough that may linger for up to three weeks.

Colds increase susceptibility to bacterial infections such as strep throat, middle ear infections, and sinus infections. Individuals with symptoms that do not begin to improve within a week; or those with chest **pain**, persistent fever (fever for longer than a few days), difficulty breathing, productive cough, skin rash, swollen glands, or whitish spots on the tonsils or throat should consult a health care practitioner. The health care practitioner will determine if these patients have acquired secondary bacterial infections that require treatment with **antibiotics**.

People who have **emphysema**, chronic pulmonary disease, diabetes, or a weakened immune system—either from diseases such as **AIDS** or leukemia, or as the result of immunosuppressive medications (**corticosteroids**, **chemotherapy** drugs)—should consult a health care practitioner when they experience cold symptoms. Patients with these chronic health problems are at greater risk for secondary infections.

Diagnosis

Colds are readily diagnosed using a focused history and **physical examination**. There are no laboratory tests readily available to detect or isolate the causative virus. When patients seek medical care, the health care practitioner (physician or mid-level practitioner) may perform a **throat culture** or blood test to rule out a secondary bacterial infection.

Though viruses cause both colds and **influenza** (flu), influenza is usually a more serious viral illness. A cold develops gradually over the course of a day or two. Patients may have a runny nose, sneezing, mild sore throat, headache and body aches, but usually they do not have fever or feel completely exhausted. Influenza symptoms develop suddenly. They are similar to cold symptoms, but usually more severe. Patients with influenza generally feel sicker than those with colds because the influenza virus produces symptoms throughout the body—muscle aches, weakness, fever, and chills.

Allergies also produce rhinitis (runny nose). Symptoms of allergic rhinitis—sneezing, nasal congestion, and itchy, runny nose—are commonly caused by

dust mites, animal dander, or indoor molds. Other environmental irritants such as smoke, pollen, pollutants, pesticides, and perfumes may also trigger allergic rhinitis. Allergies are usually more persistent than the common cold. An allergist can perform tests to determine if the persistent cold-like symptoms are attributable to an allergic reaction. Also, some people get a runny nose when they go outside in winter and breathe cold air. This type of runny nose, called vasomotor rhinitis, is not a symptom of a cold.

Treatment

There are no medicines that will cure the common cold. Given time, the body's immune system will make antibodies to fight the infection, and the cold will resolve without any intervention. Antibiotics are useless against a cold. There are, however, medications to provide symptom relief. Pharmaceutical companies in the United States promote an array of products designed to relieve cold symptoms. Most products contain **antihistamines**, decongestants, and/or pain relievers.

Antihistamines block the action of the chemical histamine that is produced when the cold virus invades the cells lining the nasal passages. Histamine increases blood flow and causes the cells to swell. Antihistamines relieve the symptoms of sneezing, runny nose, itchy eyes, and congestion. Side effects are dry mouth and drowsiness, especially with the first few doses. Patients should be advised against taking antihistamines if they intend to drive or operate dangerous equipment. The brand names of common over-the-counter antihistamines are Chlor-Trimeton, Dimetapp, Tavist, and Actifed. The generic names of two common antihistamines are chlorpheniramine and diphenhydramine.

Decongestants work to constrict the blood flow to the vessels in the nose. This can shrink the tissue, reduce congestion, and open inflamed nasal passages, making breathing easier. Decongestants can cause patients to feel jittery or prevent them from sleeping. They should not be prescribed for or used by patients with **heart** disease, high **blood pressure**, or **glaucoma**. The brand names of some common decongestants are Neo-Synephrine, Novafed, and Sudafed. The generic names of common decongestants are phenylephrine, phenylpropanolamine, pseudoephedrine, and in nasal sprays naphazoline, oxymetazoline, and xylometazoline.

Many over-the-counter medications are combinations of antihistamines and decongestants. They also may include an ache and pain reliever, such as acetaminophen (Datril, Tylenol, Panadol) or ibuprofen (Advil, Nuprin, Motrin, Medipren), and a cough suppressant (dextromethorphan). Common combination

medications include Tylenol Cold and Flu, Triaminic, Sudafed Plus, and Tavist D. Aspirin should not be given to children with colds because of its association with a risk of Reye's syndrome.

Nasal sprays and nose drops also are promoted to relieve nasal congestion. These usually contain a decongestant, but the decongestant can act more quickly and strongly than ones found in pills or liquids because it is applied locally, directly in the nose. Congestion usually returns after a few hours.

Patients may become dependent on nasal sprays and nose drops. If used for a long time, users may suffer withdrawal symptoms when the products are discontinued. This withdrawal condition is called rhinitis medicamentosa. Nasal sprays and nose drops should not be used for more than a few days. Patients should be instructed to adhere to product-specific recommendations about duration and frequency of use.

Individuals have varied reactions to different cold medications and may find some more helpful than others. A medication may be effective initially, then lose some of its effectiveness. Children sometimes react differently from adults. Patients should be cautioned against giving over-the-counter cold remedies to infants without first consulting a health care professional.

Care should be taken not to exceed the recommended dosages, especially when combination medications or nasal sprays are used. Individuals should determine whether they wish to use any of these medications based on their need for symptom relief, since none of them shorten the duration of a cold. Patients confused about the use of over-the-counter cold remedies should be encouraged to seek counsel from a health care practitioner, such as a physician, mid-level practitioner, nurse, or pharmacist.

Along with the optional use of over-the-counter cold remedies, there are some self-care steps that patients can take to ease their discomfort. These include:

- Drinking plenty of fluids, but avoiding acidic juices, which may irritate the throat.
- Gargling with warm salt water (made by adding one teaspoon of salt to 8 oz of water) for a sore throat.
- Not smoking.
- Getting plenty of rest.
- Using a cool-mist room humidifier to ease congestion and sore throat.
- Rubbing Vaseline or other lubricant under the nose to prevent irritation from frequent nose blowing.
- For babies too young to blow their noses, the mucus should be suctioned gently with an infant nasal aspira-

tor. It may be necessary to soften the mucus first with a few drops of salt water.

Many alternative health care practitioners believe that people contract colds because their immune systems are weak. They observe that everyone is exposed to cold viruses, but not everyone becomes ill. The difference seems to be in the ability of the immune system to fight infection. Prevention focuses on strengthening the immune system by eating a healthy diet low in sugars and high in fresh fruits and vegetables, practicing **meditation** to reduce stress, and getting regular moderate **exercise**.

There is some scientific evidence that phytochemicals, nutrients found in fruits and vegetables, may act to prevent viral infections such as colds. An herb, *Echinacea purpurea*, is widely used to prevent and treat colds. It is believed to act as a transient (brief) immunostimulant, however, patients with autoimmune diseases should not use it since continuous use had been linked to immunosuppression.

The use of **zinc** lozenges every two hours along with high doses of **vitamin C** is another alternative therapy. Some alternative practitioners also suggest eliminating dairy products for the duration of the cold because they contend that dairy products encourage production of mucus.

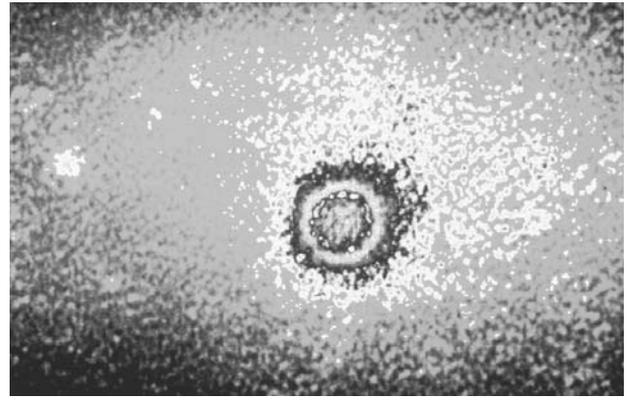

The use of zinc lozenges to treat cold symptoms remains controversial. Some studies evaluating the effectiveness of zinc gluconate lozenges found that using zinc in the first 24 hours after cold symptoms occurred shortened the duration of symptoms. Other studies refuted these findings.

Prognosis

Given time, the body will generate antibodies to the cold. Most colds last a week to ten days, and patients start feeling better within four or five days. Occasionally, a cold will lead to a secondary bacterial infection that causes strep throat, bronchitis, pneumonia, sinus infection, or a middle ear infection. These conditions usually resolve rapidly when treated with the appropriate antibiotic.

Health care team roles

Nearly all health care professionals encounter patients seeking advice about, or treatment for, cold symptoms. Physicians, mid-level practitioners, nurses, pharmacists, and health educators are often called upon to evaluate symptoms, instruct patients in self-care techniques, and reassure them that colds are self-limiting disorders that generally resolve without treatment.

Rhinovirus magnified 100,000 times. Rhinovirus causes the common cold. (CHSP/Custom Medical Stock Photo. Reproduced by permission.)

Patient education

Along with strategies to prevent the spread of cold viruses, it is vitally important for health care professionals to teach patients that antibiotics have no role in the treatment of the common cold. Antibiotics should not be prescribed for colds because, as of 2001, there are no antibiotics effective against the viruses that cause colds. Further, antibiotics should not be prescribed unnecessarily because they can produce side effects such as rash and **diarrhea**. Another dangerous **public health** consequence of overuse of antibiotics is the emergence of strains of **bacteria** that are resistant to these medications.

Prevention

It is not possible to prevent colds because the viruses that cause colds are common and highly infectious. There are, however, steps individuals can take to reduce their spread. These include:

- Washing hands well and frequently, especially after touching the nose and before handling food.
- Covering the mouth and nose when sneezing.
- Disposing of used tissues properly.
- Avoiding close contact with an infected individual during the first two to four days of their infection.
- Not sharing food, eating utensils, or cups with others.
- Avoiding crowded places where cold germs can spread.
- Eating a healthy diet and getting adequate sleep.

Community health programs

Definition

Community health programs are locally based education and treatment programs available typically to individuals who are living in poverty and/or do not have health insurance coverage. Community health programs are usually non-profit and seek funding through health department programs, donations, and government grants. Community-based health programs are typically found in communities where the services are needed the most, and the services are tailored to the populations of residents.

Description

Community health programs and clinics provide treatment, special clinics, education, and media campaigns that target a variety of issues affecting the health of a community. Many poor populations would have no other options for treatment without such neighborhood clinics and community health programs. Typical services include testing and treatment of sexually transmitted diseases; gynecological and obstetrical services; well-baby checks and immunizations; treatment of chronic diseases such as diabetes and high **blood pressure**; substance abuse programs; and general health promotion of good **nutrition** and weight management.

U.S. populations

Community-based programs will continue to be in demand to serve all populations from newborns to the elderly. Such programs are likely to become increasingly necessary to serve the growing number of immigrants moving to and living in the United States, the aging of the baby boomer generation, and the overall expansion of the population.

In the 21st century, the United States is expected to become increasingly diverse as the proportion of immigrants grows. In the next 25 years, the number of non-Hispanic white people living in the United States is expected to decrease from 72% to 62% due mostly to the increase in Hispanic populations.

Immigration also affects fertility rates because women in some immigrant populations tend to have more children. The need for **reproductive health** care and **pregnancy** prevention services are expected to increase at the community level.

The demand for services for the elderly will also increase as baby boomers age. As the health status of the elderly population improves, older adults are increasingly choosing to stay in their own homes and live independently. Senior citizens who live on a fixed income or who have limited health care coverage may be hard-pressed to pay for medications, monitoring, and treatment of age-related, chronic conditions such as diabetes, high **blood pressure**, declining eye sight, **hearing loss**, and **heart** disease.

Viewpoints

One point of debate within community health programs is the maximum income a person may earn and still be eligible for community health benefits. With limited funding, these agencies must follow guidelines for whom to offer services. In addition to those clearly living in poverty, the working poor and those with fixed

incomes may not otherwise be able to afford health care services.

The American Public Health Association (APHA) emphasizes that health care for all individuals is a basic human right. Every individual should be able to participate in his or her own health and wellbeing, and it is every citizen's responsibility to contribute to the wellbeing of all. Community-based health programs offers the opportunity to empower the community to enable all citizens to have access to optimum health. Community health directors can take the lead to promote these ends.

In collaboration with the APHA, the American Medical Association (AMA) has implemented seven goals, known as the Medicine/Public Health Initiative. They include: working to change the attitude within academic health centers; community health programs, insurance companies, and other health care delivery providers having a more health-centered approach; creating interdisciplinary teams to establish research-based programs that focus on relevant health problems; expanding the public's understanding of medicine, and, in turn, helping those in medicine understand public health; developing a common research agenda for public health; and developing a framework for integrating health promotion into clinical and community settings.

Professional implications

The AMA emphasizes that the success of health education and promotion lies with many disciplines collaborating and working cooperatively. Health care professionals, such as physicians, social workers, nurses, health educators, environmental health engineers, and behavioral health professionals, have their own unique training, skills, and tools. Public health is a multidisciplinary field. By contributing a population-based perspective on health and disease, public health practitioners can collaborate with medical professionals to optimize resources and ideas and contribute more effectively to improving the health of the community. Community-based health clinics and centers are in need of professionals who can lobby legislators to support funding for programs, in addition to lobbyists who can work with government agencies such as the **Health Care Financing Administration (HCFA)**, which oversees **Medicaid** funding.

Meghan M. Gourley

Complementary nursing therapies

Definition

Complementary therapies are treatment modalities originating outside of Western medical practices that are used in addition to traditional Western medical practices. Alternative therapies are treatment modalities used in place of traditional Western medicine. The two terms are sometimes used interchangeably. The term integrative therapy may be used to describe the use of complementary and alternative (CAM) therapies with traditional Western medical practice. The National Center for Complementary and Alternative Medicine (NCCAM) at the National Institutes of Health defines complementary and alternative medical practices as “practices that are not currently an integral part of conventional medicine.”

Description

The NCCAM groups CAM practices into five categories:

- **Alternative medical systems.** This category includes acupuncture and traditional Chinese medicine (TCM), the ancient Indian practice of Ayurveda, **homeopathy**, naturopathy, and practices considered traditional to other cultures. The term medical system means that these practices incorporate the use of dietary recommendations, **exercise**, **meditation**, and/or herbal remedies as part of the total treatment plan.
- **Mind-body interventions.** These include biofeedback, prayer, meditation, hypnosis, dance, music and art ther-

apies, guided imagery, progressive muscle **relaxation**, and visualization. Many of these techniques aid in stress-reduction and can be taught to patients, either individually or in groups.

- Biologically based therapies. Included in this category are herbal remedies and supplements, special diets such as Dr. Dean Ornish's program (low-fat, vegetarian, meditation, exercise, and support group) for **cardiac rehabilitation** patients, vitamin therapy, or the use of laetrile or shark cartilage.
- Manipulative and body-based methods. Osteopathy, chiropractic, massage, and reflexology are considered manipulative therapies.
- Energy therapies. These practices are based on the philosophy that an energy field exists around the body. The goal of practices such as reiki, qi gong, and **therapeutic touch** (TT) is to reestablish a healthy energy field so that the body can then work to heal itself. The use of magnets to manipulate the energy field is another example.

Describing CAM practices using the vocabulary of Western medicine is often a challenge, as the concept of life force, or chi, does not exist. However, a health practitioner who has been with a dying patient will recognize that, when the patient has died, there is a physical difference in how the patient looks. They do not just look asleep, for that which made them alive is now gone. It is this rather ephemeral quality that is described as chi.

Acupuncture has existed for thousands of years. Treatment is based on the belief that the acupuncture points connect a system of meridians, or energy pathways, to the internal organs. When energy flows freely, health is experienced. Disease or illness represents a blockage of the flow of energy throughout the body. TCM uses acupuncture along with herbal remedies and diet to reestablish balanced energy. Acupuncture may use an herb called moxa to enhance the stimulation of the acupuncture points. **Acupressure** involves the stimulation of the meridian points by manual pressure rather than with the fine acupuncture needles. Acupuncture has been successfully used to treat dental **pain** and the nausea associated with **pregnancy**, postsurgical anesthesia, and **chemotherapy**. According to the NCCAM, the World Health Organization lists about 40 conditions for which acupuncture may be beneficial.

Ayurveda is a traditional Indian medical system based on the belief that disease and illness result when there is an imbalance of the three doshas, which represent qualities governing body type, as well as the seasons and the different times of day. Each body type is susceptible to its own set of illnesses. Treatment to reestablish balance involves diet, herbal supplements, **yoga**, meditation, and massage with certain herbal oils.

Homeopathy functions on the philosophy that substances causing illness can be used in very dilute quantities to reestablish health. The more the substance is diluted, the more potent it becomes. Homeopathic remedies come in tablet, liquid, and cream form, and are used for children as well as for adults. The Food and Drug Administration (FDA) regulates the manufacture of homeopathic remedies.

Mind-body therapies emphasize the healing power intrinsic within the human body. Biofeedback uses a machine that both records physical measurements, such as skin temperature and **blood pressure**, as well as giving visual or auditory cues to teach the individual to control these factors usually considered involuntary. Patients suffering from migraines may use biofeedback to learn to warm their hands and cool their foreheads, thus providing relief on demand. Patients may learn a meditation technique in order to control the effect of **stress** on the body, perhaps to decrease their high **blood** pressure. Many meditation techniques exist. In meditation, the individual tries to focus on a word, feeling, breathing pattern, or state of being in order to free the mind of other thoughts. Guided imagery is a technique encouraging individuals to utilize all their senses to create a peaceful, calming image in their mind. This technique works well with children, and can be used to distract from pain or **anxiety**. In progressive muscle relaxation, the individual tightens then relaxes the muscles of the body, starting with the feet and moving towards the head. This process helps the person become more aware of the feeling of tight versus relaxed muscles, and enables the body to achieve greater physical relaxation. Nurses can teach these techniques to their patients, empowering them with ways to manage the stress in their daily lives.

Herbal remedies and supplements are used for therapeutic purposes and may be a part of an alternative system, such as Chinese medicine or naturopathy. They may be taken in tablet form, drunk as a tea, applied in a carrier cream, or inhaled in a vapor. Aromatherapy uses essential oils to stimulate the **brain** through the sense of **smell** to bring about a physiological effect such as relaxation or mood elevation. While individual herbal remedies are being investigated, such as the use of garlic to reduce cholesterol levels, or the use of saw palmetto for benign prostatic hyperplasia (enlarged prostate), the interaction of herbs with standard medications has often not been thoroughly researched.

Infant massage can be taught to new parents to facilitate bonding, and to teach them how to soothe their newborn. Infant massage has been used with infants in the intensive care unit to reduce their level of stress from being in an over-stimulating, noisy environment, address

their emotional needs, foster weight gain, and enable earlier discharge.

Reflexology involves a directed massage of the feet or hands. Points on the hands and feet are believed to correspond with internal organs, similar to the connection between acupuncture points, meridians, and internal organs. In reflexology, the practitioner applies pressure to specific points on the feet or hands to stimulate or remove energy blockages, thereby promoting healing and restoring health.

Prayer and the use of support groups are other important methods that can have an impact on an individual's health. Individuals with **cancer** who attended support groups were found to live longer than those who did not attend a support group.

Therapeutic touch (TT) is an energy technique developed by a **registered nurse** and university professor, Dr. Dolores Kreiger. Practitioners use their hands to sense the energy around a patient, feeling for areas where the energy is stagnant, or blocked. The patient may feel a sense of warmth or tingling while the practitioner is working to rebalance the energy. The goal is to promote the patient's innate ability to self-heal by reestablishing free-flowing energy. TT has been used to decrease pain, allowing a patient to prolong the time period between pain medication, to accelerate the rate of wound healing, and to promote relaxation.

Viewpoints

A 1998 study reported that in 1997 an estimated \$21.2 billion was spent on CAM services, of which \$12.2 billion was spent out-of-pocket. This figure is greater than the amount spent for all hospitalizations in the United States in 1997. Nurses may choose to believe in the validity of CAM or to believe that these, or some of these, practices represent medical quackery. Regardless of their personal belief, nurses need to recognize that many of their patients will believe and/or follow these practices. Respect for a patient's belief system is fundamental to the practice of nursing. Because of this, nurses must become knowledgeable about CAM practices in order to provide better nursing care to their patients. As research studies using CAM practices report beneficial outcomes, the definition of which therapies are considered alternative and which are considered mainstream changes. For this reason, it may be best not to label a therapy as CAM in discussing its use with a patient. In addition, patients' cultural backgrounds affect which therapies are mainstream to them.

Professional implications

As patient interest in and use of CAM increases, nurses need to be aware of these practices, regardless of whether or not they have been scientifically proven to be effective. CAM and nursing intersect at many points, including:

- **History and assessment.** As the nurse documents the patient's pertinent medical history, CAM practices need to be included. Asking open-ended questions, such as "What do you use to help your migraine pain?", may elicit a different response from the patient than the question, "Do you use alternative medicine for your migraine pain?" A 1999 study of women with **breast cancer** reported that while 72% of the women were engaged in at least one form of complementary medicine, only 54% informed their health care professional of their CAM use, although 94% told their alternative practitioner what medical treatments they were receiving. Reasons cited included concern of ridicule and perceived lack of interest from the professional. Patients requiring surgery may take herbal remedies that could interact with anesthesia medications. Knowledge of all the medications and supplements that the patient is taking could be critical.
- **Triage.** Nurses may receive telephone calls from patients who want to know if a particular herbal remedy is effective for their or their child's condition. In addition, patients may call after taking a remedy and experiencing an adverse side effect. Knowledge of herbal remedies could facilitate proper diagnosis.
- **Nurse as practitioner.** Nurses may choose to study CAM practices, become proficient in their use, and integrate their use into an existing nursing practice. However, nurses must keep in mind the legal implications of adding CAM therapies to their existing practice, to ensure they continue to practice within the legal boundaries of their license.

Complete blood count

Definition

A complete **blood** count (CBC) is a series of tests used to evaluate the composition and concentration of the cellular components of blood. It consists of the following tests: red blood cell (RBC) count, white blood cell (WBC) count, and platelet count; measurement of hemoglobin and mean red cell volume; classification of white blood cells (WBC differential); and calculation of **hematocrit** and **red blood cell indices**. The hematocrit is the percentage of blood by volume that is occupied by the red cells (i.e., the packed red cell volume). Red blood cell indices are calculations derived from the red blood

cell count, hemoglobin and hematocrit that aid in the diagnosis and classification of anemia.

Purpose

The CBC provides valuable information about the blood and to some extent the bone marrow which is the blood-forming tissue. The CBC is used for the following purposes:

- As a preoperative test to ensure both adequate oxygen carrying capacity and hemostasis.
- To identify persons who may have an **infection**.
- To diagnose anemia.
- To identify acute and chronic illness, bleeding tendencies, and white blood cell disorders such as leukemia.
- To monitor treatment for anemia and other blood diseases.
- To determine the effects of **chemotherapy** and radiation therapy on blood cell production.

Precautions

The CBC requires a sample of blood collected from a vein. The nurse or phlebotomist performing the venipuncture should observe **universal precautions** for the prevention of transmission of bloodborne pathogens. The collection tube must be filled completely, as under-filling increases the anticoagulant (EDTA) to blood ratio, which will crenate red blood cells. The tourniquet should be removed from the arm as soon as the blood flows to prevent hemoconcentration. If a fingerstick is used to collect the blood, care must be taken to wipe away the first drop, and not to squeeze the finger excessively as this causes the blood to be diluted by tissue fluid. The tests should be performed within four hours of collection or the sample must be refrigerated. Samples stored at 35-46°F (2-8°C) may be measured for up to 18 hours. Samples must be thoroughly mixed prior to measurement. Many drugs affect the results by causing increased or decreased RBC, WBC, and/or platelet production. Medications should be taken into account when interpreting results.

Description

The CBC is commonly performed on an automated hematology analyzer using well mixed whole blood anticoagulated with EDTA. A CBC is a group of tests used to quantify the number of RBCs, WBCs, and platelets, provide information about their size and shape, measure the hemoglobin content of RBCs, determine the percentage and absolute number of the five white blood cell types, and identify early and abnormal blood cells. These tests are

performed simultaneously, (usually in less than one minute), using an automated hematology analyzer. When the performance limit of the automated hematology analyzer is exceeded, sample dilution or pretreatment, manual smear review, or manual cell counts may be required. Such conditions include very low or elevated cell counts, and the presence of cold agglutinins, lipemia, and cell fragments. For example, a manual WBC count may be performed when the automated WBC count is below 500 per microliter. A manual microscopic evaluation of a stained blood film is performed when an abnormal cell population is encountered. Each laboratory has established rules for determining the need for manual smear review based upon specific CBC parameters. For example, a manual differential is always performed when nucleated red blood cells are found on an electronic cell count.

Electronic cell counting

Electronic blood cell counting is based upon the principle of impedance (i.e., resistance to current flow). Some hematology analyzers combine impedance counting with light scattering to measure platelets. A small sample of the blood is aspirated into a chamber (the WBC counting bath) and diluted with a balanced isotonic saline solution that is free of particles. The diluted blood sample is split into two parts, one for counting RBCs and platelets and the other for counting WBCs. The RBC portion is transferred to the RBC/platelet counting bath where it is diluted further. The other portion remains in the WBC bath and a detergent (lysing agent) is added to destroy (hemolyze) the red blood cells. A small portion of the diluted fluid in each bath is allowed to flow past a small aperture. An electrical current is produced in each aperture by two electrodes, one on the inside and the other on the outside of the aperture. The saline solution is responsible for conducting current between the electrodes. The cells move through the aperture one at a time. When a cell enters the aperture, it displaces a volume of electrolyte equal to its size. The cell acts as an electrical resistor, and impedes the flow of current. This produces a voltage pulse the magnitude of which is proportional to the size of the cell. Instrument electronics are adjusted to discriminate voltage pulses produced by different cells. These adjustments are called thresholds. For example, the threshold for counting a RBC is equivalent to a cell volume of 36 femtoliters or higher. Voltage pulses that are equivalent to volumes between 2-20 femtoliters are counted as platelets. This process is repeated two more times so that the RBC, WBC, and platelet counts are performed in triplicate. Each time frame for counting is several seconds and many thousands of cells are counted. The computer processes the counting data first by determining the

agreement between the three counts. If acceptable criteria are met the counts are accepted and used to calculate the result. The computer mathematically corrects the count for the random chance of two cells entering the aperture simultaneously. The voltage pulses for each cell type are sorted and displayed. The RBC and platelet sizes are plotted as a histogram, and the WBC sizes are plotted as a scattergram. This process produces cell counts with coefficients of variation that are on the order of tenfold lower than can be achieved by manual cell counting.

The hemoglobin concentration is measured optically using the solution in the WBC bath. The lysing agent contains potassium cyanide that reacts with the hemoglobin to form cyanmethemoglobin. The optical density of the cyanmethemoglobin is proportional to hemoglobin concentration. Source light from a small tungsten lamp or an LED that produces monochromatic light is directed through the sample contained in a small tube behind the bath. An interference filter on the other side of the tube transmits unabsorbed monochromatic light (e.g., 525 nm) to a photodiode. The photodiode current is proportional to the light it receives. This electronic signal is converted to an inverse log voltage that is proportional to the optical density of the solution. The optical density reading for the diluent is subtracted from the sample and the value is multiplied by a calibration factor (determined by measuring a calibrating solution) in order to calculate hemoglobin concentration.

The voltage pulses produced by the white blood cells depend upon the size of the cell and its nuclear density. Therefore, the pulses may be analyzed to differentiate between the types of WBCs found. For example, lymphocytes are the smallest WBCs and comprise the lower end of the size scale. Monocytes, prolymphocytes, and immature granulocytes comprise the central area of the WBC histogram, and mature granulocytes comprise the upper end. In addition to cell sizing, automated instruments may use any of three other methods to distinguish between subpopulations. These are radio frequency conductance, forward and angular light scattering, and fluorescent staining.

Red blood cell count

The red cells, the most numerous of the cellular elements, carry oxygen from the **lungs** to the body's tissues. They are released from the bone marrow into the blood in an immature form called the reticulocyte that still retains much of the cellular RNA needed for hemoglobin production. Reticulocytes may be counted on some automated analyzers and are an index to recovery from anemia. The average life span of RBCs in the circulation is approximately 110 days.

The red blood cell (RBC) count determines the total number of red cells (erythrocytes) in a sample of blood. Most **anemias** are associated with a low RBC count, hemoglobin, and hematocrit. Common causes include excessive bleeding; a deficiency of **iron**, **vitamin B₁₂**, or **follic acid**; destruction of red cells by antibodies or mechanical trauma; bone marrow malignancy and fibrosis; and structurally abnormal hemoglobin. The RBC count is also decreased due to **cancer**, kidney diseases, and excessive IV fluids. An elevated RBC count may be caused by **dehydration**, hypoxia, or polycythemia vera. Hypoxia may result from high altitudes, chronic obstructive lung diseases, and congestive **heart failure**.

Hematocrit and cell indices

The hematocrit is a test that measures the volume of blood in percent that is comprised of the red blood cells. Automated cell counters calculate the hematocrit by multiplying the RBC count by the mean red cell volume (see MCV below). A decrease in the number or size of red cells also decreases the amount of space they occupy, resulting in a lower hematocrit. Conversely, an increase in the number or size of red cells increases the amount of space they occupy, resulting in a higher hematocrit. Thalassemia minor is an exception in that it usually causes an increase in the number of red blood cells, but because they are small, it results in a decreased hematocrit.

The three RBC indices are used to determine the average size and hemoglobin content of the RBCs and they help determine the cause of anemia. The three indices are described below:

- Mean corpuscular volume (MCV)—the average size of the red blood cells expressed in femtoliters. MCV is calculated by dividing the hematocrit (as percent) by the RBC count in millions per microliter of blood, then multiplying by 10.
- Mean corpuscular hemoglobin (MCH)—the average amount of hemoglobin inside an RBC expressed in picograms. The MCH is calculated by dividing the hemoglobin concentration in grams per deciliter by the RBC count in millions per microliter, then multiplying by 10.
- Mean corpuscular hemoglobin concentration (MCHC)—the average concentration of hemoglobin in the RBCs expressed in percent. It is calculated by dividing the hemoglobin in grams per deciliter by the hematocrit, then multiplying by 100.

The mechanisms by which anemia occurs will alter the RBC indices in a predictable manner. Therefore, the RBC indices permit the physician to narrow down the

possible causes of an anemia. The MCV is an index of the size of the RBCs. When the MCV is below normal, the RBCs will be smaller than normal and are described as microcytic. When the MCV is elevated, the RBCs will be larger than normal and are termed macrocytic. RBCs of normal size are termed normocytic. Failure to produce hemoglobin results in smaller than normal cells. This occurs in many diseases including **iron deficiency anemia**, thalassemia (an inherited disease in which globin chain production is deficient), and anemias associated with chronic infection or disease. Macrocytic cells occur when division of RBC precursor cells in the bone marrow is impaired. The most common causes of macrocytic anemia are vitamin B₁₂ deficiency, folate deficiency, and **liver** disease. Normocytic anemia may be caused by decreased production (e.g., malignancy and other causes of bone marrow failure), increased destruction (hemolytic anemia), or blood loss. The RBC count is low, but the size and amount of hemoglobin in the cells is normal.

White blood cell count

The majority of CBCs include both a WBC count and an automated differential. A differential determines the percentage of each of the five types of mature white blood cells. An elevated WBC count occurs in infection, allergy, systemic illness, inflammation, tissue injury, and leukemia. A low WBC count may occur in some viral infections, **immunodeficiency** states, and bone marrow failure. The WBC count provides clues about certain illnesses, and helps physicians monitor a patient's recovery from others. The differential will reveal which WBC types are affected most. For example, an elevated WBC count with an absolute increase in lymphocytes having an atypical appearance is most often caused by infectious mononucleosis. The differential will also identify early WBCs which may be reactive (e.g., a response to acute infection) or the result of a leukemia.

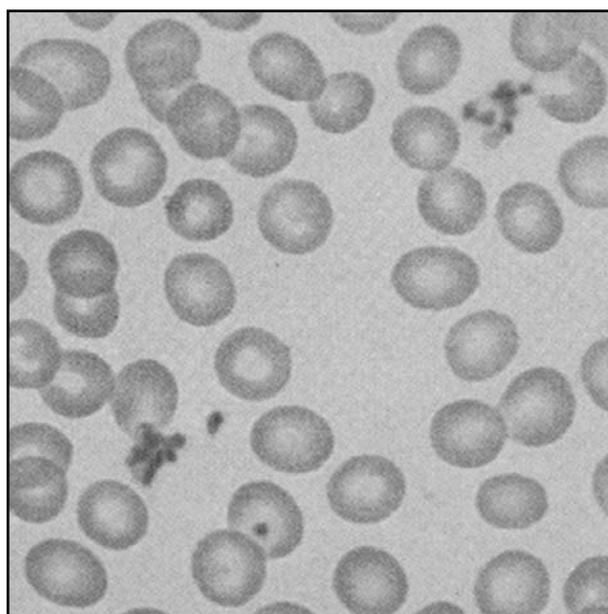

When the electronic WBC count is abnormal or a cell population is flagged, meaning that one or more of the results is atypical, a manual differential is performed. In that case, a wedge smear is prepared. This is done by placing a drop of blood on a glass slide, and using a second slide to pull the blood over the first slide's surface. The smear is air dried, then stained with Wright stain and examined under a **microscope** using oil immersion (1000x magnification). One hundred white cells are counted and identified as either neutrophils, lymphocytes, monocytes, eosinophils, or basophils based on the shape and appearance of the nucleus, the color of cytoplasm, and the presence and color of granules. The purpose is to determine if these cells are present in a normal distribution, or if one cell type is increased or decreased. Any atypical or immature cells also are counted.

In addition to determining the percentage of each mature white blood cell, the following tests are performed as part of the differential:

- Evaluation of RBC morphology is performed. This includes grading of the variation in RBC size (anisocytosis) and shape (poikilocytosis); reporting the type and number of any abnormal RBCs such as target cells, sickle cells, stippled cells, etc.; reporting the presence of immature RBCs (polychromasia); and counting the number of nucleated RBCs per 100 WBCs.
- An estimate of the WBC count is made and compared to the automated or chamber WBC count. An estimate of the platelet count is made and compared to the automated or chamber platelet count. Abnormal platelets such as clumped platelets or excessively large platelets are noted on the report.
- Any immature white blood cells are included in the differential count of 100 cells, and any inclusions or abnormalities of the WBCs are reported.

WBCs consist of two main subpopulations, the mononuclear cells and the granulocytic cells. Mononuclear cells include lymphocytes and monocytes. Granulocytes include neutrophils (also called polymorphonuclear leukocytes or segmented neutrophils), eosinophils, and basophils. Each cell type is described below:

- Neutrophils are normally the most abundant WBCs. They measure 12-16 μm in diameter. The nucleus stains dark purple-blue, and is divided into several lobes (usually three or four) consisting of dense chromatin. A neutrophil just before the final stage of maturation will have an unsegmented nucleus in the shape of a band. These band neutrophils may be counted along with mature neutrophils or as a separate category. The cytoplasm of a neutrophil contains both primary (azurophilic) and secondary (specific) granules. The secondary granules are lilac in color and are more abundant, almost covering the pink cytoplasm. Neutrophils are phagocytic cells and facilitate removal of **bacteria** and antibody-coated antigens. The neutrophilic granules are rich in peroxidase, and aid the cell in destroying bacteria and other ingested cells.
- Eosinophils are 14-16 μm in diameter and contain a blue nucleus that is segmented into two distinct lobes. The cytoplasm is filled with large refractile orange-red granules. The granules contain peroxidase, hydrolases, and basic **proteins** that aid in the destruction of phagocytized cells. Eosinophils are increased in allergic reactions and parasitic infections.
- Basophils, like eosinophils, are 14-16 μm in diameter and have a blue nucleus that is bilobed. The cytoplasm

Wright's stain of normal red blood cells and platelets.
(Delmar Publishers, Inc. Reproduced by permission.)

of the basophil is filled with large dark blue-black granules that may obscure the nucleus. These contain large amounts of histamine, heparin, and acid mucopolysaccharides. Basophils mediate the allergic response by releasing histamine.

- Lymphocytes are the second most abundant WBCs. They may be small (7-9 μm in diameter) or large (12-16 μm in diameter). The nucleus is dark blue and is nearly round or slightly indented and the chromatin is clumped and very dense. The cytoplasm is medium blue and usually agranular. An occasional lymphocyte will have a few azurophilic granules in the cytoplasm. Lymphocytes originate in the lymphoid tissues and are not phagocytic. They are responsible for initiating and regulating the **immune response** by the production of antibodies and cytokines.
- Monocytes are the largest WBCs, measuring 14-20 μm in diameter. They have a large irregularly shaped and folded blue nucleus with chromatin that is less dense than other WBCs. The cytoplasm is gray-blue, and is filled with fine dust-like lilac colored granules. Monocytes are phagocytic cells that process and present antigens to lymphocytes, an event required for lymphocyte activation.

Platelet count

Platelets are disk-shaped structures formed by the detachment of cytoplasm from megakaryocytes. They aid in the coagulation process by attaching or adhering to the

walls of injured **blood vessels**, where they stick together to form the initial platelet plug. A low platelet count may occur in patients with **AIDS**, viral infections, lymphoma, and lupus erythematosus, or in patients taking certain drugs, most notably quinine and quinidine. Decreased platelet production is also a cause of thrombocytopenia, and may be due to aplastic anemia, leukemia, lymphoma, or bone marrow fibrosis. A low platelet count can occur due to increased destruction. This can result from alloantibody production which is often drug-induced (heparin treatment being a prominent cause). Increased destruction also results from autoantibody production as occurs in idiopathic thrombocytopenic purpura (ITP) and thrombotic episodes that consume platelets such as occur in thrombotic thrombocytopenic purpura (TTP), disseminated intravascular coagulation (DIC), and hemolytic-uremic syndrome (HUS). Inherited (congenital) thrombocytopenia can be caused by Glanzmann's thrombasthenia, von Willebrand's disease, Fanconi syndrome, and Wiskott-Aldrich syndrome.

Thrombocytosis, an increased platelet count, is most often caused by a reaction to injury or inflammation. In these cases the platelet count increases transiently and is usually within the range of 400,000-800,000 per microliter. Persistent or higher counts are usually associated with myeloproliferative disease (malignant disease involving blood forming cells) such as chronic granulocytic (myelogenous) leukemia, polycythemia vera, or primary (essential) thrombocythemia.

The platelet count is most often measured by impedance counting but is performed manually when the platelet count is very low, platelet clumping is observed, or abnormally large (giant) platelets are present. Often these abnormalities and others such as cryoglobulinemia, cell fragmentation (hemolysis), and microcytic RBCs are signaled by abnormal RBC and platelet indices and abnormal population flags. An abnormal mean platelet volume or platelet histogram indicates that morphological platelet abnormalities are present and the platelets should be observed from a stained blood film to characterize the abnormality. The platelet count can be estimated using the Wright-stained blood smear used for a differential WBC count by multiplying the average number of platelets per oil immersion field by 20,000. Platelet estimates should correlate with actual counts. When they disagree, the platelet count should be repeated and a manual count performed if necessary.

Preparation

The CBC does not require fasting or any special preparation.

Aftercare

Discomfort or bruising may occur at the puncture site. Applying pressure to the puncture site until the bleeding stops helps to reduce bruising; warm packs relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be treated accordingly.

Complications

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with this test.

Results

CBC values vary by age and sex. Normal values are ultimately determined by the laboratory performing the test. As a guide, the normal values for men and non-pregnant women are as follows:

- WBCs: 4500 to 11,000 per microliter for women and men, with neutrophils representing 50-70%, lymphocytes 25-35%, monocytes 4-6%, eosinophils 1-3%, basophils 0.4-1%, and bands 0-5%.
- RBCs: 4.2 to 5.0 million per microliter for women; 4.5 to 6.2 million per microliter for men.
- Hemoglobin: 12-15 g/dL for women; 13.6 to 17.2 g/dL for men.
- Hematocrit: 35-47% for women; 42-52% for men.
- Platelets: 150,000 and 350,000 per microliter.
- Reticulocyte count: 0.5-1.5%.

Normal adult results for red blood cell indices are as follows:

- MCV: 80-98 fl (femtoliters).
- MCHC: 32-36%.
- MCH: 27-31 pg (picograms).
- RDW: 11.5-14.5%.

In addition to normal values, critical values (alert, panic values) are established for hemoglobin (and hematocrit), WBC count, and platelet count. Precipitously low hemoglobin is associated with hypoxia that can have life-threatening complications. Extremely low WBCs indicates an inability to fight infection and a high risk of sepsis. A severely reduced platelet count predisposes the patient to spontaneous internal bleeding. Representative critical values are shown below.

- Hemoglobin: less than 5.0 g/dL.
- Hematocrit: less than 15%.
- Platelet count: less than 30,000 per microliter.

KEY TERMS

Anemia—A diminished oxygen carrying capacity caused by a decrease in the size, number, or function of red blood cells.

Capillaries—The smallest of the blood vessels that bring oxygenated blood to tissues.

EDTA—A colorless compound used to keep blood samples from clotting. Its chemical name is ethylenediaminetetraacetic acid. EDTA functions by binding the calcium in the blood sample.

Hematocrit—The volume of blood occupied by the red blood cells expressed in percent.

Hemoglobin—A protein inside red blood cells that carries oxygen to body tissues.

Hypochromic—A descriptive term applied to a red blood cell with a decreased concentration of hemoglobin.

Macrocytic—A descriptive term applied to a larger than normal red blood cell.

Mean corpuscular hemoglobin (MCH)—A measurement of the average weight of hemoglobin in a red blood cell.

Mean corpuscular hemoglobin concentration (MCHC)—The measurement of the average concentration of hemoglobin in a red blood cell.

Mean corpuscular volume (MCV)—A measure of the average volume of a red blood cell.

Mean platelet volume (MPV)—A measure of the average volume of a platelet.

Microcytic—A descriptive term applied to a smaller than normal red blood cell.

Normochromic—A descriptive term applied to a red blood cell with a normal concentration of hemoglobin.

Normocytic—A descriptive term applied to a red blood cell of normal size.

Red blood cell indices—Measurements that describe the size and hemoglobin content of red blood cells.

Red cell distribution width (RDW)—A measure of the variation in size of red blood cells.

Thrombocyte—Another name for platelet.

Thrombocytopenia—An abnormally low platelet count.

Thrombocytosis—An abnormally high platelet count. It occurs in polycythemia vera and other disorders in which the bone marrow produces too many platelets.

- WBC count: less than 2,500 per microliter and greater than 30,000 per microliter.

Abnormal blood count results are seen in a variety of conditions. One of the most common is anemia, which is characterized by a low RBC count, hemoglobin, and hematocrit. The category into which a person's anemia is placed is in part based upon the red blood cell indices provided. The indices provide a significant clue as to the cause of the anemia, but further testing is needed to confirm a specific diagnosis. The most common causes of macrocytic anemia (high MCV) are vitamin B₁₂ and folic acid deficiencies. Lack of iron in the diet, thalassemia (a type of hereditary anemia), and chronic illness are the most common causes of microcytic anemia (low MCV). Normocytic anemia (normal MCV) can be caused by kidney and liver disease, bone marrow disorders, leukemia, excessive bleeding, or hemolysis of the red blood cells. Iron deficiency and thalassemia are the most common causes of hypochromic anemia (low MCHC). Normocytic anemias are usually also normochromic and share the same causes. The red cell distribution width (RDW) is increased in anemias caused by deficiencies of

iron, vitamin B₁₂, or folic acid. Abnormal hemoglobins, such as in sickle cell anemia, can change the shape of red blood cells as well as cause them to hemolyze. The abnormal shape and the cell fragments resulting from hemolysis increase the RDW. Conditions that cause more immature cells to be released into the bloodstream, such as severe blood loss, will increase the RDW. The larger size of immature cells creates a distinct size variation.

Infections and leukemias are associated with increased numbers of WBCs. Increases or decreases in the percentage of each white cell can be associated with a number of diseases or conditions, including cancer, leukemia, anemia, **multiple sclerosis**, **allergies**, parasitic and viral diseases, infections, and tissue damage.

Health care team roles

The CBC is ordered by a physician. A nurse or phlebotomist usually draws the blood to be used for the test. A clinical laboratory scientist/medical technologist or clinical laboratory technician/medical laboratory technician performs the test. The laboratory personnel are

responsible for notifying the physician when a critical limit is encountered. A clinical pathologist may be consulted when abnormal findings that indicate a serious blood disease are noted, such as early cells or cells containing inclusions.

Computed radiography

Definition

Computed radiography, or CR, is a digital image acquisition and processing system for radiography that uses computers and laser technology. It was developed in the mid-1980s. CR images can be recorded on laser-printed film or transmitted and stored digitally. This technological change has a significant impact on hospital operating costs and efficiency because radiography is the most common method of diagnostic imaging. It accounts for 70% of all imaging procedures, in comparison to 10% for CT scans and 6% for MRIs.

Purpose

The purpose of CR is to produce accurate radiographic images without the use of film, thereby streamlining the storage, display, and transmission of patient data. Because CR allows the radiographer to correct images immediately following exposure, the need for retake exposures is dramatically reduced. In a CR system, corrections made in the image are relayed to the radiographer through an s number. This value tells the

radiographer whether the system had to brighten or darken the image, and to what degree, in order to produce a usable image. The adjusted image can then be printed on a film by a laser printer.

In addition to providing clear diagnostic images that can be adjusted before printing, CR simplifies the process of transmission for purposes of consultation. CR images can easily be sent to other physicians or facilities for consultation via computer networks. Furthermore, CR systems permit considerable reductions in the cost of storage space for diagnostic images. Given the rapid rise in operating costs of full-service radiology departments, many newer facilities and some larger hospitals have installed CR systems.

Precautions

Radiation levels

One problematic aspect of CR is that it requires a higher dose of radiation to produce an image comparable to those produced by the film-screen method. The higher dose is necessary because the plate speed is approximately half that of the current screens used in film-screen combinations. The speed of the plate is directly related to the amount of radiation needed to create the x-ray image. Keeping the patient's exposure to radiation "ALARA," or "as low as is reasonably achievable," has always been one of the goals of radiologic imaging. On the other hand, some radiologists note that patients may receive lower total dosages of radiation from CR imaging because fewer repeat exposures are required.

Performance considerations

A second problematic aspect of CR is that although its contrast resolution is better than that of conventional radiographic films, its spatial resolution is not as good. This drawback is especially apparent in mammograms and chest radiographs. One study that compared six different systems for chest radiography found that the CR system performed the least well, even though it was tested under the normal operating conditions for its setting.

Description

Computed radiography is an imaging technology in which a phosphor imaging plate replaces the older combination of film-screen radiography. Phosphors are substances that become luminescent (emit light) when they are excited by ultraviolet light or other forms of radiation. The imaging plate consists of either aluminum or a steel frame with honeycombed carbon fiber on one side. This side is the x-ray attenuating side. Inside is the phosphor

imaging plate, which replaces the older film-screen cassette. The plate is contained in standard-size radiographic cassettes that can be used in existing radiographic tables and stands.

The radiographer positions the patient and inserts the imaging plate cassette with the carbon-fiber side facing the x-ray tube. When the phosphor inside the imaging plate is exposed to x rays, its electrons are excited to higher energy levels. The radiographer then places the plate in a scanner, in which a helium-neon laser irradiates the excited electrons in the phosphor. The electrons emit light and return to a lower energy level. The light given off is converted first to an analog electrical signal which is then digitized, or converted into numerical data. The data can be recorded as an image on laser-printed film or transmitted and stored digitally.

Picture-archiving communications systems (PACS)

Picture-archiving communication systems, or PACS, are computer systems that allow several physicians to view radiographic images from multiple locations at the same time, whether in different departments of the same hospital or from remote facilities. CR images can be scanned, reviewed by the technologist for accuracy, and made available within three minutes to both the radiologist and the admitting physician. PACS improve hospital efficiency by eliminating the risk of losing or misplacing x-ray films as well as minimizing the need for storage space.

Complications

Systems conversion

One of the major challenges in the implementation of computed radiography in any institution is acceptance by the clinical staff. The task of retraining radiologists and technologists as well as ancillary staff can be daunting. Lastly, the increasing complexity of radiographic equipment requires greater cooperation between the engineers and scientists who develop the equipment and the health care personnel who use them. Gradual introduction of CR, along with smooth coordination of the technology experts and the clinical staff, is usually the best way of moving toward full departmental conversion.

Newer technology

An additional complication to implementing CR systems is that they no longer represent cutting-edge imaging technology. Within the past few years, a system called digital radiography, or DR, has been introduced. It

KEY TERMS

Cassette—The thin container that holds the film or the laser plate during radiographic exposure.

Digital radiography (DR)—A newer form of filmless imaging that produces digital images on a computer monitor without the use of cassettes.

Digital recording—A method of recording audio or visual data in which an input wave form is sampled thousands of times per second, and each sample is given a binary numerical value.

Film-screen—The combination of x-ray film and screens used in current conventional methods of radiographic imaging.

Phosphor—A substance that emits light when it is struck by light of a certain wavelength. Some phosphors are luminescent only when struck by ultraviolet light.

Picture-archiving communication system (PACS)—A digitized system for storing CR or DR images that replaces older film storage, manual filing, and manual routing systems.

Screen—The layer lining the cassette that changes the x-ray into light

resembles CR in that it transmits, displays, and stores images without the use of film, but it differs from CR in that it is strictly digital and does not use cassettes at all. While the advantages of CR include its portability and its lower production cost, DR offers superior contrast resolution, immediate image readout, and considerable time savings. The first productivity studies comparing the two imaging systems have found that a CR examination takes between three and four times as long as an examination using digital radiography. In one hospital near Boston, the average two-view chest radiograph required 9.9 minutes with a CR system but only 2.5 minutes with DR. Most of the time difference appears to be due to the steps required to process the CR cassettes. While some hospitals are using both CR and DR systems, others are concerned that CR technology may not have a long enough future in spite of its lower initial costs to justify implementing it at all.

Results

CR does, however, offer significant advantages in diagnostic quality over conventional film-screen methods. The latest enhancements for CR include energy sub-

traction, which makes it possible to view bone-only and soft tissue-only images of the chest, and dynamic range control, which makes it possible to study both bone and soft tissue on the same image. Another benefit of the CR system is that the images are available immediately on the monitor for evaluation and post-processing enhancement. In addition, the images can be evaluated by an off-site radiologist with a monitor hooked up to the hospital's system. Lastly, CR is a portable system that can be used at the patient's bedside or in the emergency room as well as in a radiology clinic.

Health care team roles

With computed radiography as with conventional film-screen technology, the exposures can be made by a radiologic technologist or a radiologist. The radiologist will interpret the images as part of the process of differential diagnosis. A PACS system will allow the radiologist to consult with colleagues in other parts of the hospital or other institutions.

Computers in health care

Definition

Once used primarily as back-office record keepers and financial calculators, computers and their networks now play increasingly significant roles in patient care. They are increasingly used by health-care practitioners for patient information, record keeping, communicating with colleagues, devising strategies for patient care, interpreting lab results, and research. The fast processors and large **memory** capacity of today's computers, along with the Internet and other networks, have expanded the role of computers into virtually every aspect of health care.

Description

From the moment a patient walks into a hospital, doctor's office or clinic, computers are involved in his or her care. Patient information is often entered electronically to generate an electronic chart. Some organizations integrate this information with practice management software, helping staff schedule patient procedures and manage the financial matters.

Computer workstations in exam rooms can now allow clinicians to access patient information, lab results, and educational material. Electrocardiograms and other lab and radiology tests are often analyzed initially by computer programs to save staff time. Some radiology departments have begun to use digital "filmless" imaging technologies, and computers are even slowly entering the chaotic environment of the operating room, where perioperative nurses use workstations to document procedures.

Computers are being used to help avert medical errors—a critical need, since, according to an Institute of Medicine report important, an estimated 44,000 to 98,000 Americans die each year from preventable errors. Computer systems in some hospitals monitor patients in intensive-care units or operating rooms, alerting clinicians to anything abnormal, such as a sharp decrease in hemoglobin levels, for example. Instead of writing prescriptions on paper, some clinicians now use computer-based systems that not only suggest **drug dosages** but

Computers can be used to view patient information, help with diagnoses, and communicate with colleagues at other facilities. (Custom Medical Stock Photo. Reproduced by permission.)

check for **allergies** and interactions as well. Some clinicians also use handheld computers to enter patient notes and check medical references.

In addition to computerizing individual hospital departments, computers are being used to tie disjointed departments together and to standardize health care information over the entire industry. Aside from promising monetary savings and improved efficiency, such departmental integration is expected to help hospitals adhere to insurance company and government requirements. The federal Health Insurance Portability and Accountability Act (HIPAA), designed to protect confidential health care information, has pushed health care organizations to use consistent standards in their dealings with patients and insurers. Such standardization also promises to improve research by allowing scientists to track **public health** records more accurately and to better identify both treatments for, and causes of, disease.

The Internet has quickly become an integral part of health care. Patients can check their **medical records**, research drug interaction information, or find information on clinical trials and experimental medical treatment. Health care practitioners use the Internet for research, to

gain continuing medical education (CME) credits, and to check patient information. To help manage this information overload, several websites provide customized health information and access to research tools such as the National Library of Medicine's Medline/PubMed, a search engine that provides access to millions of citations from research journals. The Internet can also educate people about disease prevention and help them adopt a healthy lifestyle. Specialty websites, whose topics range from mental health to infectious diseases, allow individuals to conduct disease screenings and lifestyle and quality-of-life assessments.

In addition, government health organizations, such as the Centers for Disease Control and Prevention, use the web to provide public health information to state and local health departments, health professionals, and the general public. The World Health Organization (WHO) and its member organizations have created a vast global computer network called the Library and Information Networks for Knowledge (LINK); the agency also supports an electronic database called WHOLIS. Both the library and the database support the WHO's mission to improve international public health. Once a communica-

ble disease outbreak has been confirmed, for example, information is placed on the web for the general public.

Several Internet applications can even provide telemedical services, such as long-distance mammograms to underserved women. Other applications help patients suffering from chronic diseases such as **asthma**, diabetes, and **heart** disease to monitor their conditions. Still another computer program allows diabetics to download data from a **blood** glucose meter, enter information about their medications, diet, and symptoms, and transmit this data to healthcare providers.

Viewpoints

Although computers have improved patient care, administrative efficiency, and disease tracking, their increasing use also poses several challenges. Consistent, standardized data coding is one example. Maintaining patient privacy is another concern. In an electronic world of integrated departments and shared databases, **patient confidentiality** can be difficult to maintain unless great care is taken with sensitive patient information (like HIV status or drug-abuse history), and staff is trained to protect the confidentiality and security of patient information. Another consideration: making sure technology is reliable enough to be trusted. Poorly designed pharmaceutical software could result in drug errors, for example.

Professional implications

Nurses, who have traditionally gathered, stored, and maintained patient information, have an especial need for computer training. Even beginning nurses should have basic word processor, database, spreadsheet, and E-mail skills, according to a panel of researchers affiliated with the American Nurses Association (ANA). As computers become ever-more integrated into patient care, disease prevention, and health promotion, as well as into medicine's administrative processes, nurses need information literacy as much as they need computer literacy. This means that they must be able to recognize when information is needed and know how to track down and use it appropriately, according to the ANA panel.

Reflecting this shift, some nurses have chosen to augment their training with courses in nursing informatics, a field that was officially recognized as a specialty for registered nurses by the American Nurses Association in 1992. This specialty is a combination of nursing science, information processing theory, and computer science.

Concussion

Definition

Concussion is a trauma-induced change in mental status, associated with confusion and amnesia, that may or may not be accompanied by a brief loss of consciousness.

Description

A concussion occurs when the head hits or is hit by an object, or when the **brain** is jarred against the **skull** with sufficient force to cause temporary loss of function in the higher centers of the brain. The injured person may remain conscious or briefly lose consciousness and become disoriented for some minutes after the blow. According to the Centers for Disease Control and Prevention, approximately 300,000 people sustain mild to moderate sports-related brain injuries each year, most of them young men between the ages of 16 and 25.

While a concussion usually resolves on its own without lasting effect, it can set the stage for a much more serious condition. “Second impact syndrome” occurs when a person with a concussion, even a very mild one, suffers a second blow before fully recovering from the first. The brain swelling and increased intracranial pressure that can result is potentially fatal. More than 20 such cases have been reported since the syndrome was first described in 1984.

Causes and symptoms

Causes

Most concussions are caused by motor vehicle accidents and **sports injuries**. In motor vehicle accidents, concussion can occur without an actual blow to the head. Instead, concussion occurs because the skull suddenly decelerates or stops, which causes the brain to be jarred against the skull. Contact sports, especially football, hockey, and boxing, are among those most likely to lead to concussion. Other significant causes include **falls**, collisions, or blows due to bicycling, horseback riding, skiing, and soccer.

The risk of concussion from football is extremely high, especially at high school level. Studies show that approximately one out of every five players suffers a concussion or more serious brain injury during their brief high-school careers. The rate at the collegiate level is approximately one person in 20. Rates for hockey players are not known with certainty but are believed to be similar.

A concussion is usually accompanied by another area of brain injury on the opposite side of the head from the initial blow. This is called a **contrecoup injury**. It is caused by the impact of the brain on the opposite side of the skull after the initial blow.

Concussion and lasting brain damage is an especially significant risk for boxers, since the goal of the sport is, in fact, to deliver a concussion to the opponent. For this reason, the American Academy of Neurology has called for a ban on boxing. Repeated concussions over months or years can cause cumulative **head injury**. The cumulative brain injuries suffered by most boxers can lead to permanent brain damage. Multiple blows to the head can cause “punch-drunk” syndrome or **dementia pugilistica**, as evidenced by Muhammed Ali, whose **Parkinson’s disease** is a result of his career in the ring.

Young children are likely to suffer concussions from falls or collisions on the playground or around the home. **Child abuse** is, unfortunately, another common cause of concussion.

Symptoms

Symptoms of concussion include:

- headache
- disorientation relative to time, date, or place
- amnesia for the events immediately preceding the blow
- confusion
- dizziness
- vacant stare or confused expression
- incoherent or incomprehensible speech
- incoordination or weakness
- nausea or vomiting
- double vision
- ringing in the ears (tinnitus)

These symptoms may last from several minutes to several hours. More severe or longer-lasting symptoms may indicate more severe brain injury. A person with a concussion may or may not lose consciousness from the blow. If consciousness is lost, the duration is usually brief, for several minutes at most. More prolonged unconsciousness indicates more severe brain injury.

The severity of concussion is graded on a three-point scale. This is used as a basis for treatment decisions.

- Grade 1: no loss of consciousness, transient confusion, and other symptoms that resolve within 15 minutes.

- Grade 2: no loss of consciousness, transient confusion, and other symptoms that require more than 15 minutes to resolve.
- Grade 3: loss of consciousness for any period of time.

Days or weeks after the accident, a person may show signs of:

- headache
- poor attention and concentration
- **memory** difficulties
- anxiety
- depression
- sleep disturbances
- light and noise intolerance

The occurrence of such symptoms is called “post-concussion syndrome.”

Diagnosis

It is very important for those attending a person with a concussion to pay close attention to the person’s symptoms and progression immediately after the accident. The duration of unconsciousness and degree of confusion are very important indicators of the severity of the injury and help guide the diagnostic process and subsequent treatment decisions.

A trained health professional may make an immediate assessment based on the severity of the symptoms; a neurological exam of the pupils, coordination and sensation; and brief tests of orientation, memory, and concentration. Persons with very mild concussions may not need to be hospitalized or have expensive diagnostic tests. Questionable or more severe cases may require a computed tomography scan (CT) or **magnetic resonance imaging** (MRI) scan to look for brain injury.

Treatment

The symptoms of concussion usually clear quickly and without lasting effect, if no further injury is sustained during the healing process. Guidelines for returning to sports activities are based on the severity of a concussion.

A grade 1 concussion (no loss of consciousness, transient confusion, and other symptoms that resolve within 15 minutes) can usually be treated with rest and continued observation alone. The person may return to sports activities the same day, but only after examination by a trained professional, and after all symptoms have completely resolved. If the person sustains a second concussion of any severity that same day, contact sports

should be discontinued and not resumed until there have been no symptoms, during both rest and activity, for one week.

A person with a grade 2 concussion (no loss of consciousness, transient confusion, and other symptoms that require more than 15 minutes to resolve) must discontinue sports activity for the day, should be evaluated by a trained professional, and should be observed closely throughout the day to make sure that all symptoms have completely cleared. Worsening of symptoms, or continuation of any symptoms beyond one week, indicates the need for a CT or MRI scan. Return to contact sports should only occur after one week with no symptoms, both at rest and during activity, and following examination by a physician. Following a second grade 2 concussion, the person should remain symptom-free for two weeks before resuming contact sports.

A person with a grade 3 concussion (involving any loss of consciousness, no matter how brief) should be examined by a medical professional either on the scene or in an emergency room. More severe symptoms may warrant a CT or MRI scan, along with a thorough neurological and physical exam. The person should be hospitalized if any abnormalities are found or if confusion persists. Prolonged unconsciousness and worsening symptoms require urgent neurosurgical evaluation or transfer to a trauma center. Following discharge from professional care, a person should be closely monitored for neurological symptoms that may arise or worsen. If headaches or other symptoms worsen or last longer than one week, a CT or MRI scan should be performed. Contact sports should be avoided for one week following unconsciousness of only seconds, and for two weeks following unconsciousness of a minute or more. A person receiving a second grade 3 concussion should avoid contact sports for at least a month after all symptoms have cleared, and then resume them only with the approval of a physician. If signs of brain swelling or bleeding are seen on a CT or MRI scan, an athlete should not return to the sport for the rest of the season at the earliest, if not indefinitely.

For someone who has sustained a concussion of any severity, it is critically important to avoid the possibility of another blow to the head until well after all symptoms have cleared to prevent second-impact syndrome. The guidelines above are designed to minimize the risk of this syndrome.

Prognosis

A concussion usually leaves no lasting neurological problems. Nonetheless, symptoms of post-concussion syndrome may last for weeks or even months.

Studies of concussion in contact sports have shown that the risk of sustaining a second concussion is even greater than for the first, if the person continues to engage in the sport.

Health care team roles

A doctor, nurse, athletic trainer, or emergency medical technician may provide an initial evaluation at the time of the concussion. These health care team members can usually evaluate a grade 1 or 2 concussion. A neurologist, neurosurgeon, or trauma specialist should evaluate a concussion in a hospital. A neurologist or neurosurgeon should provide follow-up for grade 3 concussions. A nurse may provide post-concussion supportive care. Radiologists may obtain and interpret CT or MRI scans.

Prevention

Many cases of concussion can be prevented by using appropriate protective equipment. This includes using seat belts and air bags in automobiles, and wearing helmets in all contact sports. Helmets should also be worn when bicycling, skiing, or horseback riding. Soccer players should avoid heading the ball when it is kicked at high velocity from close range. Playground equipment should be underlaid with soft material, either sand or special matting.

The value of high-contact sports such as boxing, football, or hockey should be weighed against the high risk of brain injury during a young person's participation in the sport. Steering a child's general enthusiasm for sports into activities less apt to produce head impacts may reduce the likelihood of brain injury.

KEY TERMS

Amnesia—A loss of memory that may be caused by brain injury, such as concussion; the loss may be temporary or permanent.

Contrecoup injury—An injury, usually involving the brain, in which the tissue damage is on the side opposite the site of the trauma.

Parkinson's disease—A neurological disorder that includes a fine tremor, muscular weakness and rigidity, and an altered way of walking.

Tinnitus—A sensation of ringing in the ears in the absence of external sources of noise.

Consciousness, levels of

Definition

The everyday meaning of the word “consciousness” corresponds fairly closely to how most psychologists use the term. To be conscious is to be aware.

Description

Most of the time, we are aware of whatever activity happens to be at the center of our current attentional focus. For example, in order to read this sentence the readers need to focus their attention on the appropriate line on the page, and concentrate on extracting meaning from what they are reading. Such conscious attention is, however, very selective. Research has demonstrated that a great deal of our mental activity is performed outside of conscious awareness. Consciousness is like the tip of an iceberg. It allows us to exert purposeful control over our current activities, and to communicate our mental states to others. We selectively attend to only a small fraction of the stimulation to which we are constantly exposed. We ignore many sources of external information, but can be made instantly aware of them. Upon reflection, it is obvious that we are operating at various levels of consciousness throughout the day. Do students daydream in class, and later wonder what the teacher said? When people brush their teeth, are they thinking about how clean they are getting them? There are a variety of states or lev-

els of consciousness that have been studied extensively by psychologists. A few of them are described below.

Sleep

Perhaps the most frequent and conspicuous altered state of consciousness is experienced during sleep. Sleep is typically studied by means of an electroencephalograph. It produces a visual record (called an EEG) of the changes in electrical activity in the **brain** that occur during sleep. Changes in muscle activity and eye movements are also monitored. There are four major stages of sleep that are distinguished from one another on the basis of the electrical activity associated with each. There is also a distinctive fifth stage, known as REM (rapid eye movement) sleep. During this phase the brain’s electrical activity is similar to that of the waking state. The sleeper’s eyes dart about rapidly, even though the lids remain closed. Apart from the occasional twitch, there is a total suppression of muscle movement. The sleeper is essentially paralyzed. Because the brain’s motor cortex is active during this stage, REM sleep is sometimes referred to as “paradoxical sleep.” There is considerable internal activity, but an external calmness. REM sleep is the stage during which almost all dreaming occurs. REM sleep is usually accompanied by genital arousal in both males and females, although such arousal is unrelated to dream content. Regardless of the stage of sleep, there is no evidence that any substantive learning can take place during sleep. Despite extravagant claims, listening to a foreign language while sleeping is not going to make someone bilingual.

Hypnosis

Most of us have seen Hollywood movies in which a hypnotist puts somebody in a trance and then ostensibly induces them to perform silly and sometimes dangerous activities. There are reports of criminal investigations having been assisted by witnesses whose memories have been hypnotically enhanced. “Age regression” demonstrations show hypnotized subjects apparently reliving experiences from their childhood. Are these memories accurate? Does hypnotism produce an altered state of consciousness? Can hypnosis cause people to act against their will?

There are two competing explanations of what goes on during hypnosis. The social-cognitive approach views hypnosis as a social phenomenon. According to this perspective, hypnosis is not a unique physiological state and the behaviors produced by hypnosis can also be produced by other means. Hypnotized people are simply in a heightened state of suggestibility. Most people know what is supposed to happen during a hypnosis session. If the hypnotist’s suggestions are believed to be irresistible,

then people will comply with them. It's not that people are being deliberately deceptive. Their behaviors are genuine enough but they reflect beliefs about hypnosis and the role of hypnotized subjects, rather than the skills of the hypnotist or an altered state of consciousness.

The dissociation approach views hypnosis as a procedure that produces a split between two basic functions of consciousness—the executive function that we use for controlling our own behavior, and the monitoring function that is used for observing it. Hypnosis is assumed to disconnect these two components of consciousness, thereby preventing hypnotic experiences from entering normal consciousness. The two approaches are not necessarily contradictory. Certainly there is abundant evidence that social scripts play a role in many hypnotically induced behaviors. Numerous studies have shown that normal subjects who are asked to pretend to be hypnotized produce behaviors that are indistinguishable from those of hypnotized subjects. In another study, hypnotized subjects were given what they were told was a blank piece of paper. In reality, the number 8 was written on it. After hypnosis, those who reported that the paper was blank were told that only fakers would say that. They were then asked to draw what had been on the paper. Almost all drew the number 8. As far as hypnotically enhanced memories are concerned, such testimony is rarely admissible in court. The problem is that hypnotically revived memories often combine fact with fiction. Under hypnosis, people are more likely to use their imagination to construct or retrieve their recollections. Consequently, there is a danger that people will confidently assert having a **memory** of something they never experienced.

Hypnosis continues to be an active area of research. It is used in **psychotherapy** and is sometimes useful in alleviating chronic **pain**. Regardless of what the underlying mechanism might be, there is no evidence that hypnosis produces exceptional psychological feats or behaviors.

Automatic and controlled processing

It's not easy for us to talk on the phone while simultaneously carrying on a conversation with somebody else in the same room. Such difficulty illustrates a fundamental principle of cognition, namely that our cognitive resources are limited. We simply do not have the mental wherewithal to focus on several different tasks at once. If so, how do we manage to execute two activities at the same time, for example reading the newspaper and listening to the radio? The answer is that there are two different levels of conscious control over our behavior. The first is referred to as “automatic processing” because it

requires relatively little conscious awareness, and makes little demand on limited attentional capacity. When a person drives a car while mentally reviewing the previous days' events, he is demonstrating automatic processing. Automatic processing develops with practice as the component parts of the activity become well learned.

“Controlled processing” refers to behaviors that require effortful and deliberate concentration. It requires substantial use of cognitive resources. Consequently tasks requiring controlled processing can usually only be performed one at a time. Automatic processing is rapid and effortless, but somewhat inflexible. Controlled processing is slower, effortful, but adaptable.

This distinction between automatic and controlled processing is directly relevant to the current controversy about the use of cell phones while driving. There is good evidence to suggest that such behavior poses significant risks. For most adults, driving a car is a relatively automatic activity. For this reason, talking on the phone while driving may seem like a victimless crime. However, driving is not always automatic. When the unexpected happens, concentration is required. A driver in the midst of an animated conversation may not recognize an impending emergency and/or may not be able to respond with appropriate speed when it is recognized.

Subliminal perception

To what extent can we be influenced by stimuli whose presence we are not even aware of? There are numerous laboratory studies that show that individual words can be processed, even when presented so quickly that the viewer has no awareness of the word's identity. There is also evidence that patients under **general anesthesia** can apparently remember information (i.e., words) presented while they are unconscious. But what about more extraordinary claims? Can we be induced to buy a product or change our behavior on the basis of images or directives that are presented outside of conscious awareness? In a word, no. Before changing one's habitual response to a stimulus, one would have to be aware of perceiving it. There is no evidence to suggest that people initiate actions on the basis of subliminally presented stimuli.

Contact lenses

Definition

Contact lenses are small, light-weight plastic devices worn on the eye that correct refractive errors in **vision**. While they appear to be worn in direct contact with the cornea, they actually float on a layer of tears that separates them from the cornea.

Purpose

Contact lenses correct or improve the vision of people with nearsightedness (**myopia**), farsightedness (**hyperopia**), **presbyopia**, and **astigmatism**. In recent years, some people also wear contact lenses not for medical reasons, but rather to change their eye color.

Precautions

People allergic to certain plastics should not wear contact lenses manufactured from that type of material.

Patients with dry eye or severe seasonal **allergies** may find contact lenses uncomfortable and may prefer **eye glasses**. A careful patient history needs to be taken by the physician or contact lens technician to make sure these problems are addressed.

Eye care professionals should ensure that contact lens patients who have disposable or planned replacement lenses keep strictly to their replacement schedules. Contact lenses wear out over time and can damage patients' eyes. Deposits also can build up on the lenses, leading to lid and eye infections.

Patients who have lenses they can sleep in (extended wear lenses) also are advised not to keep their contact lenses in their eyes for longer periods than directed by their physician. Adherence to the schedules recommended by their physicians helps patients avoid **infection** and long-term damage to the cornea.

People employed in certain occupations may be prohibited from wearing contact lenses, or may be required to wear safety eyewear over the contact lenses. Physicians and employers should be consulted for recommendations.

Description

Ophthalmologists (M.D.s) or optometrists (O.D.s) dispense contact lenses. The prices for lenses vary for the different types. Some physicians offer a "global fee" to their patients that includes the contact lens fitting, lenses, and follow-up visits.

Over 32 million people in the United States wear contact lenses. These lenses provide a field of view unobstructed by eyeglass frames. They do not fog-up or get splattered and are less noticeable than any eyeglass style. On the other hand, they take time to get accustomed to; require more measurements for fitting; require many follow-up visits to the eye doctor; can lead to complications such as infections and corneal damage (but only if not cared for properly or replaced as prescribed); and may not correct astigmatism as well as eye glasses.

Originally, hard contact lenses were made of a material called PMMA. Although still available, it is rarely used because it does not allow oxygen to pass through the lens. The more common types of contact lenses are:

- Rigid gas-permeable (RGP) daily-wear lenses are made of plastic that does not absorb water, but does allow oxygen to permeate from the atmosphere to the cornea. (This is important because the cornea has no **blood** supply and needs to acquire oxygen from the atmosphere through the film of tears that moves beneath the lens.) They must be removed and cleaned each night.
- Rigid gas-permeable (RGP) extended-wear lenses are made from plastic that also does not absorb water and is more permeable to oxygen than the plastic used for daily-wear lenses. They can be worn for up to a week, then cleaned, and reinserted.
- Daily wear soft lenses are made of plastic that is permeable to oxygen and absorbs water; therefore, they are soft and flexible. These lenses must be removed and cleaned each night, and they do not correct all vision problems. Many patients find it easier to become accustomed to soft lenses, but these lenses are more prone to ripping and do not last as long as rigid lenses.
- Extended-wear soft lenses are highly permeable to oxygen, are flexible by virtue of their ability to absorb water, and can usually be worn for up to one week. They do not correct all vision problems.

- Extended-wear disposable lenses are soft lenses worn continually for up to six days and then discarded, with no need for cleaning.
- One type of disposable soft lenses are worn for one day and then discarded by the patient. Doctors believe these lenses reduce the risk of infection due to poor cleaning habits or over-wearing lenses. They can be price prohibitive for some patients at \$1 a day.
- Planned-replacement soft lenses are daily wear lenses that are replaced on a regular schedule, most commonly every two weeks, monthly, or quarterly. They must also be cleaned.

Soft contact lenses come in a variety of materials. High Dk materials provide high oxygen permeability and allow greater comfort for patients. Advances in toric contact lenses also allow individuals with astigmatism to achieve better visual correction from contact lenses with more comfort.

There are also different kinds of RGP and soft multifocal contact lenses available. There are five basic designs and over one hundred brands that offer variations of these designs. The optics of bifocal contact lenses are improving dramatically, as baby boomers move into presbyopia and more research dollars are devoted to this area. Monovision, where one contact lens corrects for distance vision while the other corrects for near vision, also may be an option for presbyopic patients. However, monovision may affect depth perception and may not be appropriate for everyone. Contact lenses also come in a variety of tints. Soft contact lenses are available that can change eye color. Even though such lenses have no prescription, they must still be fitted and checked to ensure that an eye infection does not occur. People should never wear someone else's contact lenses. This can lead to infection or damage to the eye.

Preparation

Before contact lenses are prescribed, the patient's eyes are examined by an optometrist or an ophthalmologist. Contact lens technicians, ophthalmic nurses, and ophthalmic technicians also may assist with the exam, although frequently their findings are verified by the physician.

Eyeglass prescriptions, if necessary, are then given to patients. A separate contact lens-fitting exam is necessary if the patient wants contact lenses. This is sometimes performed by the doctor, but in many cases is completed by a contact lens technician.

Before prescribing contact lenses, a technician performs an evaluation. He or she conducts a written and oral interview with the patient to determine if the patient

is a viable contact lens candidate. The technician then assesses the technical aspects of the patient's ocular status, since good eye health is required to wear lenses. The patient's palpebral aperture and visual iris diameter is measured to determine the appropriate diameter for the contact lens. The technician also tests the patient's tear quantity. A poor tear film is a contraindication for contact lenses use. Using instrumentation and information gained from the patient's eye exam, the technician determines what type of lens is best for the patient. For example, RGPs are commonly given to astigmatic patients because they provide clearer vision for these patients.

The contact lens technician selects the lens material and design, then determines the best trial lens. Based on the patient's experience with the trial lenses, the technician then determines the lens parameters. The physician reviews these findings to make the recommendation for the proper contact lenses. He or she ascertains the proper fit, and measures visual acuity and over-refraction to determine the proper lens prescription. Because a contact lens is an FDA-approved medical device placed directly onto the eye (unlike eye glasses), it cannot be issued until the eye's proper health has been ascertained via a follow-up examination. Unlike eyeglass prescriptions, a contact lens prescription includes not only the prescription, but also the contact lens material, diameter, brand, and curvature.

Before the patient is sent home with the lenses, the technician will give a detailed demonstration of inserting, removing, and cleaning the lenses. A written list of detailed instructions is usually dispensed with the lenses.

Aftercare

The doctor and technician schedule several return visits for the patient to evaluate the lens fit and performance. At these visits, eye care professionals determine whether the lens design or material needs to be modified.

Patients may be allergic to certain solutions that are used to clean or lubricate the lenses. For that reason, physicians instruct patients not to change solutions without prior approval. Contact lens wearers also are advised to seek immediate attention if they experience eye **pain**, a burning sensation, red eyes, intolerable sensitivity to light, cloudy vision, or an inability to keep the eyes open.

To avoid infection, it is important for contact lens wearers to exactly follow the instructions for lens insertion, removal, and cleaning. Soft contact lens wearers should never use tap water to rinse their lenses or to make up solutions. All contact lens wearers should always carry a pair of glasses and a contact lens case with them,

KEY TERMS

Astigmatism—A vision condition that occurs when the cornea is slightly irregular in shape. This irregularity prevents light from focusing properly on the retina.

Cornea—The clear outer covering of the front of the eye.

Index of refraction—A constant number for any material that is an indicator of the degree of the bending of the light caused by that material.

Lens—A device that bends light waves.

Permeable—Capable of allowing substances to pass through.

Polycarbonate—A very strong type of plastic often used in safety glasses, sport glasses, and children's eye glasses. Polycarbonate lenses have approximately 50 times the impact resistance of glass lenses.

Polymer—A substance formed by joining smaller molecules. Examples of polymers include plastic, acrylic, cellulose acetate, cellulose propionate, nylon, etc.

Presbyopia—A condition affecting people over the age of 40 where the system of accommodation that allows focusing of near objects fails to work because of age-related hardening of the lens of the eye.

Retina—The inner, light-sensitive layer of the eye containing rods and cones; transforms the image it receives into electrical messages sent to the brain via the optic nerve.

Ultraviolet (UV) light—Part of the electromagnetic spectrum with a wavelength just below that of visible light. It is damaging to living material, especially eyes and DNA.

in case the contact lenses have to be removed due to eye irritation.

Complications

Wearing contact lenses increases the risk of corneal damage and eye infections, if the lenses are not properly cleaned, if the lenses are inserted or removed with dirty hands, or if the lenses are worn for a longer period of time than recommended. However, there is little increased risk of eye infection or damage if the lenses are

worn as instructed and cared for properly. Dry eye and seasonal allergy symptoms may be exacerbated by wearing contact lenses.

Results

The normal expectation is that people will achieve 20/20 vision while wearing corrective lenses.

Health care team roles

Nursing and allied health professionals play an important role in contact lens examination and fitting. With advances in technology, technicians now have duties that formerly only a physician performed.

Contact lens technicians take the lead role in the contact lens fitting by recording the pertinent patient history, measuring the eye for the proper lens fit, and testing the tear quantity.

Advanced and intermediate level ophthalmic technicians perform refractions and determine the patient's depth perception. These professionals also may perform corneal topography (mapping).

Some of these professionals seek certification through the American Board of Opticianry and the National Contact Lens Examiners or other organizations. These organizations offer seminars and testing that helps professionals keep current with technological advances.

Physicians have become increasingly dependent on these technicians and assistants as managed care dictates they see more patients per day. By delegating these task to qualified personnel, the physicians can see more patients per day without jeopardizing patients' ocular health.

Patient education

Technicians emphasize the importance of cleaning contact lenses and adhering to any planned replacement schedule. They stress that while patients may save money by wearing lenses longer or skimping on cleaning solution, these actions increase the risk of eye infections or damage. Younger patients also are cautioned that sharing colored contact lenses with others can lead to eye infections. The importance of inserting and removing contact lenses with clean hands also is emphasized to all contact lens wearers.

Training

Optometrists and ophthalmologists receive training in **optometry** schools or medical residencies for these procedures. Contact lens technicians may complete special training courses or be trained by the physician.

Continuous passive motion device

Definition

Continuous passive motion (CPM) is a modality of postoperative treatment intended to assist recovery following joint surgery or injuries of upper or lower extremities. CPM equipment covers a range of mechanical devices designed to move the patient's joint or extremity without the use of the patient's muscles through a prescribed range of motion over extended periods of time. These devices were first introduced in the 1980s by Dr. Robert Salter, an orthopedic surgeon.

Purpose

CPM is used to reduce the adverse effects of trauma or immobilization following surgery. In physiological terms, synovial fluid is diffused without hindering tissue repair; the joint receives **nutrition**, the flow of venous **blood** is increased, and the cartilage is prevented from deteriorating. From a clinical perspective, joint swelling (**edema**) is decreased, range of motion (ROM) is maintained, tissue repair is accelerated, and the patient experiences less **pain**.

CPM devices are used as alternatives and adjuncts to conventional **physical therapy** following surgery or injury. CPM devices may also be used in bedridden surgical patients to reduce the incidence of deep vein thrombosis, to treat abnormal muscle shortening that occurs due to prolonged immobilization, and in patients with **burns** or joint sepsis.

Description

Typical CPM devices consist of a limb support resembling a splint or brace, a motor drive, and a control unit. CPM devices for the lower limb are used primarily after total knee replacement and ligament repair to provide flexion and extension of the joint. Configurations for exercising the hip, ankle, or toes are also available. Larger lower-limb CPM devices are typically designed to rest directly on the patient's bed; some are designed with the limb support suspended from an overhead traction frame. Upper-limb CPM devices are available mounted on stands that

KEY TERMS

Edema—An abnormal buildup of fluid in the tissues or joint capsules of the body, causing swelling of the involved area. Edema is a common cause of stiffness in the joints following injury or surgery.

Range of motion (ROM)—The extent to which a joint can be moved.

Sepsis—A local or generalized invasion of the body by disease microorganisms or their toxins.

Synovial fluid—A clear, viscous fluid secreted by membranes surrounding the joints. Synovial fluid helps to lubricate the joints.

Thrombosis—Coagulation or clotting of the blood inside a vein.

can be wheeled to the patient's bedside, in tabletop configurations, and as portable battery-powered units.

The motor drive of a CPM device is connected by a shaft to the limb support. The control unit contains adjustments for speed, motor reversal, and such range of motion parameters as degree of rotation, flexion, or extension. Some units are computerized and have remote control capabilities. Other units pause the continuous motion to allow for some active contraction by the patient or for the application of neuromuscular electrical stimulation.

Operation

The limb requiring CPM is strapped into the device's support. The range of motion parameters, speed, cycling time, and duration are then set. Most CPM devices have mechanical safety releases, resistance sensors, and/or automatic shut-offs for safety purposes. The most advanced CPM devices use microprocessors and load cells to measure resistance and automatically adjust parameters. Hospital patients may have 24-hour CPM operation. Patients using CPM at home may use the devices from four to six hours daily in hour-long sessions.

Patients on CPM devices should be monitored for problems with limb positioning and interference with device operation. For instance, bedsheets may become tangled in the device, or the patient's limb may become trapped, resulting in injury. Patients with urinary incontinence should be monitored carefully during CPM, because body fluids are an electrical hazard. All patients on CPM devices should be monitored for unnecessary

discomfort, pain, and chafing. Most manufacturers offer accessories or configurations to adjust for variations in patient limb size.

Maintenance

CPM devices are low-maintenance equipment since they are designed for continuous use. They do, however, require frequent checks for wear of moving parts and malfunctioning.

Health care team roles

The use of a CPM device is most often prescribed by a physician or orthopedic surgeon, and overseen by nursing, physical therapy, or rehabilitation staff.

Training

Manufacturers of CPM devices provide training for clinical staff. In addition, detailed user manuals are provided for reference during operation and maintenance. Patients using CPM devices at home should be given instructions regarding proper use of the device.

Contraception

Definition

Contraception is the use of a method, device, or medication to prevent **pregnancy** by interfering with ovulation, fertilization, and/or implantation. Another term for contraception is birth control.

Purpose

The purpose of contraception is to allow individuals to engage in sexual intercourse without it resulting in pregnancy.

Precautions

There are many methods of contraception. Factors to consider in choosing a method include:

- **Safety.** What are the risks of using this method? Can its use result in any damage to the female or male reproductive tract? Is its use associated with a higher risk of certain cancers? What are the consequences of its long-term use? Does its use affect future fertility?
- **Access.** Is a prescription needed to gain access to this method?
- **Cost.** How expensive is this method?
- **Insurance.** Is the cost of this method covered by my health insurance?

- **Effectiveness.** If this method is used as directed, what is the likelihood that it will fail to prevent a pregnancy?
- **Ease of use.** Is this method easy or difficult to use correctly?
- **Timing.** Is this method effective the first time it is used or put in place, or is it necessary to use it for a while before it will be effective?
- **Frequency.** How frequently will the individual engage in sexual intercourse?
- **Temporary versus permanent.** Does this method provide temporary birth control, or is it considered a permanent method? If permanent, could it be reversed in the future?
- **Ethics.** Is this method acceptable within the context of the individual's religious or ethical beliefs?
- **Benefits.** Other than its ability to provide contraception, does its use have any benefits to the individual's health?
- **Postpartum.** How soon after pregnancy can this method of birth control be used? Is it safe while breastfeeding? Does fertility return?

Description

During a woman's reproductive years, from its onset at menarche to its termination at **menopause**, an egg, or ovum, is released each month from one of her two ovaries, and it travels through the adjacent fallopian tube and into the uterus. If the egg is fertilized, it implants into the lining of the uterus and undergoes changes that eventually lead to the development of a fetus. In tandem with the release of the egg, the lining of the uterus, called the endometrium, undergoes changes that will enable it to support a pregnancy should the released egg become fertilized. When the egg is not fertilized, the endometrium that has built up in preparation for the pregnancy is shed. This tissue and the non-fertilized egg leave the uterus through the cervix and exit the body through the vagina in the form of menstrual secretions.

Birth control methods vary in targeting different aspects of this monthly process. The primary methods of birth control are hormonal, barrier, spermicides, intrauterine devices (IUDs), surgical, and periodic abstinence. In choosing a form of birth control it is important to understand how each method works, as well as its associated risks, benefits, and side effects.

- **Hormonal.** Hormonal methods of birth control include oral birth control pills. Birth control pills, sometimes called the Pill, come in two forms: combination, containing both estrogen and progestin, and progestin only, referred to as the mini-pill. Both forms suppress ovula-

Various contraceptives. (Photograph by Michael Keller. *The Stock Market*. Reproduced by permission.)

tion, thicken cervical mucus, and prevent implantation. Both require prescriptions. The hormone doses in the pills are kept as low as possible, while still being effective as a contraceptive. For this reason it is extremely important that they are taken on a daily basis. Skipping doses can put a woman at risk of becoming pregnant and she should supplement the pill with the use of a barrier method. In the first month a woman begins oral contraception, she may not be fully protected, so a barrier method should be used as a back-up. In a survey conducted by Planned Parenthood, only 28% of women take the Pill correctly, and only 42% actually take it on a daily basis. Because of the hormones used, women who suffer from migraines, diabetes, have had breast or uterine **cancer**, or who smoke, may need to choose another method. Women should always mention their use of birth control pills to their primary health care provider, as some medications prescribed for other conditions may interact with oral contraceptives. Use of the Pill can make other medications less effective, or exaggerate their effectiveness. Serious potential side effects of the combined pill include the formation of **blood clots**, **myocardial infarction**, and stroke. Because oral contraceptives suppress ovulation, their use can decrease a woman's risk of getting ovarian cancer. Some women find that their oral contraceptive improves skin problems. Hormonal contraception can be used by breastfeeding mothers, but usually not until the milk supply has been well established. In the case of the mini-pill, it can usually be started earlier, as it does not decrease milk volume. The combination pill can decrease the volume and lower the protein content of the breast milk. Oral contraceptives do not protect against any sexually transmitted diseases, so a condom should be used for that purpose in addition to taking the Pill.

- Depo-Provera and Lunelle are two brands of contraception given by injection. Depo-Provera is the trade name for the contraceptive depot medroxyprogesterone acetate (DMPA). Lunelle is a combination of estrogen and progesterone. They provide protection for about 12 weeks. They may be a good choice for women who have trouble remembering to take the Pill on a daily basis, for those for whom privacy of using a contraceptive is important, and for those engaging frequently in sexual intercourse. They work by suppressing ovulation, fertilization, and implantation. This method may not be a good choice for women who have had **breast cancer**, blood clots, **heart** attack or stroke, major depression, high cholesterol or **blood pressure**, diabetes, migraines, or abnormal results on **liver function tests**. If given within the first five days of a woman's menstrual cycle, they are considered protective against pregnancy during the first month of use. Side effects include irregular vaginal bleeding, loss of menstruation after one year of use, nausea, breast tenderness, depression, weight gain, vaginal dryness, and increased facial hair. After a woman stops using DMPA, it may take 18 months before a woman is able to become pregnant. They do not provide protection against sexually transmitted disease.
- Barrier methods. Barrier methods work by preventing the sperm from reaching and fertilizing the egg. Male and female condoms, diaphragms, and cervical caps work by creating a membrane through which the sperm cannot travel. Spermicides and the contraceptive sponge contain chemicals that decrease the sperm's ability to travel towards the egg. Condoms, diaphragms and caps should be used in conjunction with spermicides to increase overall effectiveness. Spermicides come in several forms: foam, cream, gel, sponge, and vaginal suppository. Condoms provide the most protection against sexually transmitted diseases. The diaphragm and cervical cap require fitting by a health care practitioner and a prescription. The other barrier methods are available without a prescription. Barrier methods are used at the time of sexual intercourse. They are less effective than hormonal methods of contraception. Individuals who have latex **allergies**, or who have had an allergic reaction to bananas, avocados or chestnuts, should speak with their health care provider before trying a condom, diaphragm, or cap. The allergic reaction may be mild, with symptoms such as runny nose, itching or a rash, or may be severe, resulting in **anaphylaxis** in which breathing can be obstructed by swelling. Early signs of anaphylaxis include rash, flushed skin, dizziness, or a tingling sensation. Medical help should be sought right away. A condition called toxic shock syndrome (TSS) has been

occasionally reported with diaphragm use. Signs of TSS include high **fever**, vomiting, **diarrhea**, flu-like symptoms such as aching joints or **sore throat**, dizziness, and rash. The diaphragm should be removed right away and the woman should call her practitioner. Diaphragm and cervical caps need to be refitted with weight gain or loss, and after a few years need to be replaced because the rubber begins to tear or decompose, rendering them ineffective.

- **Intrauterine devices (IUDs).** The IUD is a small, plastic device that is inserted by a health care practitioner into a woman's uterus. While in place it seems to prevent implantation by altering the endometrium. It is also thought that the consistency of the cervical mucus is changed, affecting sperm motility, preventing fertilization. It is easy to have it inserted and can be removed at any time by a practitioner. One brand contains **copper** and can be left in place for ten years, another contains progestin and needs to be replaced after one year. IUDs have a string attached at one end that hangs into the vagina. This not only assists in its ultimate removal, but also allows a woman to check periodically that it is still in its proper place. If the string appears to be shorter or longer than when inserted, the woman should have its placement checked by her practitioner. The string does not function as a wick, so it does not draw fluid up into the uterus. The IUD is not a good choice for a woman with a sexually transmitted disease or a history of pelvic inflammatory disease (PID). It is usually inserted during a menstrual period by a health care provider. Some practitioners may require the woman to have a negative **pregnancy test** done just prior to insertion. Some women may experience spotting between periods, or heavier periods with more cramping while using the copper IUD. Because the IUD was inserted through the cervix, a woman may be at a somewhat higher risk of **infection**, until the cervix closes tightly again (around three weeks). Two rare side effects can occur: the IUD imbedding into the uterus and the migration of the IUD into the abdominal cavity, requiring surgery to remove it. There is also a higher risk of pelvic inflammatory disease and infection of the reproductive organs, which could result in sterility, or require removal of the uterus. IUDs do not protect against sexually transmitted diseases.
- **Surgical sterilization.** Individuals who have completed their childbearing may choose a permanent form of contraception: surgical sterilization. In the male, this is known as a vasectomy. The vasectomy blocks the sperm from mixing with the seminal fluid. Sperm continue to be produced, but are reabsorbed by the body. Vasectomy does not affect the man's ability to have an erection, to ejaculate, nor does it affect the production

of male hormones. It is not effective immediately, as some sperm are still present in the unblocked portion of the tubes. A sperm analysis needs to be done to check for the presence of sperm. Until this process is completed, the man and his partner need to use another form of contraception to prevent a pregnancy. For the woman sterilization is known as tubal ligation, tubal sterilization, or having one's tubes tied. In tubal ligation the fallopian tubes are cut or blocked, preventing the egg from passing through towards the uterus. The ovum will continue to be released each month, but will be reabsorbed by the body after being blocked in the fallopian tube. Menstrual cycles continue as usual, and hormone production is not affected. It is effective immediately. Surgical sterilization is considered permanent and irreversible, although some individuals have been successful at having the process reversed. In a small percentage of cases, the surgery is not successful and the woman becomes pregnant. Both surgeries are done through small incisions, and on an outpatient basis. This form of birth control is not recommended for very young individuals, or those who have not yet had families. Because they involve surgery, complications associated with surgery, such as infection, bleeding, or a reaction to the anesthesia, can occur. Tubal ligation and vasectomy do not provide protection against sexually transmitted diseases. For the individual undergoing the sterilization, the surgery must be voluntary.

- **Periodic abstinence.** Periodic abstinence, or fertility awareness, is a technique of birth control based on abstaining from sexual intercourse on those days when a woman might become pregnant. The same techniques can be used by couples trying to conceive, by identifying the days when a woman is most likely to become pregnant. Using periodic abstinence often requires taking a class to learn the techniques used. The techniques employed are basal body temperature (BBT), cervical mucus identification, and a calendar method. The most effective use is the combination of all three techniques to predict which are the safe and which are the unsafe days for intercourse. Couples may then use this information to abstain from intercourse or use a barrier form of contraception on unsafe days. The calendar method keeps track of a woman's menstrual cycle. The cervical mucus identification method teaches the woman the differences in the vaginal secretions at various times of her cycle, which helps to identify when ovulation is most likely taking place. The BBT method charts the first temperature of the morning. Just prior to ovulation there is a slight dip in the basal temperature, followed by a slight temperature elevation when the woman ovulates. This method requires the use of a special **thermometer** that is more finely calibrated than one used

KEY TERMS

Anaphylaxis—A serious allergic response that can be fatal if not treated. In anaphylaxis the individual undergoes a hypersensitive reaction to a substance. Initial signs may include itching, wheezing, coughing and shortness of breath. If left untreated, the individual's respiratory passages may begin to swell, blocking the flow of air. Anaphylaxis is a medical emergency, and can result in death.

Ectopic pregnancy—A pregnancy that implants outside of the uterus, most commonly in a fallopian tube. An ectopic pregnancy can cause the fallopian tube to rupture, causing severe internal bleeding and pain. A woman with an ectopic pregnancy must seek medical care right away.

Triage—To organize or sort patients according to the degree or severity of their condition.

Vaginal suppository—Medication that is bullet-shaped, and is inserted into the vagina, where it melts and is absorbed.

for checking the presence of a fever. This combination of techniques requires that a woman's menstrual cycles are quite regular, that she has the ability to keep careful records, and that she and her partner(s) can abstain from intercourse or use a barrier method for much of the month. The readings are not accurate when the woman is sick, and may be affected by certain medications.

- Post-coital contraception. No method of contraception is 100% effective. If birth control was not used or if it failed during intercourse, or in the event of rape, the possibility of pregnancy exists. Some **reproductive health** centers and physicians offer emergency contraception that is used within 72 hours of unprotected sex, failed contraception, or rape. It involves taking oral doses of progestin or an estrogen-progestin combination, similar to that used in oral contraceptives. Some women experience dizziness or nausea and vomiting following the treatment. If a woman has had a positive pregnancy test and wishes to terminate the pregnancy, she may choose between surgical or medical abortion. Medical abortion involves the use of hormonal therapy, referred to in the United States as RU486. Planned Parenthood offers more information about these options through the telephone number listed below in Resources, and on their web site.

Preparation and aftercare

Preparation for the different contraceptive choices varies. Oral contraceptives need to be taken on a daily basis, and require a prescription, a thorough **health history**, and a visit to a health care provider. Injected hormonal contraception requires periodic visits for the injection. Barrier methods must be used every time there is intercourse, these methods differ in how long they may remain in the vagina, and whether ejaculation can be repeated without the use of a new barrier device. The IUD requires insertion and removal by a practitioner. Surgical sterilization is usually done in an outpatient facility. Patients will be given post-surgical instructions to follow, including which symptoms necessitate contacting their physician. Practitioners will want to be sure that this irreversible decision was made carefully and competently and that the patients are aware that there is a failure rate. Some follow-up care may be necessary. Periodic abstinence requires careful monitoring of a woman's fertility and the ability to abstain from intercourse or use barrier methods on unsafe days.

Complications

Complications of contraception vary according to the method used. Hormonal complications involve a response to the particular hormone and dosage used. Bleeding between periods or difficulty regaining regular menstruation or fertility following their discontinuance may occur. Oral contraceptives can interfere with the effectiveness of other medications. Women over 35 who smoke should not use oral contraceptives, as smoking places them at greater risk of heart attack or stroke. Barrier methods may produce a local reaction to the spermicide use. Spermicide packages should be checked for an expiration date. If used after expiration, they are not reliable. Diaphragm use is associated with the risk of toxic shock syndrome. Individuals unaware of their latex allergy may have a small allergic reaction, or could go into anaphylaxis. IUDs do have a serious but rare risk of puncturing the uterine wall, and also carry a risk of pelvic inflammatory disease with potential complications such as sterility if untreated. IUDs may be expelled from the uterus, so it is important to periodically check for the string that is attached to it. Women who become pregnant while using the IUD are at greater risk of an ectopic pregnancy. Surgical sterilization involves the risks of surgery, such as bleeding, or infection due to the anesthesia used. Vasectomy is only effective once all stored sperm has been ejaculated. Fertility awareness carries a higher risk of pregnancy, and if hands are not washed prior to checking the cervical mucus, **bacteria** could be introduced into the vagina and spread.

Results

The end result of effective contraception is prevention of pregnancy. Individuals choosing contraception must weigh the risks of the method against its ease of correct use and its success rate of preventing pregnancy. Hormonal methods are usually at least 95% effective. Barrier methods range from 60–80% effective. The IUD is considered 99% effective. Sterilization is about 99% effective. Fertility awareness is about 85% effective. Of course, effectiveness depends on consistent, careful use.

Health care team roles

Pharmacists are involved in filling the prescriptions of various forms of birth control. Having prescriptions filled at the same pharmacy provides protection against the possibility of interactions between different medications. Nurses provide education to patients on the various forms of birth control the individual is considering. Nurses are also involved in the care of patients seeking surgical contraception, as well as triaging calls from patients when they call their health care providers with questions and concerns about possible side effects. If a patient suspects an IUD has been dislodged, a radiology technician may take an imaging scan to locate the IUD.

Cooling treatments

Definition

Cooling or cold treatments are used to decrease **pain**, minimize swelling, and slow the inflammatory response secondary to injury (usually acute). Cold treatments slow the local physiological activity of the tissues, decrease nerve transmission, and decrease muscle guarding and spasm, thus minimizing potential damage to tissues when injury has occurred. Another name for cold or cooling treatments is cryotherapy.

Purpose

The most common reasons for cooling treatments are sprains, bruises, **burns**, eye injuries, and muscle spasms. Cooling treatments are used to help alleviate the resulting swelling, pain, and discoloration of the skin. They also help to cool the body if **fever** or hyperthermia exists. The body can sustain temperatures up to 104°F (40°C) with relative safety, however temperatures above 104°F (40°C) are more likely to cause damage to the **brain**, muscles, **blood**, and **kidneys**.

Cooling treatments slow chemical reactions within the body. For this reason, cooling tissues below normal body temperature (98.6°F [37°C]) can prevent injury from inadequate oxygen or **nutrition**. Interestingly, cold water drowning victims suffering from hypothermia (cooling of the body below its normal temperature) have been successfully resuscitated after long periods underwater without medical complications because of this effect. For the past 40 years, **heart** surgeons have been experimenting with hypothermia to protect tissues from lack of blood circulation during an operation. Neurosurgeons are also working with hypothermia to protect the very sensitive brain tissues during periods of absent or reduced blood flow. However, the major use for cooling treatments is to alleviate pain and swelling after acute injury.

Precautions

Before using cryotherapy nurses and other allied health team members need to make sure patients do not have sensation deficits or circulatory problems.

A technician uses a hose that blows cold, dry air directly onto goalkeeper Carlos Roa's injury. (Photograph by Oscar Pipkin. AP/Wide World Photo. Reproduced by permission.)

Description

There are many types of cooling treatments that offer relief of pain and decrease inflammation during acute injury:

- Ice bags: For application of deep cold. A very simple and inexpensive method.
- Ice massage: Simply rubbing ice on the skin, usually in a circular motion.
- Cryo-compression units: Usually a pad that fits around the affected area. Tubes or lines provide constant (cold) fluid under pressure from a mechanical device.
- Vapocoolant sprays: Either Ethel chloride or Fluoromethane type sprays that provide local pain relief and decreased muscle spasm.
- Gel packs: Packs are stored in the freezer until needed, and they contain a gel that can be refrozen any time.
- Immersion: Placing the limb, area, or joint in a bin of ice water.
- Cold bags (chemical): Bags with separate pouches containing chemicals within. The pouches are broken by squeezing the entire bag, the chemicals mix by means of an endothermic chemical reaction, and yield cold.

Preparation

Cooling treatments are prepared a number of ways:

- Ice bags: Plastic bags filled with ice applied over a towel for 20 minutes.
- Ice massage: Usually performed with a Styrofoam cup filled with water that has been frozen. Treatment lasts until skin is numb.
- Cryo-compression units: These units provide both cooling and mechanical compression of the affected area. A large pad or cuff is placed around the area.
- Vapocoolant sprays: An aerosol spray is usually used for treating trigger points (local muscular spasm with high sensitivity).
- Gel packs: Reusable gel packs are stored in a freezer until gel is completely frozen. Use with caution and less time than ice bags.
- Immersion: Usually, ice is frozen and placed in a bib of water, providing a very complete cold treatment. They should be used for about 15–20 minutes.
- Cold bags (chemical): Kept at room temperature until needed with no need for freezing. They do not provide intense cold; more of a cooling treatment. Can be used for up to 30 minutes.

Aftercare

Nurses and other allied health professionals should realize that there are three to four stages of cold sensation perceived by the patient: The first is the feeling of cold followed by (second stage) the patient feeling a burning sensation. The third stage is a dull aching over the area and finally (fourth stage) the patient reports feeling numbness. Removal of the cold treatment occurs when the skin feels numb. Sometimes the dull aching, or third stage, is not felt.

Complications

Nurses and allied health professionals also need to be aware that in instances where vaso constriction is contraindicated, cryotherapy should not be used. Furthermore, some patients may be oversensitive to cold and have an allergic type reaction. Excessive duration of cooling treatments may cause sensitivity.

Results

Cold treatments are usually the optimum treatment for acute injuries such as strains, sprains, bruises, and trigger points. Cryotherapy is one of the easiest and

effective treatments in decreasing pain, swelling, and muscle spasms.

Health care team roles

Nurses and other allied health team members should use the RICE principle when treating an acute injury: rest the area, ice the area, apply compression, and elevate the area.

Copper

Description

Copper is an essential mineral that plays an important role in **iron** absorption and transport. It is considered a trace mineral because it is needed in very small amounts. Only 70–80 mg of copper are found in the body of a normal healthy person. Even though the body needs

very little of it, copper is an important nutrient that holds many vital functions in the body.

Copper is essential for normal development of the body because it:

- Participates in a wide variety of important enzymatic reactions in the body.
- Is a component of or a cofactor for approximately 50 different enzymes. These enzymes need copper to function properly.
- Is essential for iron absorption and transport. Iron is needed to make hemoglobin, a main component of red **blood** cells. Therefore, copper deficiency is often linked to iron-deficiency anemia.
- Is required to build elastin and collagen, which are an important components of bones and connective tissues. Therefore, copper is believed to protect the bones and joints against degeneration and **osteoporosis**.
- Is required for melanin production. People with copper deficiency may have pale skin and hair.
- Is a key mineral for the **immune system**. Copper promotes wound healing. Studies show that **premature infants** or children with genetic copper defects are at high risk of getting infections and would significantly improve with copper supplementation.
- Attacks free radicals. Copper is a strong antioxidant. It works by attaching itself to the enzyme Superoxide dismutase (SOD). Copper also binds to a protein to form ceruloplasmin, which is an antioxidant.
- Helps the body produce energy. Copper participates in many oxidative reactions that break down **fats** in fat tissue to produce much needed energy. Copper deficiency has been associated with high cholesterol levels.
- Is necessary for normal functioning of insulin. Copper deficiency is also associated with poor blood glucose control.
- Is needed for normal functioning of the cardiovascular system.
- Protects the structure and function of the nervous system, including the **brain**. Copper protects nerve fiber by maintaining myelin, the insulating sheath that surrounds nerve cells. It also aids the transmission of nerve signals in the brains.

General use

Copper supplements may be beneficial in treating or preventing copper deficiency. Copper deficiency used to be relatively rare because the body requires so little of it, only about 2 mg per day. In addition, it is available naturally in a variety of foods such as whole grains, shellfish,

nuts, beans, and leafy vegetables. Additional sources of copper are the copper water pipes that run through homes or the copper cookware in the kitchen. These sources leach copper into the water we drink and the food we eat. The level of copper in drinking water is sometimes so high that it becomes a public concern. However, scientists now realize that copper deficiency, especially borderline cases, is more common than once thought. Copper deficiency is currently on the rise due to a decrease of whole foods in the diet and high consumption of fatty and processed foods.

Besides dietary causes, certain diseases or conditions may reduce copper absorption, transport, or increase its requirements, resulting in abnormally low copper blood levels. Increased copper intake through diet or supplementation may be necessary in the following conditions:

- premature infants fed only cow's milk
- pregnant women
- malnutrition
- celiac disease, sprue, **cystic fibrosis**, or short-bowel syndrome (These diseases cause poor absorption of dietary copper.)
- kidney disease
- high consumption of **zinc** or iron (These **minerals** interfere with copper absorption.)
- highly processed foods (Copper is stripped away during food processing.)
- Menkes syndrome (In this disease, copper deficiency is caused by genetic defects of copper transport. Menkes syndrome patients cannot use copper supplied by the diet efficiently.)

Symptoms of copper deficiency include:

- anemia
- malnourished infants
- prominently dilated veins
- pale hair or skin
- poorly formed bones
- nervous system disorders
- high cholesterol levels
- **heart** disease
- loss of **taste**
- increased susceptibility to infections
- infertility
- birth defects

Exceeding the daily requirement is dangerous, however, because copper toxicity commonly occurs. Copper

toxicity is a very serious medical problem. Acute toxicity due to ingestion of too much supplement, for example, may cause nausea, vomiting, abdominal **pain**, **diarrhea**, dizziness, headache, and a metallic taste in the mouth. Chronic toxicity is often caused by genetic defects of copper **metabolism**, such as Wilson's disease. In this disease, copper is not eliminated properly and is allowed to accumulate to toxic levels. Copper is therefore present at high concentration where it should not be, such as in the **liver**, the lens of the eye, **kidneys**, or brain.

Disease prevention

Copper is a good antioxidant. It works together with an antioxidant enzyme, superoxide dismutase (SOD), to protect **cell membranes** from being destroyed by free radicals. Free radicals are any molecules that are missing one electron. Because this is an unbalanced and unstable state, a radical is desperately finding ways to complete its pair. Therefore, it reacts to any nearby molecules to either steal an electron or give away the unpaired one. In the process, free radicals initiate chain reactions that destroy cell structures. Like other antioxidants, copper scavenges or cleans up these highly reactive radicals and changes them into inactive, less harmful compounds. Therefore, it can help prevent **cancer** and many other degenerative diseases or conditions such as premature aging, heart disease, autoimmune diseases, arthritis, **cataracts**, **Alzheimer's disease**, or diabetes.

Osteoporosis

Copper may play a role in preventing osteoporosis. **Calcium** and **vitamin D** have long been considered the mainstay of osteoporosis treatment and prevention. However, a recent study has shown that they can be even more effective in increasing bone density and preventing osteoporosis if they are used in combination with copper and two other trace minerals, zinc and manganese.

Rheumatoid arthritis

Copper has been a folklore remedy for rheumatoid arthritis since 1500 B.C. in ancient Egypt. Some people believe that wearing jewelry made of copper may relieve arthritic symptoms. To evaluate the effect of copper for the treatment of rheumatoid arthritis, Dr. Walker and his colleagues conducted a study of 77 arthritic patients. Patients were divided into two groups: treatment group wearing copper jewelry and placebo group wearing nothing or aluminum jewelry. In this study, patients who wore copper bracelets felt significantly better than those in the placebo group. In addition, patients in the treatment group reported recurrences of symptoms after the bracelets were removed. To explain the effects of the cop-

per bracelets, these researchers suggested that copper contained in the bracelets was dissolved in sweat and then absorbed through the skin. They suspected that copper's effectiveness may be related to its role as an antioxidant. They also believe that copper may function as both an anti-inflammatory agent and as an antioxidant. Thus, it is possibly effective in reducing inflammatory response to such conditions as rheumatoid arthritis.

Preparations

Copper is contained in many multivitamin/mineral preparations. It is also available as a single ingredient in the form of tablets. These tablets should be swallowed whole with a whole cup of water preferably with meals to avoid **stomach** upset. A person may choose any of the following preparations: copper gluconate, copper sulfate, or copper citrate. However, copper gluconate may be the least irritant to the stomach.

Zinc and copper compete with each other for absorption in the gastrointestinal tract. As a result, excessive copper intake may cause zinc deficiency, and vice versa. Therefore, a person should take zinc and copper supplements together in ratios of 10:1 or 15:1.

Precautions

Take heed to the following:

- Persons who take copper supplements should inform their doctors for proper instruction and monitoring of side effects. Copper toxicity due to excessive doses of copper supplements have been reported.
- Although there currently is no recommended daily allowance RDA established for copper, 2 mg of copper per day is considered sufficient and safe. Nausea and vomiting may occur in persons taking more than 20 mg of copper daily.
- It is not known if copper supplementation may harm a growing fetus. However, as with any drugs, pregnant or nursing women should not take copper or any other supplements or drugs without first consulting their doctors.
- In certain areas, drinking water may contain high levels of copper. Periodic checks of copper levels in drinking water may be necessary.
- Because individual antioxidants often work together as a team to defend the body against free radicals, the balance between copper, zinc, and iron must be maintained. Excessive intake of one nutrient might result in a deficiency of other minerals and decrease resistance to infections and increase risk of heart disease, diabetes, arthritis, and other diseases.

KEY TERMS

Antioxidants—Antioxidants are nutrients that deactivate reactive molecules (free radicals) and prevent harmful chain reactions.

Minerals—Inorganic chemical elements that are found in plants and animals and are essential for life. There are two types of minerals: major minerals, which the body requires in large amounts, and trace elements, which the body needs only in minute amounts.

Side effects

A person should stop taking copper supplements and seek medical help immediately if having the following signs or symptoms:

- anemia
- nausea
- vomiting
- abdominal pain

Interactions

Factors that increase copper concentrations

Certain disorders have been known to increase copper levels. Persons with these conditions should not take copper supplements as they may cause copper toxicity.

- recent heart attacks
- lupus erythematosus
- cirrhosis of the liver
- schizophrenia
- leukemia and some other forms of cancer
- viral infections
- ulcerative colitis (This inflammatory bowel disease may cause accumulation of copper in the body. Excessive amount of copper may worsen many symptoms of this disease by increasing susceptibility to infections and inhibiting wound healing.)
- Wilson's disease (This disease causes accumulation of copper in the tissues. As a result, these patients have liver disease, mental retardation, tremor, and poor muscle coordination. They also have copper deposits in the cornea of the eyes. To manage this disease, patients are put on a low-copper diet and given penicillamine, a drug that attaches itself to copper and increases its excretion.)

Copper deficiency see **Mineral deficiency**

Coronary angiography see **Cardiac catheterization**

Coronary artery disease

Definition

Coronary artery disease is a stenosis (narrowing) or blockage of the arteries and vessels that provide oxygenated **blood** to the **heart**. It is caused by atherosclerosis (hardening of the arteries), an accumulation of fatty plaque on the inner linings of arteries. The resulting blockage restricts blood flow through the coronary arteries. When blood flow is completely cut off, the result is **myocardial infarction** (heart attack).

Description

Coronary artery disease, also called coronary heart disease or atherosclerotic heart disease, is the leading cause of death for men and women in the United States. According to the American Heart Association, in 1998

one in every five deaths in the United States was caused by coronary artery disease. About every 29 seconds one American will have a heart attack; about every minute one American will die from a heart attack. Fourteen million Americans have active symptoms of coronary artery disease. Many millions more have asymptomatic (silent) coronary disease, the first indication of which can be sudden death.

Coronary artery disease occurs when the coronary arteries become partially blocked or clogged, thereby depriving the heart muscle of oxygen (myocardial ischemia). When the blockage is temporary or partial, angina (chest **pain** or pressure) may occur. When the blockage completely and suddenly cuts off the flow of blood, the result is myocardial infarction.

Healthy coronary arteries are clean, smooth, and slick. The artery walls are flexible and can expand to let more blood through when the heart needs to work harder. Atherosclerosis is thought to begin with an injury to the linings of the inner walls of the arteries. This injury makes them susceptible to atherosclerosis and thrombosis (blood clots).

Causes and symptoms

Coronary artery disease is usually caused by atherosclerosis. Cholesterol and other fatty substances accumulate on the inner wall of the arteries. This attracts fibrous tissue, blood components, and **calcium**, which harden into flow-obstructing plaques. If a blood clot suddenly forms on one of these plaques it can convert a partial obstruction to a total occlusion. This is known as coronary thrombosis. Congenital defects and spasms of a coronary artery may also block blood flow. There is evidence that **infection** from organisms such as chlamydia **bacteria** may be responsible for some cases of coronary artery disease.

A number of major contributing factors increase the risk of developing coronary artery disease. Some risk factors can be modified and others cannot. Persons with more of these risk factors are at greater risk of developing coronary artery disease.

Major risk factors

Major risk factors significantly increase the chance of developing coronary artery disease. Risk factors that cannot be changed include:

- Heredity. People whose parents have coronary artery disease, particularly those who develop it at younger ages, are more likely to be diagnosed with it. African-Americans are also at increased risk because they expe-

rience a higher rate of severe **hypertension** than whites.

- **Gender.** Men under the age of 60 years of age are more likely to have myocardial infarctions than women of the same age. Over age 60, however, women have coronary artery disease at a rate equal to that of men.
- **Age.** Men over age 45 and women over age 55 years are more likely to have coronary artery disease. Occasionally, coronary disease affects individuals in the 30s. Older adults (those over 65) are more likely to die of a myocardial infarction. Older women are twice as likely as older men to die within a few weeks of a myocardial infarction.

Major risk factors that can be changed are:

- **Smoking.** Smoking greatly increases both the risk of developing coronary artery disease and resulting mortality. Smokers have two to four times the risk of non-smokers for sudden cardiac death and are more than twice as likely to have a myocardial infarction. They are also more likely to die within an hour of a heart attack. Second-hand smoke may also increase risk.
- **High cholesterol.** Cholesterol is produced by the body, and obtained from eating animal products such as meat, eggs, milk, and cheese. Age, gender, heredity, and diet affect cholesterol level. Risk of developing coronary artery disease increases as blood cholesterol levels increase. When combined with other factors, the risk is even greater. Total cholesterol of 240 mg/dL or more poses a high risk, and 200–239 mg/dL a borderline high risk. For LDL (low-density lipoprotein) cholesterol, high risk starts at 130–159 mg/dL, depending on other risk factors. Low levels of HDL (high-density lipoprotein) increases the risk of coronary disease; high HDL protects against it.
- **Hypertension (high blood pressure).** High blood pressure makes the heart work harder, and over time, weakens it. It increases the risk of myocardial infarction, stroke, kidney failure, and congestive **heart failure**. Blood pressure of 140 over 90 or above is considered high. When hypertension is combined with **obesity**, smoking, high cholesterol, or diabetes, the risk of myocardial infarction or stroke increases several times.
- **Sedentary lifestyle and lack of physical activity.** Inactivity increases the risk of coronary artery disease. Even modest physical activity is beneficial if done regularly.
- **Diabetes mellitus.** The risk of developing coronary artery disease is significantly increased for diabetics. More than 80% of diabetics die of some type of cardiovascular disease.

Contributing risk factors

Contributing risk factors have been linked to coronary artery disease, but their precise contribution to the development of disease is not known yet. Contributing risk factors are:

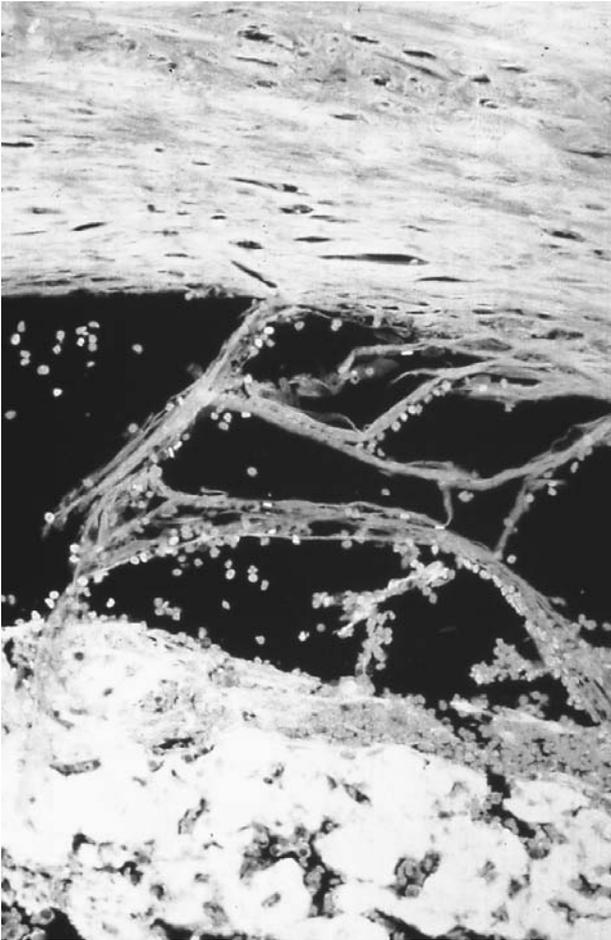

- **Obesity.** Excess weight increases the strain on the heart and increases the risk of developing coronary artery disease, even if no other risk factors are present. Obesity increases both blood pressure and blood cholesterol, and can lead to diabetes.
- **Stress and anger.** Stress and anger can produce physiological changes that contribute to the development of coronary artery disease, in part by increasing the risk of thrombosis. Stress, the mental and physical reaction to life's irritations and challenges, increases heart rate and blood pressure and can injure the lining of the arteries. Evidence shows that anger increases the risk of dying from heart disease. The risk of heart attack is more than double after an episode of anger.

Angina (chest pain) is the main symptom of coronary heart disease but it is not always present. Symptoms of angina typically include chest pain that may be described as heaviness, tightness, a burning sensation, squeezing, or pressure behind the breastbone. This pain may radiate to the left arm, neck, or jaw. Many people have no symptoms of coronary artery disease before having a heart attack; 63% of women and 48% of men who died suddenly of coronary artery disease had no previous symptoms of the disease, according to the American Heart Association.

Diagnosis

The diagnosis of coronary artery disease is made by the physician after a medical history, **physical examination**, and basic screening tests have been performed. The diagnostic work-up includes evaluation of body weight, blood pressure, blood lipid levels, and fasting blood glucose levels. Other diagnostic tests include resting and **exercise** electrocardiogram (ECG), **echocardiography**, radionuclide scans, and coronary **angiography**. A treadmill exercise (stress) test also may be used as a screening test for patients with significant risk factors but are asymptomatic.

An ECG may reveal if a patient has had a previous myocardial infarction (MI) or is having a MI. An ECG taken on a patient with coronary artery disease, who is not having chest pain during the ECG and has not had a prior MI, may be completely normal. An ECG technician places electrodes on the patient's chest, arms, and legs. These electrodes send impulses of the heart's activity through an oscilloscope (a monitor) to a recorder that traces them on

A fluorescent microscopy of a fresh thrombus of the coronary artery. (Photograph by J.L. Carson, Custom Medical Stock Photo. Reproduced by permission.)

paper. The test takes about 10 minutes and is performed in a physician's office. A definite diagnosis cannot be made from **electrocardiography**. About 50% of patients with significant coronary artery disease have normal resting electrocardiograms. Another type of electrocardiogram, known as an exercise **stress test**, measures how the heart and **blood vessels** respond to exertion when the patient is exercising on a treadmill or a stationary bike. This test is performed in a physician's office or an exercise laboratory. It takes 15-30 minutes. Like many medical tests, it does not have 100% accuracy. It sometimes gives a normal reading when the patient has a heart problem or an abnormal reading when the patient does not.

If the electrocardiogram reveals a problem or is inconclusive, the next step is exercise echocardiography or nuclear myocardial scanning (radionuclide angiography). Echocardiography, cardiac ultrasound, uses sound waves to create an image of the heart's chambers and valves. A technician presses a hand-held transducer

against the patient's chest to obtain an image that can be displayed on a monitor. It does not visualize the coronary arteries, but can detect abnormalities in heart wall motion caused by coronary disease. Performed in a cardiology outpatient diagnostic laboratory, the test takes about 30-60 minutes.

Nuclear myocardial scanning enables physicians to see if the myocardium (heart muscle) is being adequately perfused by the coronary arteries. Performed by radiologists and radiology technicians, nuclear scans involve injecting a small amount of radiopharmaceutical, such as thallium or sestamibi, into a vein. A camera that uses gamma rays to produce an image of the radioactive material records pictures of the heart. A radionuclide scan is comparable, in terms of radiation exposure, to a **chest x ray**. The tiny amount of radioactive material used disappears from the body in a few days. Radionuclide scans cost about four times as much as exercise stress tests but provide more information.

In nuclear myocardial scanning, a camera passes back and forth over the patient who lies on a table. Usually performed in a hospital's nuclear medicine department, the procedure takes 30-60 minutes.

Nuclear myocardial scanning is usually performed in conjunction with an exercise stress test. When the stress test is completed, thallium or sestamibi is injected. The patient resumes exercise for one minute to absorb the thallium. For patients who cannot exercise, cardiac blood flow and heart rate may be increased by intravenous dipyridamole (Persantine) or adenosine. Thallium or sestamibi scanning is done twice, immediately after injecting the radiopharmaceutical and again four hours (and maybe 24 hours) later. Usually performed in a hospital's nuclear medicine department, each scan takes about 30-60 minutes.

Coronary angiography is the gold standard (most accurate method) for establishing the diagnosis of coronary artery disease, but it is also the most invasive. During coronary angiography the patient is awake but sedated. ECG electrodes are placed on the patient's chest and an intravenous line is inserted. A local anesthetic is injected into the site where the catheter will be inserted. The invasive cardiologist inserts a catheter into a groin artery and guides it into the aorta. A contrast dye is injected directly into the coronary arteries to determine whether they are obstructed. Coronary angiography is performed in a **cardiac catheterization** laboratory either in an outpatient or inpatient surgery unit. It takes from 30 minutes to two hours.

Treatment

Coronary artery disease can be treated many ways. The choice of treatment depends on the severity of the disease. Treatments include lifestyle changes and drug therapy, percutaneous transluminal coronary **angioplasty**, and coronary artery bypass surgery. Coronary artery disease is a chronic disease requiring lifelong care. Angioplasty or bypass surgery is not a “cure.”

Patients with less severe coronary artery disease may gain adequate control through lifestyle changes and drug therapy. Many of the lifestyle changes that prevent disease progression—a low-fat, low-cholesterol diet, weight loss if needed, exercise, and not smoking—also help prevent the disease from developing.

Drugs such as nitrates, beta-blockers, and calcium-channel blockers relieve chest pain and complications of coronary artery disease, but they cannot clear blocked arteries. Nitrates (nitroglycerin) improve blood flow to the heart. Beta-blockers (acebutelol, propranolol) reduce the amount of oxygen required by the heart during stress. One type of calcium-channel blocker (verapamil, diltiazem hydrochloride) helps keep the arteries open and reduces blood pressure. Aspirin helps prevent blood clots from forming on plaques, reducing the likelihood of myocardial infarction. Cholesterol-lowering medications are also indicated in most cases.

Percutaneous transluminal coronary angioplasty and bypass surgery are invasive procedures to improve blood flow in the coronary arteries. Percutaneous transluminal coronary angioplasty, usually called coronary angioplasty or PTCA, is a non-surgical procedure. A catheter tipped with a balloon is threaded through an artery in the groin into the blocked coronary artery. The balloon is inflated, compressing the plaque to enlarge the blood vessel and open the blocked artery. The balloon is deflated, and the catheter is removed. Coronary angioplasty is performed by an invasive cardiologist in a hospital and generally requires a stay of one or two days. Coronary angioplasty is successful about 90% of the time, but one-third of the time the artery restenoses (narrows again) within six months. The procedure can be repeated. It is less invasive and less expensive than coronary artery bypass surgery.

In coronary artery bypass surgery, a healthy vein from an arm, leg, or the internal mammary artery is used to build a detour (bypass) around the coronary artery blockage. Bypass surgery is appropriate for those patients with blockages in two or three major coronary arteries, those with severely narrowed left main coronary arteries, and those who have not responded to other treatments. It is performed in a hospital under **general anesthesia**. A heart-lung machine is used to support the

patient while the healthy vein or artery is attached past the blockage to the coronary artery. About 70% of patients who have bypass surgery experience complete relief from angina; about 20% experience partial relief. Only about 3-4% of patients per year experience a return of symptoms. Survival rates after bypass surgery decrease over time. At five years after surgery, survival expectancy is 90%; at 10 years about 80%, at 15 years about 55%, and at 20 years about 40%.

Three newer surgical procedures for unblocking coronary arteries are currently being evaluated. Atherectomy is a procedure in which the cardiologist shaves off and removes strips of plaque from the blocked artery. In laser angioplasty, a catheter with a laser tip is inserted into the affected artery to burn or break down the plaque. A metal coil, called a stent, may be implanted permanently to keep a blocked artery open. Stenting is gaining popularity as an alternative to more invasive surgery.

Prognosis

In many cases, coronary artery disease can be successfully treated. Advances in medicine and healthier lifestyles have caused a substantial decline in death rates from coronary artery disease since the mid-1980s. New diagnostic techniques enable doctors to identify and treat coronary artery disease in its earliest stages. New technologies and surgical procedures have extended the lives of many patients who would otherwise have died. Research on coronary artery disease continues.

Health care team roles

Patients with coronary artery disease are most often treated by primary care physicians with consultation from cardiologists and cardiovascular surgeons when needed. Nurses, ECG technicians, laboratory technologists, and other allied health professionals have important roles in the diagnosis of coronary artery disease as well as in the institution of timely treatment. Nurses and other practitioners involved in triage or screening in the emergency department must accurately assess patients with chest pain or other indications of coronary artery disease.

ECG technicians, radiology technicians, and laboratory technologists are responsible for performing the diagnostic imaging studies, ECG and blood chemistries, to confirm the diagnosis of coronary artery disease. During the hospitalization, nurses, dietitians, respiratory and physical therapists collaborate to plan a **cardiac rehabilitation** program and provide patient and family education.

KEY TERMS

Angina—Chest pain that happens when diseased blood vessels restrict the flow of blood to the heart. Angina is often the first symptom of coronary artery disease.

Atherosclerosis—A process in which the walls of the coronary arteries thicken due to the accumulation of plaque in the blood vessels. Atherosclerosis is the cause of coronary artery disease.

Beta-blocker—A drug that blocks some of the effects of fight-or-flight hormone adrenaline (epinephrine and norepinephrine), slowing the heart rate and lowering the blood pressure.

Calcium-channel blocker—A drug that blocks the entry of calcium into the muscle cells of small blood vessels (arterioles) and keeps them from narrowing.

Coronary arteries—The main arteries that provide blood to the heart. The coronary arteries surround the heart like a crown, coming out of the aorta, arching down over the top of the heart, and dividing into two branches. These are the arteries in which coronary artery disease occurs.

HDL cholesterol—High-density lipoprotein cholesterol is a component of cholesterol that helps protect against heart disease. HDL is nicknamed “good” cholesterol.

LDL cholesterol—Low-density lipoprotein cholesterol is the primary cholesterol molecule. High levels of LDL increase the risk of coronary heart disease. LDL is nicknamed “bad” cholesterol.

Plaque—A deposit of fatty and other substances that accumulate in the lining of the artery wall.

Triglyceride—A fat that comes from food or is made from other energy sources in the body. Elevated triglyceride levels contribute to the development of atherosclerosis.

Patient education

Nurses, physical therapists and dieticians work together to educate patients and their families. Patients are taught to recognize and accurately describe symptoms such as pain, pressure, or heaviness in the chest, left arm, or jaw. Patients are advised to report any changes in the intensity or quality of their pain to nurses or other health care professionals while in the hospital. When

necessary, they are counseled by nursing or pharmacy technicians about the use of sublingual (under the tongue) nitroglycerin to relieve chest pain. They are instructed to seek medical attention immediately should serious symptoms return after they have been discharged.

Along with instruction about medication, follow-up care, and the importance of participating in cardiac rehabilitation, patients are informed about ways to reduce their risk for myocardial infarction or other complications of coronary artery disease. This education is tailored to the individual patient’s needs. It may include referral to a smoking cessation program; nutritional counseling to reduce dietary fat and sodium and achieve a desirable body weight; and recommendations to increase physical activity. **Patient education** also addresses treatment of any coexisting illnesses such as diabetes; and instruction about ways to more effectively manage stress and anger.

Prevention

A healthy lifestyle can help prevent coronary artery disease and help keep it from progressing. A heart-healthy lifestyle includes eating right, regular exercise, maintaining a healthy weight, no smoking, moderate drinking, no recreational drugs, controlling hypertension, and managing stress. Cardiac rehabilitation programs are excellent to help prevent recurring coronary problems for patients at risk and those with a history of coronary events and procedures.

Corticosteroids

Definition

A group of natural and synthetic analogues of the hormones secreted by the hypothalamic-anterior pituitary-adrenocortical (HPA) axis, more commonly referred to as the **pituitary gland**. These include glucocorticoids, which are anti-inflammatory agents with a large number of other functions; mineralocorticoids, which control salt and water balance primarily through action on the **kidneys**; and corticotropins, which control secretion of hormones by the pituitary gland.

Purpose

Glucocorticoids have multiple effects, and are used for a large number of conditions. They affect glucose utilization and fat **metabolism**, bone development, and are potent anti-inflammatory agents. They may be used for replacement of natural hormones in patients with pituitary deficiency (Addison's disease), as well as for a wide number of other conditions including but not limited to arthritis, **asthma**, anemia, various cancers, and skin inflammations. Additional uses include inhibition of nausea and vomiting after **chemotherapy**, treatment of **sep-**

Photograph of cortisone. (Michael Siegel/Phototake NYC. Reproduced by permission.)

tic shock, treatment of **spinal cord** injuries, and treatment of hirsutism (excessive hair growth). The choice of drug will vary with the condition. Cortisone and hydrocortisone, which have both glucocorticoid and mineralocorticoid effects, are the drugs of choice for replacement therapy of natural hormone deficiency. Synthetic compounds, which have greater anti-inflammatory effects and less effect on salt and water balance, are usually preferred for other purposes. These compounds include dexamethasone, which is almost exclusively glucocorticoid in its actions, as well as prednisone, prednisolone, betamethasone, trimacinolone, and others. Glucocorticoids are formulated in oral dosage forms, topical creams and ointments, oral and nasal inhalations, rectal foams, and ear and eye drops.

Mineralocorticoids control the retention of sodium in the kidneys. In mineralocorticoid deficiency, there is excessive loss of sodium through the kidneys, with resulting water loss. Fludrocortisone (Florinef) is the only drug available for treatment of mineralocorticoid deficiency, and is available only in an oral dosage form.

Corticotropin (ACTH, adrenocorticotrophic hormone) stimulates the pituitary gland to release cortisone. A deficiency of corticotrophic hormone will have the same effects as a deficiency of cortisone. The hormone, which is available under the brand names Acthar and Actrel, is used for diagnostic testing, to determine the cause of a glucocorticoid deficiency, but is rarely used for replacement therapy since direct administration of glucocorticoids may be easier and offers better control over dosages.

Recommended dosage

Dosage of glucocorticoids varies with drug, route of administration, condition being treated, and patient. Consult specific references.

KEY TERMS

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

Hormone—A substance that is produced in one part of the body, then travels through the bloodstream to another part of the body where it has its effect.

Inflammation—Pain, redness, swelling, and heat that usually develop in response to injury or illness.

Ointment—A thick, spreadable substance that contains medicine and is meant to be used on the outside of the body.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies; or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies; or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Fludrocortisone, for use in replacement therapy, is normally dosed at 0.1 mg/day. Some patients require higher doses. It should normally be administered in conjunction with cortisone or hydrocortisone.

ACTH, when used for diagnostic purposes, is given as 10 to 25 units dissolved in 500 ml of 5% Dextrose Injection infused IV over eight hours. A long-acting form, which may be used for replacement therapy, is given by subcutaneous (SC) or intramuscular (IM) injection at a dose of 40 to 80 units every 24–72 hours.

Precautions

The most significant risk associated with administration of glucocorticoids is suppression of natural corticosteroid secretion. When the hormones are administered, they suppress the secretion of ACTH, which in turn reduces the secretion of the natural hormones. The extent of suppression varies with dose, drug potency, duration of treatment, and individual patient response. While sup-

pression is seen primarily with drugs administered systemically, it can also occur with topical drugs such as creams and ointments, or drugs administered by inhalation. Abrupt cessation of corticosteroids may result in acute adrenal crisis (Addisonian crisis) which is marked by **dehydration** with severe vomiting and **diarrhea**, hypotension, and loss of consciousness. Acute adrenal crisis is potentially fatal.

Chronic **overdose** of glucocorticoids leads to Cushingoid syndrome, which is clinically identical to Cushing's syndrome and differs only in that in Cushingoid, the excessive steroids are from drug therapy rather than excessive glandular secretion. Symptoms vary, but most people have upper body **obesity**, rounded face, increased fat around the neck, and thinning arms and legs. In its later stages, this condition leads to weakening of bones and muscles with rib and spinal column **fractures**.

The short term adverse effects of corticosteroids are generally mild, and include indigestion, increased appetite, insomnia, and nervousness. There are also a very large number of infrequent adverse reactions, the most significant of which is drug-induced paranoia. Delirium, depression, menstrual irregularity, and increased hair growth are also possible. Consult detailed reviews for further information.

Long-term use of topical glucocorticoids can result in thinning of the skin. Oral steroid inhalations may cause fungal overgrowth in the oral cavity. Patients must be instructed to rinse their mouths carefully after each dose. Corticosteroids are **pregnancy** category C. The drugs have caused congenital malformations in animal studies, including cleft palate. Breastfeeding should be avoided.

Because fludrocortisone has glucocorticoid activity as well as mineralocorticoid action, the same hazards and precautions apply to fludrocortisone as to the glucocorticoids. Overdose of fludrocortisone may also cause **edema**, **hypertension**, and congestive **heart failure**.

Corticotropin has all the same risks as the glucocorticoids. Prolonged use may cause reduced response to the stimulatory effects of corticotropin.

Warnings and contraindications

Use corticosteroids with caution in patients with the following conditions:

- osteoporosis or any other bone disease
- current or past **tuberculosis**
- glaucoma or **cataracts**

- infections of any type (virus, **bacteria**, fungus, amoeba)
- sores in the nose or recent nose surgery (if using nasal spray forms of corticosteroids)
- underactive or overactive thyroid
- liver disease
- stomach or intestine problems
- diabetes
- **heart** disease
- high **blood pressure**
- high cholesterol
- kidney disease or **kidney stones**
- myasthenia gravis
- systemic lupus erythematosus (SLE)
- emotional problems
- skin conditions that cause the skin to be thinner and bruise more easily

Interactions

Corticosteroids have many **drug interactions**. Consult specific references.

Cosmetic dentistry

Definition

Cosmetic, or aesthetic, dentistry focuses on improving appearance and facial self-image by correcting the alignment, shape, and color of teeth. Dental professionals

who offer cosmetic options can improve the appearance of stained, chipped, and misshapen teeth, and correct uneven gums and replace old fillings with nearly invisible filling materials. Cosmetic dentistry procedures are elective and, therefore, often not covered by insurance.

Description

The most popular option in cosmetic dentistry is tooth bleaching, an area that is experiencing a 15 to 20% growth a year. Most dental practices offer tooth bleaching, which involves the use of at-home and in-office supervised whitening systems that brighten stained, discolored, or dull-looking teeth.

Veneers are the second most popular cosmetic dentistry option. Used to correct chipped, cracked or worn teeth, veneers are ultra thin tooth coverings, sometimes made of porcelain or composite materials. Bonding is another process also used to correct chipped, cracked, or worn teeth.

Crowns, dental bridges, and dental implants can be used to replace missing teeth or correct bite dysfunction. Today's newer technology includes porcelain and ceramic tooth replacements that look real and blend with existing teeth.

Cosmetic dentists can correct excessive or uneven gums with cosmetic surgery. Many patients with old or unsightly fillings also can opt to have them replaced by a dentist, who can use resin and porcelain filling materials or crowns to eliminate the look of the previous fillings.

Causes and symptoms

Anyone who is unhappy with his or her smile is a candidate for cosmetic dentistry. The reason might be a general displeasure with the look of one's teeth or a specific aesthetic dental concern. While the reasons for improvement vary, the most common causes are staining due to aging, tobacco use, coffee intake, **fluorosis**, and tetracycline use. Patients also often want to improve the shape and position of their teeth. Diastemas (spaces between teeth), slight rotations, and malformation of the teeth (e.g., peg laterals, barrel shape teeth) are common reasons for correcting the shape and the position of the teeth.

Diagnosis

The diagnosis of an aesthetic problem involves looking at the entire face; the color of the eyes, skin, and lips often influence the appearance of teeth. The face evaluation is usually divided into imaginary thirds: the first section goes from the hairline to eyebrows, the second from eyebrows to the base of the nose, and the third from the

KEY TERMS

Bleaching—Tooth whitening using a chemical such as carbamide peroxide or hydrogen peroxide.

Bridge—A fixed or removable dental appliance used to replace missing teeth and to restore the mouth to function.

Caries—Demineralization or calcified tooth tissue, which, if left untreated, results in soft, discolored areas, pain, and eventual loss of the tooth.

Crown—A gold, porcelain, or stainless steel cover used to replace a tooth structure that has been lost to decay, accident, or injury.

Dental implant—A fixed dental appliance that replaces missing teeth.

Diastema—An abnormally large space between two teeth.

Periodontitis—Inflammation and infection of gingival tissue, ligaments, and alveolar bone that support teeth.

Veneers—Porcelain or composite laminates that are bonded to the surface teeth to improve aesthetics and function.

base of the nose to the lower border of chin. Aesthetic smiles are diagnosed by the dentist, who looks for asymmetry and mobility of the upper and lower lips; midline in relation to the front teeth; gumline; tooth and gum contours; tooth color; tooth to length proportion and relationships; and, finally, restorations. Several factors must be taken into account when assessing these variables, including age, gender, race, and personality.

When examining the tooth shade, specifically, certain factors should be considered, such as the light source and surrounding colors. Bleaching of teeth will change the shade of the tooth structure only, which can pose a problem if the patient has several tooth-colored restorations.

Treatment

Minor corrections in shape and positions can be done with direct resin bonding and ceramic veneers. If the problem is related to position and is considered to be moderate to severe, it is possible to correct it through the placement of veneers, full crowns, or by orthodontic treatment.

Bonding involves applying an enamel-like material to the tooth's surface and sculpting it to an aesthetically

pleasing shape. Once it hardens, the dentist polishes and refines the new tooth. One of the advantages of direct resin bonding over ceramic veneers is that bonding can be done in one session without laboratory involvement, which helps to control cost. The major advantage of direct composite resin restorations is conservation of the tooth structure because, in some cases, little or no enamel removal is required. Longevity, the main advantage of ceramic veneers, is superior to resin bonding.

Discoloration caused by extrinsic staining, such as coffee, tea, red wine, tobacco, aging, and some types of medications, are usually yellow or brown in color and can be improved by vital bleaching, using a 10% carbamide peroxide solution. The concentration may be slightly higher or lower, depending on the stains. Discoloration caused by intrinsic staining, such as after root canal treatment, pulp bleeding, tetracycline medication, fluorosis, and some types of inherited disease, are usually blue, gray, or brown and often requires a non-vital bleaching treatment. Non-vital bleaching treatment is done internally to the tooth structure, meaning the bleaching agent is placed inside the tooth crown.

Prognosis

The term aesthetics takes into consideration the psychological interpretation of beauty. Because of this subjectivity, it is extremely important to establish a common goal and line of communication between the dentist and the patient. Communication is particularly important when the patient's expectations exceed the reality of what is possible to achieve. Studies support significant differences among the preferences of dentists and patients for cosmetic dentistry.

The results of aesthetic dentistry vary according to the different procedures. It should be noted that the results of the bleaching treatment are not predictable, since it varies according to each case. For the most part, it is possible to lighten the tooth shade on the first few days of treatment.

The success of any restoration depends on patient compliance. It is important that the patient be informed about maintenance of his or her treatments, and understand that the results of bleaching are not permanent. Explanations of the etiology of oral diseases, risk factors, and preventive measures are also warranted; these may help to motivate patients keep their new smiles healthy.

Health care team roles

Identification of imperfections in patients' smiles might be done by dental hygienists during care. They may refer patients to the dentist for cosmetic dentistry.

Trained dental hygienists can coordinate patients' bleaching procedures. Dental assistants help explain what is involved in the cosmetic dental solutions and inform the patient that, in most cases, insurance does not reimburse for cosmetic dentistry. Dental assistants also work with dentists during cosmetic dental procedures and can assist patients and dentists in selecting tooth shades.

Prevention

Patients can help to keep their teeth healthy and white with good nutritional and lifestyle habits. Preventive measures to reduce or eliminate dental disease, including caries, **periodontitis**, and **oral cancer**, are essential to obtaining and maintaining an optimal dental health and aesthetic appearance.

Maintenance remains important after cosmetic dentistry. The proper maintenance of tooth color restorations is important to improve and increase the lifetime of the restorations. This includes cessation or decrease in tobacco use, and cessation or decrease in the intake of **caffeine** products and stain-producing foods and beverages. Acidic products can also cause erosion of the tooth structure. The use of soft toothbrushes and non-abrasive toothpaste will avoid unnecessary tooth abrasion. Some types of whitening toothpaste can have large particle size, which can act as an abrasive on the restoration surface.

Creutzfeldt-Jakob disease

Definition

Creutzfeldt-Jakob disease (CJD) is a transmissible, rapidly progressing, fatal neurodegenerative disorder related to "mad cow disease."

Description

Before 1995, Creutzfeldt-Jakob disease was little known outside the medical profession. Indeed, most physicians did not know much about the disease, and few had ever seen a patient with the disease. But with the discovery of a "new variant" form, the possibility that those with the disease became infected simply by eating beef, and the radical theory that the infectious agent is a rogue protein, CJD has become one of the most talked about diseases in the world, and has taken on a significance far beyond the small number of deaths it currently causes each year.

First described in the 1920s, CJD is a neurodegenerative disease causing a rapidly progressing **dementia** which ends in death, usually within eight months of the onset of symptoms. It is also a very rare disease, affecting only about one in every million people in the population worldwide. In the United States, CJD is thought to affect about 250 people each year. CJD affects adults of all ages, but is rare in young adults and most common between ages 50 and 75.

Spongiform encephalopathies

The most obvious pathologic feature of CJD is the formation of numerous, fluid-filled spaces in the **brain** (vacuoles), giving the brain a sponge-like appearance. CJD is one of several human spongiform encephalopathies, diseases that produce this characteristic change in brain tissue. Others include kuru; Gerstmann-Straussler-Scheinker disease, predominantly characterized by cerebellar ataxia; and fatal familial insomnia, associated with progressive insomnia, autonomic system dysfunction, and weakness caused by motor system dysfunction.

Kuru was prevalent among the Fore people in Papua New Guinea. The disease was spread from infected individuals after their deaths through the practice of ritual

cannibalism, in which the relatives of the dead person honored him by consuming his organs, including the brain. Discovery of the infectious nature of kuru won the Nobel Prize for Carleton Gajusek in 1976 and also alerted the medical world to the possibility of slow-acting infectious agents, collectively termed slow-virus diseases. The incubation period for kuru was four to 30 years or more. While kuru has virtually disappeared following the cessation of cannibalistic practices, several new cases continue to arise each year.

Cases of CJD have been grouped into three types: familial, iatrogenic, and sporadic.

- Familial CJD, representing 5–15% of cases, is inherited in an autosomal dominant manner, meaning that either parent may pass along the disease to a child, who may then develop CJD later in life.
- Iatrogenic CJD occurs when a person is infected during a medical procedure, such as organ donation and transplantation, **blood** transfusion, or brain surgery. The rise in organ donation has increased this route of transmission. Grafts of infected corneas and dura mater (the tissue covering the brain) have been linked with the transmission of CJD. Another source is hormones concentrated from the pituitary glands of cadavers, some of whom carried CJD, for use in people with growth hormone deficiencies. Iatrogenic **infection** represents a small fraction of all cases. The incubation period between exposure to the infectious agent is very long and is estimated to be from less than 10 to more than 30 years.
- Sporadic CJD represents at least 85% of all cases. Sporadic cases have no identifiable source of infection. Death usually follows the appearance of the first symptoms within eight months.

Animal forms and “mad cow disease”

Six different forms of spongiform encephalopathy are known to occur in other mammals: scrapie in sheep, recognized for more than 200 years; chronic wasting disease in elk and mule deer in Wyoming and Colorado; transmissible mink encephalopathy; exotic ungulate encephalopathy in some types of zoo animals; feline spongiform encephalopathy in domestic cats; and bovine spongiform encephalopathy (BSE) in cows. All of these are classified as slow-virus diseases.

BSE was first recognized in Britain in 1986. Besides the spongiform changes in the brain, BSE causes dementia-like behavioral changes. This is the origin of the name “mad cow disease.” BSE is thought to be an altered form of scrapie that was transmitted to cows when sheep offal (slaughterhouse waste) was included in their feed.

The use of slaughterhouse offal in animal feed has been common in many countries and has been practiced for at least 50 years. The trigger for the BSE epidemic in Britain seems to have come in the early 1980s, when the use of organic solvents for preparation of offal was halted there. It seems likely that these solvents had destroyed the scrapie agent, thereby preventing infection. The change in preparation procedure opened the way for the agent to “jump species” and cause BSE in cows that consumed scrapie-infected meal. The slaughter of infected (but not yet visibly sick) cows at the end of their useful farm lives, and the use of their carcasses for feed, spread the infection rapidly and widely. For at least the first year after BSE was initially recognized in British herds, infected bovine remains continued to be incorporated into feed, spreading the disease still further. It is thought that most cows with BSE became infected as a result of eating meal containing offal from other cows, not sheep. Although milk from infected cows has never been shown to contain or pass the infectious agent, passage from infected mother to calf has occurred through unknown means.

Beginning in 1988, the British government took steps to stop the spread of BSE, banned the use of bovine offal in feed and other products, and ordered the slaughter of infected cows. By then, the slow-acting agent had become epidemic in British herds. In 1992, it was diagnosed in over 25,000 animals (1% of the British herd). By mid-1997, the cumulative number of BSE cases in the United Kingdom had risen to more than 170,000. The feeding ban apparently did slow the spread of the epidemic. The number of new cases each week fell from a peak of 1,000 in 1993 to fewer than 300 two years later.

The export of British feed and beef to member countries was banned by the European Union, but cases of BSE had developed in Europe by then. About 1,000 cases were identified in Europe by 1997. In 1989, the United States banned the import of British beef and began monitoring U.S. herds in 1990. As of 2001, the U.S. Department of Agriculture reports that BSE has not been detected in the United States. One case has been reported in Canada in a cow imported from Britain.

New-variant CJD: the jump to humans

From the beginning of the BSE epidemic, scientists and others in Britain feared that BSE might jump species again to infect humans who had consumed infected beef. In 1995, this fear seemed to be realized with the first cases of a new variant of Creutzfeldt-Jacob disease, termed nvCJD. Its victims, 81 as of the beginning of 2001, tend to be much younger than the 60–65 average for CJD, and the time from symptom onset to death has

averaged 12 months instead of eight. EEG abnormalities characteristic of CJD are not typically seen in nvCJD.

Evidence is growing stronger that nvCJD is in fact caused by BSE.

- The majority of cases have occurred in Britain, the location of the original BSE epidemic
- BSE injected into monkeys produces a disease very similar to nvCJD
- BSE and nvCJD produce the same brain lesions after the same incubation period when injected into laboratory mice
- Brain **proteins** isolated from nvCJD victims, but not from the other forms of CJD, share similar molecular characteristics with brain proteins of animals that died from BSE.

While definitive proof is still lacking as of 2001, many researchers feel that the connection between BSE and nvCJD has been strongly established.

Assuming that BSE is the source, the question that has loomed from the beginning is the number of people that will eventually be affected. Epidemiological models of infectious disease produce estimates ranging from less than 100 to tens of thousands, depending on the assumptions used by those creating the mathematical models. The incubation period of nvCJD in humans is not known, nor are the genetic and environmental risk factors that influence susceptibility. The quantity of infectious agent needed to cause the disease is not known with precision. It is estimated that humans have eaten between one and two million infected cattle, most in the earliest stages of the epidemic. Estimates cannot be based on the very few cases that have developed to date. These cases could represent the very few people with the right combination of exposure and susceptibility to a relatively fast-developing infection, or they could be the first few victims of a slower-acting, more highly infectious agent. Only time will tell.

Causes and symptoms

Causes

It is clear that Creutzfeldt-Jakob disease is caused by an infectious agent, but it is not yet clear what type of agent that is. Originally assumed to be a virus, evidence is accumulating that, instead, CJD is caused by a protein called a “prion,” (proteinaceous infectious particle) that is transmitted between persons who have CJD. The other spongiform encephalopathies are also hypothesized to be due to prion infection.

If this hypothesis is proved true, it would represent one of the most radical new ideas in biology since the discovery of DNA. All infectious diseases, in fact, all

life, use nucleic acids—DNA or RNA—to code the instructions needed for reproduction. Inactivation of nucleic acids destroys the capacity to reproduce. However, when these same measures are applied to infected tissue from spongiform encephalopathy victims, infectivity is not destroyed. Furthermore, purification of infected tissue to concentrate the infectious fraction yields protein, not nucleic acid. While it remains possible that some highly stable nucleic acid remains hidden within the purified protein, this appears less and less likely as further experiments are done. The “prion hypothesis,” as it is called, is now widely accepted, at least provisionally, by most researchers in the field. The most vocal proponent of the hypothesis, Stanley Prusiner, was awarded the Nobel Prize in 1997 for his work on prion diseases.

A prion is an altered form of a normal brain protein. The normal protein has a helical shape along part of its length. In the prion form, a sheet structure replaces the helix. According to the hypothesis, when the normal form interacts with the prion form, its helical part is converted to a sheet, thus creating a new prion capable of transforming other normal forms. In this way, the disease process resembles crystallization more than typical viral infection, in which the virus commands the host’s cellular machinery to reproduce more of the virus. Build up of the sheet form causes accumulation of abnormal protein clumps and degeneration of brain cells, causing dementia and ultimately death.

The brain protein affected by the prion, called PrP, is part of the membrane of brain cells, but its exact function is unknown. It is composed of about 250 subunits, called amino acids, coded for by a gene on chromosome 20. Slight genetic differences, called polymorphisms, give rise to two slightly different normal protein forms: subunit 129 is a “methionine” in one form, but is “valine” in the other. A person may have all of one, all of the other, or a mixture of the two, depending on the individual’s genetic inheritance. Both forms have the normal helical structure, and function normally. However, susceptibility to prion conversion is influenced by subunit 129: a person with a mixture of forms is more resistant to conversion, and a person with all valine appears to be somewhat more susceptible than one with all methionine. Exposure to the infectious agent is, of course, still required for disease development. Prion diseases are not contagious in the usual sense, and transmission from an infected person to another person requires direct inoculation of infectious material.

Familial CJD, on the other hand, does not require exposure but develops through the inheritance of other, more disruptive mutations in the gene for the normal PrP protein. Researchers believe these mutations increase the likelihood that the protein will spontaneously “flip” to the sheet form; once created, these abnormal proteins can

then convert other normal-form molecules. The other two inherited human prion diseases, Gerstmann-Straussler-Scheinker disease and fatal familial insomnia, involve different mutations in the same gene.

The large majority of CJD cases are sporadic, meaning they have no known route of infection or genetic link. Causes of sporadic CJD are likely to be diverse and may include spontaneous genetic mutation, spontaneous protein changes, or unrecognized exposure to infectious agents. It is highly likely that future research will identify more risk factors associated with sporadic CJD.

Symptoms

About one in four people with CJD begin their illness with weakness, changes in sleep patterns, weight loss, or loss of appetite or sexual drive. A person with CJD may first complain of visual disturbances, including double **vision**, blurry vision, or partial loss of vision. Some visual symptoms are secondary to cortical blindness related to death of nerve cells in the occipital lobe of the brain responsible for vision. This form of visual loss is unusual in that patients may be unaware that they are unable to see. These symptoms may appear weeks or months before the onset of dementia.

The most characteristic symptom of CJD is rapidly progressing dementia, or loss of mental function. Dementia is marked by:

- **memory** losses
- impaired abstraction and planning
- language and comprehension disturbances
- poor judgment
- disorientation
- decreased attention and increased restlessness
- personality changes and psychosis
- hallucinations

Muscle spasms and jerking movements, called myoclonus, are also a prominent symptom of CJD. Balance and coordination disturbance (ataxia) is common in CJD and is more pronounced in nvCJD. Stiffness, difficulty moving, and other features characteristic of **Parkinson's disease** may develop and can progress to akinetic mutism, or a state of being unable to speak or move.

Diagnosis

CJD is diagnosed by a clinical neurological exam and **electroencephalography** (EEG), which shows characteristic spikes called triphasic sharp waves. **Magnetic resonance imaging** (MRI) or computed tomography scans (CT) should be performed to exclude

other forms of dementia. CJD typically shows atrophy or loss of brain tissue. Lumbar puncture, or spinal tap, may be done to rule out other causes of dementia and to identify elevated levels of marker proteins known as 14-3-3. Cell count, chemical analysis, and other routine tests are normal in CJD. Another marker, neuron-specific enolase, may also be increased in CJD. A conclusive diagnosis of CJD can only be accomplished after death using material obtained from a brain **autopsy**.

Treatment

There is no cure for CJD. There is no treatment that slows the progression of the disease. Drug therapy and nursing care are intended to minimize psychiatric symptoms and increase comfort for affected persons. However, the rapid progression of CJD frustrates most attempts at treatment, since ever-worsening cognitive deficits and more prominent behavioral symptoms develop so quickly. Despite the generally grim prognosis, a few individuals with CJD progress more slowly and live longer than the average. For these persons, treatment will be more satisfactory.

Prognosis

Creutzfeldt-Jakob disease is invariably fatal, with death following symptom onset by an average of eight months. About 5% of patients live longer than two years. Death from nvCJD has averaged approximately 12 months after onset.

Health care team roles

Physicians are usually involved in initial identification of CJD. Nurses may provide supportive care. Radiologists obtain CT and MRI scans. Surgeons or physicians obtain spinal fluid. Pathologists and laboratory technicians process samples of bodily fluids and tissues.

Prevention

There is no known way to prevent sporadic CJD, by far the most common type. Not everyone who inherits the gene mutation for familial CJD will develop the disease, but at present, there is no known way to predict who will and who won't succumb. The incidence of iatrogenic CJD has fallen with recognition of its sources, the development of better screening techniques for infected tissue, and the use of **sterilization techniques** for **surgical instruments**, which inactivate prion proteins.

Strategies for preventing nvCJD are a controversial matter, as they involve a significant sector of the agricultural industry and a central dietary element in many

countries. The infectious potential of contaminated meat is unknown, because the ability to detect prions within meat is limited. Surveillance of North American herds strongly suggests that no cases of BSE have been confirmed as of 2001. Strict regulations on imports of European livestock make future outbreaks highly unlikely. Therefore, avoidance of all meat originating in North America simply on grounds of BSE risk is a personal choice unsupported by current data. The ban on the export of British beef continues in countries of the European Union, although some herds in these countries have developed low levels of infection as well.

Crohn's disease

Definition

Crohn's disease is a type of inflammatory bowel disease (IBD) caused by inflammation along any portion of the alimentary canal (the mouth to the anus).

Description

Although Crohn's disease may involve any part of the alimentary canal, it most commonly affects the **small intestine**. There is evidence that the inflammation is an autoimmune response—when products of the **immune system** attack the body itself instead of attacking a foreign substance such as a virus or **bacteria**.

The part of the small intestine most commonly affected is the last part of the ileum, also known as the terminal ileum. The colon (**large intestine**) is less commonly involved. Inflammation may also occur in other areas of the alimentary canal, less frequently affecting the mouth, esophagus, or **stomach**.

Crohn's disease differs from ulcerative colitis, the other major type of IBD, in the following ways:

- The inflammation of Crohn's disease may be discontinuous, meaning that areas of involvement in the intestine may be separated by normal, unaffected segments of intestine. The affected areas are called "regional enteritis," while the normal areas are called "skip areas."
- The inflammation of Crohn's disease is transmural; this means it affects all the layers of the intestinal wall, while ulcerative colitis affects only the lining of the intestine.
- Ulcerative colitis does not usually involve the small intestine; in rare cases it involves the terminal ileum (so-called "backwash" ileitis).

In addition to inflammation, Crohn's disease causes ulceration. These ulcers occur because the inflammation has caused areas of tissue destruction.

Crohn's disease may be diagnosed at any age, although most diagnoses are made between the ages 15-35. About 0.02-0.04% of the population suffers from this disorder. It affects equal numbers of males and females. Whites are more frequently affected than other racial groups, and people of Jewish origin are between three and six times more likely to suffer from IBD. IBD runs in families; an IBD patient has a 20% chance of having other relatives who are fellow sufferers.

Crohn's disease is a chronic disorder. Though symptoms can be effectively controlled, patients are not completely cured of the underlying disease.

Causes and symptoms

The cause of Crohn's disease is unknown. No infectious agent has been positively identified as the cause of Crohn's disease. Some researchers have theorized that a certain bacterium may have originally been responsible for triggering the immune system, resulting in the abnormal activation of the immune system in the intestines that occurs in Crohn's disease.

Symptoms of Crohn's disease depend on which section of the alimentary canal is affected. Symptoms may include **diarrhea**, **fever**, abdominal **pain**, loss of appetite, weight loss, and fatigue. Some patients experience severe pain that mimics **appendicitis**. Unlike patients with ulcerative colitis, it is rare for patients with Crohn's disease to notice **blood** in their bowel movements. Because Crohn's disease severely limits the ability of the affected intestine to absorb the nutrients from food, a patient may have signs of malnutrition, depending on the amount of intestine affected and the duration of the disease.

The combination of severe inflammation, ulceration, and scarring that occurs in Crohn's disease can result in serious complications, including intestinal obstruction, intra-abdominal **abscess** formation, and fistula formation.

An obstruction is a mechanical blockage in the intestine. This obstruction, called a stricture, prevents the intestinal contents from passing beyond the point of the blockage. The intestinal contents "back up," resulting in constipation, vomiting, and intense pain. Although rare in Crohn's disease (because of the increased thickness of the intestinal wall due to swelling and scarring), severe bowel obstruction can result in an intestinal wall perforation (a hole in the intestine). A hole in the intestinal wall would allow the intestinal contents, containing bacteria, to enter the abdominal cavity, causing a severe, life-threatening **infection** known as peritonitis.

Abscess formation is the development of a walled-off pocket of pus. A patient with an abscess in the abdomen will have fever, abdominal pain, and may have a lump or mass that can be palpated (felt) through the wall of the abdomen.

Fistula formation is the formation of abnormal channels. These channels may connect one loop of the intestine to a neighboring section of intestine. Fistulas may connect an area of the intestine to the vagina or urinary bladder, or may drain an area of the intestine through the skin. Abscesses and fistulas commonly affect the area

around the anus and rectum. These abnormal connections allow the bacteria normally present in the intestine to enter other areas of the body, causing potentially serious infections.

Patients suffering from Crohn's disease are at increased risk of other disorders. Some of these may relate specifically to the intestinal disease, and others appear to have some relationship to the compromised immune system. The faulty absorption of the bowel can result in gallstones and **kidney stones**. Inflamed areas in the abdomen may compress and block the ureter (the tube that drains urine from the kidney to the bladder) causing failure of the kidney on the affected side. Patients with Crohn's disease also frequently suffer from extraintestinal manifestations such as:

- arthritis (inflammation of the joints)
- spondylitis (inflammation of the vertebrae, the bones of the spine)
- ulcers of the mouth and skin
- erythema nodosum (painful, red bumps on the skin)
- inflammation of several eye areas
- inflammation of the **liver**, gallbladder, and/or the ducts that carry bile between and within the liver, **gallbladder**, and intestine

The risk of developing **cancer** of the intestine is greater than average among patients with Crohn's disease, although the cancer risk is not as high as it is for patients with ulcerative colitis.

Diagnosis

Diagnosis is first suspected based on a patient's symptoms. Blood tests may reveal an increase in white blood cells, an indication that some type of inflammation is occurring in the body. The blood tests may also reveal anemia and other signs of malnutrition due to malabsorption, such as low blood protein; low **calcium**, potassium, and magnesium present in the blood; and indications of liver inflammation. Stool samples may be examined to rule out various infectious agents, and to see if the stool contains blood.

During a colonoscopic exam, a physician passes a flexible tube with a tiny, fiber-optic camera (called an **endoscope**) through the rectum and into the colon. The physician carefully examines the lining of the intestine for signs of inflammation and ulceration that might suggest Crohn's disease. A biopsy of the intestine can also be taken through the colonoscope, and the tissue will be examined under a **microscope** for evidence of Crohn's disease.

X rays can be helpful for diagnosis, and to determine how much of the intestine is involved in the disease. For these x rays, the patient must either drink a chalky solution containing barium, or receive a **barium enema**. Barium helps to "light up" the intestine, allowing more detail to be seen on the resulting x rays.

Crohn's disease and ulcerative colitis are similar, but they are distinct conditions. Although it may be difficult to determine whether a patient has Crohn's disease or ulcerative colitis, it is important to make every effort to distinguish between these two diseases because the long-term complications of the diseases are different, as is the treatment.

Treatment

Treatment for Crohn's disease aims to reduce the underlying inflammation, the resulting malabsorption/malnutrition, and relieve symptoms of abdominal pain and diarrhea. Treatment is also intended to prevent potential complications such as obstructions, abscesses, and fistulas.

Inflammation can be treated with a drug called sulfasalazine. Sulfasalazine is in part related to the sulfa **antibiotics**; its other component is a form of the anti-inflammatory chemical, salicylic acid (related to aspirin). Sulfasalazine is not well absorbed from the intestine, so it remains largely within the intestine, where it is broken down into its components. It is believed that the salicylic acid component actively treats Crohn's disease by fighting inflammation. Some patients do not respond to sulfasalazine and require **corticosteroids** such as prednisone. Corticosteroids, however, must be used carefully to avoid the various complications of these drugs, including an increased risk of infection and **osteoporosis** (weakening of the bones).

Patients with intra-abdominal abscesses or those with disease in the large bowel or ileum may be given antibiotics such as metronidazole or ciprofloxacin. Potent immunosuppressive drugs, such as 6-mercaptopurine, azathioprine, cyclosporine, and infliximab, which block the immune system and thereby reduce inflammation, may be prescribed for patients who do not respond to corticosteroids.

Serious cases of malabsorption/malnutrition may require treatment with nutritional supplements. These supplements must be in a form that can be absorbed from the damaged, inflamed intestine. Some patients find that certain foods are hard to digest, including milk, large quantities of fiber, and spicy foods. When patients are suffering from an obstruction, or during periods of time when symptoms of the disease are at their worst, they

KEY TERMS

Abscess—A walled-off pocket of pus caused by infection.

Endoscope—An instrument that can be passed into an area of the body (the bladder or intestine, for example) to allow examination of that area. The endoscope usually has a fiber-optic camera, which allows a greatly magnified image to be shown on a television screen viewed by the operator. Many endoscopes also allow the operator to retrieve a biopsy of the area examined.

Fistula—An abnormal channel that creates an open passageway between two structures that do not normally connect.

Gastrointestinal tract—The entire length of the digestive system, running from the mouth to the stomach, through the small intestine, large intestine, rectum, and anus.

Immune system—The body system responsible for combating infection by viruses, bacteria, fungi, and other foreign invaders. In autoimmune disease, these cells and chemicals turn against the body itself.

Inflammation—The result of the body's attempts to fight off and wall off an area that is infected. Inflammation results in the classic signs of redness, heat, swelling, and loss of function.

Obstruction—A blockage.

Ulceration—A pitted area or break in the continuity of a surface such as skin or mucous membrane.

may need to drink specially formulated, high-calorie liquid supplements. Those patients who are severely ill may need total **parenteral nutrition** (TPN). TPN patients receive their **nutrition** intravenously, or through a catheter inserted directly into a major vein in the chest.

A number of medications are available to help decrease the cramping and pain associated with Crohn's disease. These include loperamide, tincture of opium, and codeine. Fiber preparations (methylcellulose or psyllium) are helpful for some patients; others do not tolerate them well.

The first step in treating an obstruction involves general efforts to decrease inflammation with sulfasalazine, steroids, or immunosuppressive drugs. A patient with a severe obstruction is given no food or

drink by mouth, allowing the bowel to “rest.” Abscesses and other infections require antibiotics. Surgery may be required to repair an obstruction that does not resolve on its own, to drain an abscess, or to repair a fistula. Such surgery may involve the resection (removal) of the diseased length of the intestine.

In extremely severe cases of Crohn's disease that do not respond to treatment, patients may require a **colostomy**. In this procedure, a piece of the remaining small intestine is pulled through an opening in the abdomen. This segment of intestine is fashioned surgically to allow a special bag to be placed over it. This bag collects the stool, which can no longer pass through the large intestine and out of the anus.

Prognosis

Crohn's disease is a chronic, lifelong illness. The severity of the disease may vary, and patients may experience periods of time when the disease is not active and they are symptom free. Still, the complications and risks of Crohn's disease tend to increase over time. More than 60% of all patients with Crohn's disease will require surgery, and about half of these will require more than one operation over time. Approximately 5-10% of all Crohn's patients die of their disease, primarily due to massive infection.

Health care team roles

Crohn's disease is often diagnosed by primary care practitioners or gastroenterologists. In many instances, patients require surgical intervention. Imaging studies to assist in diagnosis are performed by x-ray technologists, and laboratory technologists may be involved in obtaining blood and stool samples for analysis.

Nurses, dieticians, and nutritional counselors have important roles in teaching patients about dietary changes to manage symptoms. Nurses, social workers, and ostomy specialists may also be involved in educating patients pre- and postoperatively about ostomy care.

Prevention

Presently, there is no way to prevent the development of Crohn's disease.

Cross infection

Definition

Cross **infection** is the physical movement or transfer of harmful **bacteria** from one person, object, or place to another, or from one part of the body to another (such as touching a staph-infected hand to the eye). When this cross infection occurs in a hospital or long-term care facility it is called a nosocomial infection. Community-acquired infections are those contracted anywhere *except* a hospital or long-term care facility.

Description

Cross infection accounts for half of all major complications of hospitalization; the rest are medication errors, patient **falls**, and other noninfectious events. In American hospitals, cross infection affects between 5–10% of patients at a cost in excess of \$4.5 billion. Further, with the advent of HMOs and incentives for outpatient care, hospitals now have a concentrated population of seriously ill patients, and an even greater risk of cross infection.

On one hand, trends toward same-day surgery, shorter hospital stays, and less-invasive surgical techniques will limit patients' exposure to hospital pathogens and invasive devices. On the other, long-term inpatients are likely to be older and sicker, requiring the use of invasive devices in treatment or management of their illness. This places them at increased risk of cross infection, a risk that is higher for public and larger hospitals and teaching institutions.

Statistics show that about 35 million patients are admitted to 7,000 acute-care institutions in the United States each year. This means that 1.75 million to 3.5 million patients are infected yearly in the United States. If 10% of all cross infections involve the bloodstream, then

175,000 to 350,000 patients acquire these life-threatening septicemic infections each year.

Causes and symptoms

Cross infections are caused by bacteria, **viruses**, **fungi**, or parasites that may already be present in the patient's body, or they may come from the environment, contaminated hospital equipment, health care workers, visitors, or other patients. A localized infection is limited to a specific part of the body and has local symptoms. An infected surgical site, for example, would exhibit an area that is red, hot, and painful. A generalized infection that enters the bloodstream causes general systemic symptoms such as **fever**, chills, low **blood pressure**, **boils** all over the body, or mental confusion.

Cross infections can occur from surgical procedures, catheters placed in the urinary tract, intravenous fluid sites, or when moisture droplets from the nose or mouth are inhaled into the **lungs**. The most common cause of cross infection is the failure of health care workers to wash their hands after taking off latex gloves or before donning a new pair. The most frequent types of cross infections occurring in facilities are urinary tract infections (UTIs), **pneumonia**, surgical site infections (SSIs), and **blood** stream infections (BSIs).

While all patients within a health care facility are vulnerable to cross infection, some patients are at greater risk than others because certain risk factors alter their susceptibility to infection. Intrinsic risk factors are those present in the patient and include age (the very young or the elderly), presence of chronic disease, or a compromised **immune system**. Extrinsic risk factors are types of interventions performed within the health care facility and the mix of patients present.

Fever is often the first sign of infection; other symptoms include rapid breathing, mental confusion, low blood pressure, reduced urine output, painful joints and muscles, and a high white blood cell count. If there is a skin break it may be red and swollen. Patients with a UTI may have **pain** when urinating along with cloudy or bloody urine. Symptoms of pneumonia include difficulty breathing, chronic deep coughing, and reluctance to lie flat because it makes breathing difficult. A localized infection causes swelling, redness, and tenderness at the site of infection.

Common cross infections

URINARY TRACT INFECTIONS. Urinary tract infections (UTIs), the most common type of cross infections, usually occur after catheterization, the placement of a catheter through the urethra into the bladder. This proce-

sure is done to empty urine from the bladder, relieve pressure in the bladder, measure urine in the bladder, put medicine into the bladder, or for other medical reasons. While there can be bacteria in or around the urethra, a healthy urinary bladder is sterile: it does not normally have any bacteria or other microorganisms in it. When a catheter is inserted, bacteria can be picked up from the urethra and carried into the bladder unless both the area and equipment are properly prepared; once in the bladder, bacteria can multiply. Infections can also arise if health care personnel fail to follow proper sterile technique when emptying the collection bag. Bacteria from the intestinal tract are the most common cause of UTIs, although fungi called *Candida albicans* are often implicated. Although UTIs are common, they are generally the least severe and least costly type of cross infection.

PNEUMONIA. Nosocomial pneumonia is the second most common type of cross infection; it is defined as an infection of the lungs that develops 48 or more hours after admittance. (Any infection that occurs within the first two days after admission is presumed to have come in with the patient.) Patients requiring invasive **respiratory therapy** may have infection rates seven to 21 times higher than those who don't need artificial ventilation. These infections occur because bacteria and other microorganisms are easily introduced into the throat by procedures such as respiratory intubation, suctioning of material from the throat and mouth, tracheostomy, and mechanical ventilation. The microorganisms can come from contaminated equipment, the hands of health care workers, or, depending on the physical health of the patient, from the patient's own bacteria. The introduced microorganisms quickly colonize the throat area, but do not yet cause an infection. Once the throat is colonized, it is easy for a patient to inhale the microorganisms into the lungs; most nosocomial pneumonia develops within two days of the infecting procedure. This is especially true for patients who cannot cough or gag very well. The occurrence of pneumonia can prolong a hospital stay by at least three or four days at considerable cost.

SURGICAL SITE INFECTIONS. Since surgery is a direct invasion of the patient's body, the natural barrier of the skin is broken, giving bacteria entrance into the normally sterile interior of the body. Surgical site infections (SSIs) can be acquired from contaminated surgical equipment, health care workers who use improper technique to change bandages postoperatively, intubations, and a depressed immune system that permits the body's natural bacteria to colonize. Other **wounds** from trauma, **burns**, and ulcers can also become infected for similar reasons.

BLOOD STREAM INFECTIONS. Many patients in health care facilities need an intravenous (IV) catheter

placed in a vein for the infusion of fluids for hydration, medications, and/or nutrients. This can cause blood stream infections (BSIs) by transmission from the surroundings, contaminated equipment, or health care workers' hands via the site of catheter insertion. A local infection can develop in the skin around the catheter, or more seriously, bacteria can enter the bloodstream through the vein and cause a generalized infection. The longer a catheter is in place, the greater the risk of infection. BSIs are the most severe of the cross infections, resulting in the most deaths, greatest prolongation of stay, and highest cost. Other procedures that put patients at risk for cross infections are gastrointestinal procedures, obstetric procedures, and kidney or **peritoneal dialysis**.

Diagnosis

An infection is suspected any time a hospitalized or home health care patient develops a fever that cannot be explained by a known illness. Some patients, however, especially the elderly, may not develop a fever. In these patients, the first signs of infection may be rapid breathing, pale clammy skin, or mental confusion.

Diagnosis of a cross infection is based on:

- signs and symptoms of the infection
- examination of wounds and catheter entry sites
- review of procedures that might have led to infection
- laboratory test results, including blood studies, **urinalysis**, and culture of any suspicious wound sites

A complete **physical examination** is conducted by the physician, nurse practitioner, or **registered nurse** caring for the individual in order to determine if an infection is present. Wounds and catheter insertion sites are examined for redness, swelling, the presence of pus, an **abscess**, or any area of exaggerated tenderness that might indicate an abscess. The registered nurse reports findings to the physician or nurse practitioner who reviews the patient's record of procedures performed to determine if any posed a risk for infection.

Medical technicians perform laboratory tests ordered by the physician or nurse practitioner to look for signs of infection. A **complete blood count** reveals the white blood cell count, a measure of macrophages whose increasing numbers indicate infection. White blood cells, blood, or "casts" (mineral crystals) may be present in the urine with a UTI as well. Cultures of blood, urine, sputum, other body fluids, or tissue are examined for infectious microorganisms, which must be identified to provide proper treatment. These cultures are obtained by taking a swab of an area or a sample of fluid, blood, or tissue and placing it in a special sterile medium that promotes bacte-

rial growth. Other tests can be done on blood and body fluids to find and identify bacteria, fungi, viruses, or other microorganisms responsible for the infection. If a patient has symptoms suggestive of pneumonia, a **chest x ray** is done to look for infiltrates—white blood cells and other inflammatory substances in the lung tissue.

Treatment

Upon identification of the infection, the patient is treated with **antibiotics** or other medications that destroy the responsible organism. Although many different antibiotics are available, bacteria strains resistant to specific antibiotics have become increasingly prevalent. In one 1998 U.S. report, only 56% of pneumococcal strains of bacteria were still sensitive to penicillin while 16% were highly resistant. At the present time, resistance is highest to penicillin, but resistance to other antibiotics such as cephalosporins, tetracyclines, and erythromycin is also rapidly increasing. Fortunately, most pneumococci are still sensitive to vancomycin, but an increasing number of vancomycin-resistant bacteria have been reported. Newer groups, called fluoroquinolones, are being used to treat resistant bacteria, as are imipenem/cilastatin (Primaxin), a carbapenem combination, and sanfetrinem, a tricyclic beta-lactam antibiotic. These are powerful new antibiotics that can combat a wide spectrum of bacteria that have become resistant to standard drugs. Unfortunately, some newer studies show that patients with infections resistant to cephalosporins may also have a cross-resistance to the fluoroquinolones. Repeated exposure even to these antibiotics, however, will eventually result in bacterial resistance. It is essential, therefore, that patients who require antibiotics be rigorous about completing their regimen and that those caring for them adhere to **aseptic technique** rigidly.

At highest risk for antibiotic-resistant pneumococci are children under two who live in areas of high antibiotic use and who have used antibiotics in the previous year. Efforts to reduce the number of resistant bacteria include teaching both the public and health care workers that a conservative approach is best when it comes to antibiotics use: not every infection needs medication. A program in Finland, for example, has nearly halved the incidence of erythromycin-resistant bacteria by limiting the use of penicillin and similar antibiotics to only serious infections. Many infections, in fact, are viral, and do not respond to antibiotic therapy.

Fungal infections are treated with antifungal medications, such as amphotericin B, nystatin, ketoconazole, itraconazole, and fluconazole, but many of these drugs have negative interactions with other medications that the patient may be using. A number of **antiviral drugs**

have been developed that slow the growth or reproduction of viruses, and these include acyclovir, ganciclovir, foscarnet, and amantadine.

Prognosis

Cross infections are serious illnesses that can cause death in about 1% of all cases. Blood stream infections in intensive care unit (ICU) patients have a mortality rate of almost 35%. Rapid diagnosis and identification of the responsible microorganism are necessary so that specific antimicrobial therapy can be started as quickly as possible.

Health care team roles

In all cases, medication for cross infection is administered by a registered nurse in a health care facility, by an intravenous infusion nurse who does home health care, or by a **licensed practical nurse** in a nursing home. These nurses must be extremely careful that the medication is given exactly as ordered and that they use sterile technique to prevent any additional cross infection. The nurse must also remain alert to additional complications or symptoms that may be significant and report these to the physician or nurse practitioner. Laboratory personnel must be very careful in utilizing sterile technique when drawing blood, as should respiratory therapists who may provide breathing treatments or suction for patients with pneumonia.

Patient education

If possible, the registered nurse can use the time during treatments to teach the patient how cross infection occurs. This is especially important when the patient is immunocompromised and, therefore, more susceptible to further infection. The nurse could explain the importance of taking medications exactly as ordered and why antibiotics are sometimes not given for illnesses. All health care personnel should explain procedures as they are performed and include the reasons for the particular treatment. The patient's family may be included in the session to further enforce the necessity of the treatment as well as the appropriate way to perform it.

Prevention

Hospitals and other health care facilities have developed extensive infection-control programs to identify all possible sources of infection, including medical procedures, that put patients at risk. The first infection-control committees and policies were developed in the late 1950s and early 1960s when a pandemic of highly virulent antibiotic-resistant *Staphylococcus aureus* swept through American hospitals. In response, the Centers for Disease

KEY TERMS

Abscess—A localized pocket of pus at a site of infection.

Candida albicans—A yeast-like fungal organism.

Catheter—A thin, hollow tube inserted into the body at specific points in order to inject or withdraw fluids.

Culture—The reproduction of microorganisms or of living tissue cells in special media that encourages their growth.

Generalized infection—An infection that has entered the bloodstream and has general systemic symptoms such as fever, chills, and low blood pressure.

Incubating—The development of an infectious disease from time of the entrance of the pathogen to the appearance of clinical symptoms.

Intubation—Placement of a tube inside the body to keep a lumen open, especially the trachea.

Localized infection—An infection that is limited to a specific part of the body.

Nosocomial infection—An infection acquired during or after hospitalization and that was not present or incubating at the time of the patient's admission. It includes any infection acquired in a facility that appears after discharge and any newborn infection that is the result of passage through the birth canal.

Peritoneal dialysis—A procedure for cleaning the blood when a patient's kidneys have failed. A catheter implanted in the patient's abdomen is used to add and remove cleansing fluid that removes waste and impurities from the bloodstream. Unlike hemodialysis, peritoneal dialysis can usually be done at home.

Systemic—Affecting the whole body.

Tracheostomy—The creation of an opening into the trachea (windpipe) through the neck, with insertion of an indwelling tube to facilitate passage of air or evacuation of secretions.

Control and Prevention (CDC; then the Communicable Disease Center) in Atlanta recommended that hospitals determine the sources of infection in hospital patients, so they could develop and apply preventive measures. One result of this was a CDC-sanctioned maximum of 250 beds for each **infection control** nurse. They further

noted that programs were most successful when data were communicated effectively to hospital staff.

Further recommendations that resulted from these initiatives included analyzing procedures with high risk of contamination, such as urinary catheterization. To minimize cross infection, it was recommended that these procedures be performed only when necessary, and that catheters or other medical devices be left in for as little time as possible. Medical instruments and equipment should be properly sterilized, with appropriate documentation and check devices, to ensure they were not contaminated. Frequent hand washing by health care workers and visitors is absolutely essential to prevent transferring infectious microorganisms to patients, and was cited as the procedure most important for prevention. Patients should be encouraged to ask their health care provider if they washed their hands before allowing them to proceed with an examination. Antibiotics should only be used when necessary because their use not only creates favorable conditions for infection with the fungal organism *Candida albicans* but their overuse has helped develop antibiotic-resistant bacteria.

Crutches and crutch walking

Definition

Crutches are orthopedic devices created to assist in weight bearing when a patient has a leg injury or weakness in the lower extremities.

Purpose

Wooden or aluminum axillary (under the arm) crutches are used to assist in weight bearing when a patient has sustained an injury to the leg, knee, ankle, or foot, such as a fracture or severe sprain. Crutches are also used following surgery on the leg, knee, ankle, or foot. Forearm crutches are used to provide stability and moderate support when a patient has generalized weakness in the lower extremities, such as for a patient with **cerebral palsy**.

Description

Axillary crutches can be either wooden or aluminum. Each crutch is comprised of two pieces of wood or aluminum that are connected at the top and middle by a crossbar and join to a third piece that extends to the floor. The top cross bar is slightly concave in shape and fits just 1-2 inches (2.54–5 cm) below the axilla. It is covered with a soft rubber pad and is used to brace the crutches against the body. The middle cross bar is round and covered with a rubber grip. It is adjusted to hand level for gripping the crutches with the hands. The third piece connects the two upper pieces, extends to the floor, and is covered by a rubber tip on the end that meets the floor. Crutches are used in pairs to provide balance and support. Aluminum crutches are lighter and easier to use. Wooden crutches are generally less expensive than aluminum crutches.

Forearm crutches are comprised of two pieces of aluminum tubing that are telescoped one within the other to adjust to the correct height of the client. They are fitted with attached, swivel-action arm cuffs that fit partially around the forearm, and with handgrips that are covered with a rubber grip. There is a rubber tip at the end of each crutch where it meets the floor.

Operation

Wooden or aluminum axillary crutches come in several sizes. The appropriate size crutches should be selected based on the patient's height. With the patient standing straight upright, one crutch is held against the patient's side. The nut bolt which attaches to the bottom piece is loosened and removed. The crutch is then adjust-

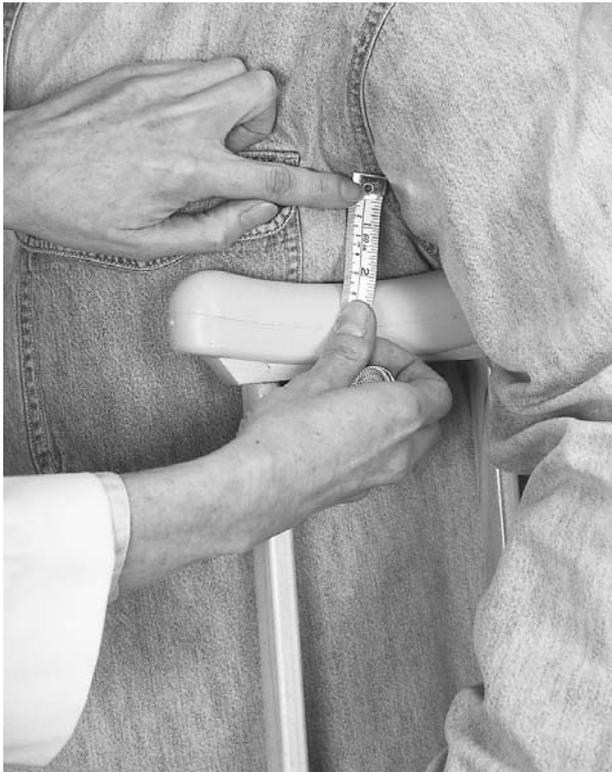

ed until it is 1-2 inches (2.54–5 cm) below the patient's axilla. The bolt is placed in the appropriate hole, and the nut wing is tightened securely to hold it in place. The patient then holds his hand down with the elbow slightly bent. The bolt and nut wing for the handgrip are loosened and moved to the correct position for the patient. The hand should be resting at the hip line with the elbow slightly bent. The bolt is placed in the appropriate hole, and the nut wing is tightened securely. The rubber tip, rubber axillary padding, and rubber handgrip are checked to ensure placement and security. The client sits back down, and the other crutch is adjusted at the base and the hand grip to exactly match the measured crutch.

Aluminum forearm crutches come in several sizes. The appropriate size crutches should be selected based upon the patient's height. With the patient standing, one crutch is adjusted by pushing in the locking mechanism and moving the height up until the forearm portion of the crutches can slip comfortably onto the patient's arm. The crutches are locked by moving the mechanism until the lock clicks securely. The arm cuff is adjusted if necessary. The crutch is checked for stability by pushing down on it. The vinyl padding on the arm cuff, the rubber handgrip, and the rubber tip at the end of the crutch are examined to be sure they are in place and secure. The client then sits back down, and the other crutch is adjusted to exactly match the measured crutch.

The patient should not attempt to use the crutches until they are fitted and all of the nut wings or locking mechanisms are secure. The hands and arms bear the patient's weight, not the axilla. The patient is instructed not to lean on the axillary pads because this can pinch the axillary nerve and cause numbness of the hands and arms. The patient is instructed on crutch safety, how to walk with crutches, how to go up and down stairs with crutches, how to sit, and how to stand up using the crutches. The patient demonstrates competency with the crutches before discharge. The patient is given written instructions about crutch walking and safety to review later after discharge.

Maintenance

The screw bolts and nut wings that hold the base of the crutches and the handgrip of the crutches should be checked daily to be sure they are securely tightened. Rubber tips that become worn or tear should be replaced at once to prevent slipping. Rubber handgrips that are torn or worn should be replaced promptly to prevent blisters on the hands or slipping of the hands. Worn or torn rubber padding at the top of axillary crutches should be replaced to prevent pressure injuries. New rubber tips or handgrips can be purchased at most drug stores. Crutches

A patient is measured for crutches. (Delmar Publishers, Inc. Reproduced by permission.)

that are kept in good repair can be reused if well maintained but should be re-measured and adjusted for each client. Forearm crutches should be checked daily before use to be sure that the height adjustment pegs are secure, the swivel-action arm cuffs fit correctly, the rubber tips are intact, and the handgrips are secure.

Health care team roles

It is most often the responsibility of a licensed nurse or physical therapist to fit crutches and teach crutch walking/safety to the patient in the health care setting. Non-professionals such as orthopedic technicians or ER staff can receive special training to fit crutches and teach crutch walking/safety in some medical settings. Patients must always be instructed on the proper use and safety factors involved in crutch walking prior to discharge with crutches.

Training

Instructing a patient about the safe use of crutches should include the following information:

- **Crutch walking:** The crutches are placed under both arms close to the body. The hands are placed firmly upon the handgrips. Both crutches and the injured limb are moved forward about 12 inches (30 cm). With the crutches braced against the body, the strength of the hands and forearms are used to push down on the handgrips as the good leg swings through and about 12 inches (30 cm) ahead of the crutches. The patient's weight is placed on the uninjured leg and the process is repeated. A slow steady rhythm is used when walking. The patient is instructed not to go too fast or swing his leg too far forward because this can cause a loss of balance. The body and head are kept upright. The patient is instructed not to lean forward or put his weight on the axillary pads. The patient is told to look ahead to where he is going and not to look at his feet. The patient practices walking forward, turning, and walking back until he has developed a rhythm and balance with the crutches.
- **Sitting:** The patient is instructed to back up against the chair until he feels the chair on the back of his legs. The patient's weight is placed on the uninjured leg, and the injured leg is advanced slightly forward. Both crutches are placed side by side on the uninjured side, beside the patient's body but not under the arm. The patient holds both handgrips together and reaches back for the armrest of the chair and the crutch handgrips as support, the patient slowly moves his injured leg forward and lowers himself into the chair. The crutches are placed nearby. Standing them on the axillary pads, when possible, makes it less likely that they will tip over and fall away from the patient.
- **Standing:** When in bed, the patient moves first to a sitting position to get his balance. The patient then inches forward to the edge of the bed or the chair. Both crutches are then placed upright and side-by-side on the uninjured side. The patient grips both handgrips firmly in his hand and rises up on his uninjured leg. The crutches are placed on either side of the body and the patient holds the handgrips. Instruct the patient to take a few minutes to get his balance. Be sure that the patient's body is upright, the crutches are positioned correctly, and his head is looking forward before beginning to walk.
- **Climbing up stairs:** Climbing stairs with crutches requires strength and flexibility. If the patient is unsure of his strength, he should be instructed to turn around and sit on the stairs and scoot himself up one stair at a time using his uninjured leg to propel him. The patient should be instructed to keep his crutches in one hand and bring them up with him. When climbing stairs with crutches, the patient leads with his uninjured leg and brings the injured leg and crutches up behind him. If the stairway has a handrail, the patient should place both crutches under the arm opposite the handrail and grip the handgrips together in one hand. The patient places his weight on the handrail and the handgrips, leans

slightly forward, and brings his uninjured leg up one step. He then brings the crutches and the injured leg up the step and advances his hand up the handrail. Once the patient has regained his balance, the process is repeated. The patient should be instructed to take his time and rest halfway up the stairs if necessary. To climb stairs with no handrail, the patient leans slightly forward and puts his weight on the handgrips of the crutches. The patient moves the uninjured leg up the step. He then shifts his weight to the uninjured leg and brings the crutches and injured leg up the step. His foot and crutch tips are kept in the middle of the step, away from the edge to avoid slipping. The patient is instructed to take his time, rest as needed, and ask for help if necessary. Having someone walk behind the patient up the stairs can add a sense of security, and the person can assist the patient into a sitting position if he becomes fatigued.

- **Going down stairs:** Going down stairs with crutches requires strength and flexibility. If the patient is unsure of his strength, he should sit down and scoot down the stairs one at a time, bracing himself with his good leg. The patient should keep his crutches in one hand and bring them down with him. When going down stairs with crutches, the patient should lead with his injured leg and crutches then bring his uninjured leg down behind him. If the stairway has a handrail, the patient should place both crutches under the arm opposite the handrail and grip the handgrips together in one hand. With his weight on his uninjured leg, the patient moves the crutches and the injured leg down one step. Then the patient places his weight on the handrail and the handgrips and brings his uninjured leg down the step. The patient should take time to regain his balance and repeat the process. The patient should be instructed to take his time and rest halfway down the stairs if necessary. To go down stairs with no handrail, the patient puts his weight on his uninjured leg and moves the crutches and injured leg down one step. The patient shifts his weight onto the handgrips of the crutches and brings the uninjured leg down the step. The patient keeps his foot and the crutch tips in the middle of the step, away from the edge to avoid slipping. The patient should be instructed to take his time, rest as needed, and ask for help if necessary. Having someone walk in front of the patient as he walks down the steps can add a sense of security, and the person can assist the patient into a sitting position if he becomes fatigued.
- **Daily maintenance:** The nut wings or locking mechanisms should be checked daily to be sure they are tightened securely. The rubber tip at the bottom of the crutches should also be checked to be sure it is secure. The tip should be replaced if it shows signs of wearing

This woman walks with aluminum crutches after her left calf and foot were removed. (Stock Boston, Inc. Reproduced by permission.)

or tearing. The rubber handgrips or vinyl arm cuffs should also be examined to be sure they are intact. They should be replaced if they show signs of wearing or tearing. The rubber axillary padding should be examined and replaced if it shows signs of wearing or tearing. New rubber tips or handgrips can be purchased at most drug stores.

- **General tips:** Items that may cause the patient to trip and fall, such as scatter rugs or extension cords, should be removed. Spilled liquids should be wiped up to avoid slipping. Items the patient needs with him can be carried in a fanny pack, apron with pockets, or knapsack to keep his hands free to grip the crutches. A non-skid bath mat should be used in the shower or tub. A tennis shoe or other flat, rubber-soled shoe should be worn on the patient's uninjured foot to avoid slipping. The patient should be careful when going through doorways to be sure that the door does not shut on his crutches. The patient should seek help to hold the door

KEY TERMS

Axillary—A term used to refer to the area in or around the axilla or armpit.

if necessary. The patient should avoid walking through water or on icy surfaces with crutches.

CT imaging equipment

Definition

CT imaging equipment includes conventional, spiral, multi-slice, and electron-beam computed tomography full-body scanners, which use x rays to acquire cross-sectional images and computer workstations to

reconstruct acquired image data for display on a viewing monitor or printed on film. Also referred to as computerized axial tomography (CAT) scanning equipment.

Purpose

Computed tomography is an x-ray imaging modality used for a variety of clinical applications. CT imaging equipment is used for spine and head imaging, gastrointestinal imaging, vascular imaging (e.g., signs of stroke, detection of **blood** clots), **cancer** staging and **radiotherapy** treatment planning, screening for cancers and **heart** disease, rapid imaging of trauma and pediatric patients, measuring bone mineral density for diagnosing **osteoporosis**, imaging of musculoskeletal disorders, detection of signs of infectious disease, and guidance of certain interventional procedures (e.g., biopsies). CT is the preferred imaging exam for diagnosing several types of cancers. CT scanners are also used to perform noninvasive angiographic imaging to assess the large **blood vessels**. Three-dimensional (3-D) image reconstruction, a feature available on many CT scanners, allows surgical procedure simulation and planning, postoperative evaluation, 3-D **angiography**, and virtual **colonoscopy**. Because computed tomography can clearly image soft tissue, bones, the **lungs**, and blood vessels, and can be used to diagnose so many diseases and conditions, CT scanners are often considered the backbone of a radiology department, and large hospitals may have multiple scanners to meet imaging demand. Because CT scanners are valuable in aiding in the evaluation of trauma and other emergency medical conditions, hospitals with large emergency volumes and major trauma centers may have a CT scanner located in and dedicated to the emergency department.

Some types of CT scanners (electron-beam and multislice, see below) have begun to be used for whole-body scanning for preventive screening purposes; that is, asymptomatic individuals can have a full-body scan to see if heart disease, cancer, or other conditions are present. This application is primarily offered by independent imaging centers and is not reimbursed by insurance companies.

Description

In general, a computed tomography scanner consists of a gantry, an x-ray system, a patient table, and a computer workstation. The gantry is a large square unit with an opening in the center through which the patient is moved during the scan. The gantry contains the x-ray system, which includes an x-ray tube, detectors, x-ray beam collimators, circuitry, and an x-ray generator. In some older CT scanners, the x-ray generator may be separate from the gantry. The patient table is designed for

both vertical and horizontal motion to accommodate various types of patient positions during the scan.

During a CT scan, the x-ray generator supplies power to the x-ray tube. X rays are produced by the x-ray tube and emitted as it is rotated around the patient. The x rays pass through the patient's body to the detectors, which, depending on the CT scanner type and model, may consist of xenon gas ionization chambers or solid-state crystals (such as cesium-iodide or cadmium-tungstate). During each rotation, the detector produces electrical signals, which are generated after exposure to the x rays. These electrical signals are transferred to the computer, processed, and reconstructed into images using preprogrammed algorithms. Each rotation of the x-ray tube and detectors is reconstructed into an image that is referred to as a slice. The slice represents a cross-section of anatomical detail, and allows the inside of anatomical structures to be visualized, which is not possible with general radiography. Collimators are located near the x-ray tube and at each detector to minimize scatter radiation and to properly define the x-ray beam for the scan. The height of the collimators determines the slice thickness.

There are several types of CT scanners currently in use that differ in configuration and scanning features. Conventional CT scanners, which were introduced in the 1970s, have cables attached to a detector array, and therefore, at the end of one x-ray tube rotation, the assembly must reverse to avoid tangling the cables. Conventional scanners, then, have the slowest scanning speed. Spiral CT scanners, also called helical or volumetric scanners, have a slip-ring configuration that allows continuous one-way rotation. In spiral scanning, the patient table is moved through the gantry while the x-ray tube and detector rotate in a spiral around the patient. Scanning speed is faster, thinner slices are acquired, and shorter patient breathholds are required than for conventional CT. Spiral CT scanners were introduced in 1989, and have since been considered a revolutionary advance in CT imaging due to the improvements in scanning speed and image quality that were possible compared to conventional CT scanners.

Multislice scanners, which were introduced in 1998 and are considered the next revolution in CT imaging, have multiple rows of detectors that allow acquisition of multiple image slices during one x-ray tube rotation. Depending on the model and manufacturer, a multislice scanner may be up to eight times faster than a single-slice spiral scanner, and slices half as thin as those acquired on a spiral scanner are attainable. Multislice technology was still under development as of 2001.

Electron-beam CT scanners, also called ultrafast CT scanners, use a different scanning technology than other CT scanners, where x-ray tube rotation is mechanical. Electron-beam CT scanners have no moving parts, which makes such a fast scanning speed possible. An electron gun produces a focused electron beam that generates a rotating x-ray fan beam after being steered along tungsten target rings. Scan times are approximately ten times faster than multislice scanners because only the electron beam moves during scanning. Electron beam CT scanners were introduced in the mid-1980s and were designed for cardiac imaging and imaging of other moving structures (e.g., lungs, colon) due to their fast scanning speed.

CT imaging equipment is often supplied with image archiving devices (e.g., compact disk jukebox, tape drive), image hard copy devices (e.g., x-ray film processor, laser imager), and networking capabilities, depending on the needs of the facility. Because CT is a digital modality, CT scanners are frequently networked with other digital equipment, such as ultrasound and **magnetic resonance imaging** (MRI) systems, to facilitate comparison of images on viewing monitors.

In small hospitals or hospitals in rural areas, a CT scanner may not be installed; rather, a mobile CT scanning service may be contracted. A spiral CT scanner is installed in a specially designed trailer, which is driven to the hospital contracting the service. Prescheduled **CT scans** are then performed for the day or days the scanner is available at the hospital. Obviously, mobile CT only accommodates imaging in cases where the exam is not urgent.

Operation

After the technologist properly preps and positions the patient on the scanning table, the technologist goes to the adjacent control room and begins the scan using the control computer workstation. Usually, the computer has preprogrammed scanning protocols for common types of scans (e.g., abdomen and pelvis, chest, head) and some computers allow customized scan protocols to be entered. During scanning, the technologist instructs the patient via an intercom system regarding breathholds and positioning. The controlling computer automatically moves the patient table according to the scanning parameters selected. The scan itself may only take five to 15 minutes, but total examination time may be up to 30 minutes, since the patient must be prepped and positioned.

When the examination is completed, the technologist processes the image data using the computer workstation. Depending on the facility, images may be sent to an x-ray film processor or laser imager to be printed as hard copy and taken to a reading room, or they may be put on a

Computed tomography (CT) equipment uses x rays to obtain cross-sectional images of soft tissues of the body. (Pete Salutos/Custom Medical Stock Photo. Reproduced by permission.)

computer diskette or transferred via a digital image management system (picture archiving and communication system) for interpretation on a viewing monitor.

Before the patient is moved off the table, the radiologic technologist should review the acquired images to be sure they are of sufficient diagnostic quality. Motion artifacts, which are streaks, blurs, or other inconsistencies in the image, may occur if the patient moves during the scan or when imaging moving structures (e.g., heart, lungs). Decreasing the acquired image slice thickness, changing the timing of the contrast material injection, and shortening the patient's breathhold time can help reduce the occurrence of motion artifacts.

The radiologic technologist should choose the scanning protocol that will provide optimal image quality with minimal radiation dose. Typical radiation doses for a CT scan are approximately equal to the amount of natural background radiation the average person is exposed to over a year. The patient radiation dose from a CT scan is slightly higher than that of a typical x-ray procedure. Newer multislice scanners may deliver a significantly higher radiation dose than single-slice spiral scanners; this higher dose is of special concern for pediatric

patients. The American Society of Radiologic Technologists (ASRT) has issued a statement regarding scanning protocols for pediatric scanning and recommends that specific scanning protocols be developed for pediatric patients and that CT equipment manufacturers develop a range of suggested parameters for pediatric patients based on weight. In addition, ASRT encourages technologists to be aware of radiation doses for their pediatric cases by using radiation shielding when necessary, adjusting patient positioning, using special dose filters, and increasing the pitch ratio (the table speed per gantry rotation) on spiral scans.

Maintenance

Due to its high cost (\$500,000 to over \$1,000,000) and technical sophistication, CT imaging equipment is usually purchased with a service contract from the manufacturer or third party service provider that covers x-ray tube and other parts replacement and emergency service repair. The facility's **biomedical engineering** department and medical physicist may also conduct annual preventive maintenance checks, as well as monthly calibration, image quality testing, and radiation dose moni-

A technologist stays at computer controls while the patient is scanned with CT equipment. (Custom Medical Stock Photo. Reproduced by permission.)

KEY TERMS

Angiography—Imaging of the blood vessels of the body conventionally performed using an x-ray system and invasive catheterization, but that is performed on some CT scanners as a noninvasive alternative, since only an intravenous injection of contrast material is required.

Contrast material—A chemical mixture injected intravenously, swallowed, or administered by enema before and/or during a CT scan to enhance imaging of the area of interest.

Digital image management system; picture archiving and communication system—Systems of computer networking that allow exchange of images over the network or Internet, archiving of images for on-line access, and viewing of patient images and other data on a display monitor. These may encompass just the radiology department or an entire facility. CT scanners are frequently networked as part of these larger systems.

Gantry—The large square unit that houses the x-ray system and related components and has an opening in the center through which the patient table is moved.

Laser imager—A device that uses laser technology to produce hard copies of CT images; used instead of an x-ray film processor.

toring. A comprehensive quality control program that includes evaluation of image resolution, patient radiation dose, accuracy, image processing, patient table movement, and other overall system performance and image quality features should be followed. The radiologic technologist may be required to assist engineering staff with maintenance checks and service repairs.

Most CT manufacturers offer remote diagnostic features on their equipment that facilitate repair of system problems. Communication via modem and telephone with service personnel and diagnostic software allows, for example, ordering of replacement parts, downloading of software to fix a problem, or immediate notification of an operational problem to repair personnel.

Health care team roles

A radiologic technologist trained in computed tomography positions the patient on the table, administers any contrast material (intravenously, oral, or by

enema), and operates the CT scanner and computer workstation. Before administering any contrast material, the technologist will screen the patient for any **allergies** to medications or iodine and take a medical history to determine whether the patient has any medical condition (e.g., diabetes, **asthma**, heart disease, kidney or thyroid problems) that may interfere with CT imaging or indicate a higher risk of reaction to the contrast material. In addition, the technologist will ask female patients whether there is a possibility of **pregnancy**. The technologist will position lead aprons on appropriate areas of the patient to minimize unnecessary radiation exposure and provide lead aprons and other shielding for any individuals who must remain in the scan room (e.g., parents with children, staff monitoring a critical patient).

During the CT scan, the technologist controls the imaging scan parameters using the computer workstation, and communicates instructions to the patient via an intercom system. The technologist is responsible for acquiring the requested images and ensuring that they are of diagnostic quality. A radiologist will interpret the CT images and compile a report that is sent to the requesting physician.

Depending on the condition of the patient, other clinical staff may be present during the CT scan. Because CT is frequently used for trauma imaging, emergency medicine staff (nurses, **emergency medical technicians**) may be required to transport and monitor the patient.

Training

Radiologic technologist education programs include specialized training on CT principles of operation, radiation dose, patient positioning and anatomy, and CT imaging techniques. Specific training for a particular CT scanner is provided by the manufacturer upon installation and/or a workshop at the manufacturer facility. Usually, training for technologists and physicians is included in the cost of the CT system and consists of three to four days of technical and clinical instruction. The manufacturer often provides follow-up on-site visits after installation.

CT scans

Definition

Computed tomography (CT) scans are completed with the use of a 360-degree x-ray beam and computer production of images. These scans allow for cross-sectional views of body organs and tissues.

Purpose

CT scans are used to image a wide variety of body structures and internal organs. Since the 1990s, CT equipment has become more affordable and available. In some diagnoses, CT scans have become the first imaging exam of choice. Because the computerized image is so sharp, focused, and three-dimensional, many tissues can be better differentiated than on standard x rays. Common CT indications include:

- **Sinus studies.** The CT scan can show details of sinusitis, and bone **fractures**. Physicians may order CT of the sinuses to provide an accurate map for surgery.
- **Brain studies.** Brain scans can detect hematomas, tumors, and strokes. The introduction of CT scanning, especially spiral CT, has helped reduce the need for more invasive procedures such as cerebral angiography.

- **Body scans.** CT scans of the body will often be used to observe abdominal organs, such as the **liver, kidneys, adrenal glands**, spleen, and lymph nodes, and extremities.
- **Aorta scans.** CT scans can focus on the thoracic or abdominal aorta to locate aneurysms and other possible aortic diseases.
- **Chest scans.** CT scans of the chest are useful in distinguishing tumors and in detailing accumulation of fluid in chest infections.

Precautions

Pregnant women or those who could possibly be pregnant should not have a CT scan unless the diagnostic benefits outweigh the risks. Pregnant patients should particularly avoid full body or abdominal scans. If the exam is necessary for obstetric purposes, technologists are instructed not to repeat films if there are errors. Pregnant patients receiving CT or any x-ray exam away from the abdominal area may be protected by a lead apron; most radiation, known as scatter, travels through the body and is not blocked by the apron.

Contrast agents are often used in CT exams and the use of these agents should be discussed with the medical professional prior to the procedure. Patients should be asked to sign a consent form concerning the administration of contrast media. One common ingredient in contrast agents, iodine, can cause allergic reactions. Patients who are known to be allergic to iodine (or shellfish) should inform the physician prior to the CT scan.

Description

Computed tomography, also called CT scan, CAT scan, or computerized axial tomography, is a combination of focused x-ray beams, a detector array, and computerized production of an image. Introduced in the early 1970s, this radiologic procedure has advanced rapidly and is now widely used, sometimes in the place of standard x rays.

CT equipment

A CT scan may be performed in a hospital or outpatient imaging center. Although the equipment looks large and intimidating, it is very sophisticated and fairly comfortable. The patient is asked to lie on a narrow table that slides into the center of the scanner, called the gantry. The scanner looks like a square doughnut with a round opening in the middle, which allows the x-ray beam to rotate around the patient. The scanner's gantry section

may also be tilted slightly to allow for certain cross-sectional angles.

CT procedure

The patient will feel the table move very slightly as the precise adjustments for each sectional image are made. A technologist watches the procedure from a window and views the images on a monitor.

It is essential that the patient lie very still during the procedure to prevent motion blurring. In some studies, such as chest CTs, the patient will be asked to hold his or her breath during image capture.

Following the procedure, films of the images are usually printed for the radiologist and referring physician to review. A radiologist can also interpret CT exams on a special viewing console. The procedure time will vary in length depending on the area being imaged. Average study times are from 30 to 60 minutes. Some patients may be concerned about claustrophobia but the width of the gantry portion of the scanner is narrow enough to preclude problems with claustrophobia, in most instances.

The CT image

While traditional x rays image organs in two dimensions, with the possibility that organs in the front of the body are superimposed over those in the back, CT scans allow for a more three-dimensional effect. Some have compared CT images to slices in a loaf of bread. Precise sections of the body can be located and imaged as cross-sectional views. The technologist's console displays a computerized image of each section captured by the x-ray beam and detector array. Thus, various densities of tissue can be easily distinguished.

Contrast agents

Contrast agents are often used in CT exams and in other radiology procedures to demonstrate certain anatomic details which, otherwise, may not be easily seen. Some contrast agents are natural, such as air or water. Other times, a water-based contrast agent is administered for specific diagnostic purposes. Barium sulfate is commonly used in gastrointestinal procedures. The patient may drink this contrast medium, or receive it in an enema. Oral and rectal contrast are usually given when examining the abdomen or gastrointestinal tract, and not used when scanning the brain or chest. Iodine based contrast media are the most widely used intravenous contrast agents and are usually administered through an antecubital (in front of the elbow) vein.

If contrast agents are used in the CT exam, these will be administered several minutes before the study begins. Abdominal CT patients may be asked to drink a contrast medium. Some patients may experience a salty taste, flushing of the face, warmth or slight nausea, or **hives** from an intravenous contrast injection. Technologists and radiologists have equipment and training to help patients through these minor reactions and to handle more severe reactions. Severe reactions to contrast are rare, but do occur.

Spiral CT

Spiral CT, also called helical CT, is a newer version of CT scanning which is continuous in motion and allows for three-dimensional recreation of images. For example, traditional CT allows the technologist to take slices at very small and precise intervals one after the other. Spiral CT allows for a continuous flow of images, without stopping the scanner to move to the next image slice. A major advantage of spiral CT is the ability to reconstruct images anywhere along the length of the study area. The procedure also speeds up the imaging process, meaning less time for the patient to lie still. The ability to image contrast more rapidly after it is injected, when it is at its highest level, is another advantage of spiral CT's high speed.

Some facilities will have both spiral and conventional CT available. Although spiral is more advantageous for many applications, conventional CT is still a superior and precise method for imaging many tissues and structures. The physician will evaluate which type of CT works best for the specific exam purpose.

Preparation

If a contrast medium must be administered, the patient may be asked to fast from about four to six hours prior to the procedure. Patients will usually be given a gown (like a typical hospital gown) to be worn during the procedure. All metal and jewelry should be removed to avoid artifacts on the film.

Aftercare

No aftercare is generally required following a CT scan. Immediately following the exam, the technologist will continue to watch the patient for possible adverse contrast reactions. Patients are instructed to advise the technologist of any symptoms, particularly respiratory difficulty. The site of contrast injection will be bandaged and may feel tender following the exam. Hives may develop later and usually do not require treatment.

Complications

Radiation exposure from a CT scan is similar to, though higher than, that of a conventional x ray. Although this is a risk to pregnant women, the exposure to other adults is minimal and should produce no effects. Although severe contrast reactions are rare, they are a risk of many CT procedures. There is also a small risk of renal failure in high-risk patients.

Results

Normal findings on a CT exam show bone, the most dense tissue, as white areas. Tissues and fat will show as various shades of gray, and fluids will be gray or black. Air will also look black and darker than fat tissue. Intravenous, oral, and rectal contrast appear as white areas. The radiologist can determine if tissues and organs appear normal by the different gradations of the gray shadows. In CT, the images which can cut through a section of tissue or organ provide three-dimensional viewing for the radiologist and referring physician.

Abnormal results may show different characteristics of tissues within organs. Accumulations of **blood** or other fluids where they do not belong may be detected. Radiologists can differentiate among types of tumors throughout the body by viewing details of their makeup.

Sinus studies

The increasing availability and lowered cost of CT scanning has led to its increased use in sinus studies, either as a replacement for a sinus x ray or as a follow-up to an abnormal sinus radiograph. The sensitivity of CT allows for location of areas of sinus **infection**, particularly chronic infection, and is useful for planning prior to functional endoscopic sinus surgery. CT scans can show the extent and location of tiny fractures of the sinus and nasal bones. **Foreign bodies** in the sinus and nasal area are also easily detected by CT. CT imaging of the sinuses is important in evaluating trauma or disease of the sphenoid bone (the wedge-shaped bone at the base of the **skull**). Sinus tumors will show as shades of gray indicating the difference in their density from that of normal tissues in the area.

Brain studies

The precise differences in density allowed by CT scanning can clearly show tumors, strokes, or other lesions in the brain area as altered densities. These lighter or darker areas on the image may indicate a tumor or hemorrhage within the brain and skull area.

A computerized axial tomography (CAT) scan of the human brain. (Custom Medical Stock Photo. Reproduced by permission.)

Different types of tumors can be identified by the presence of **edema**, by the tissue's density, or by studying blood vessel location and activity. Congenital abnormalities in children, such as hydrocephalus, may also be confirmed with CT. Hydrocephalus is suggested by enlargement of the fluid structures called ventricles of the brain.

Body scans

The body scan can identify abnormal body structures and organs. Throughout the body, a CT scan may indicate tumors or cysts, enlarged lymph nodes, abnormal collections of fluid, blood, or fat, and metastasis of **cancer**. Fractures or damage to soft tissues can be more easily seen on the sensitive images produced by CT scanning, though CT is not usually done for these types of examinations because of cost. Liver conditions, such as cirrhosis, **abscess**, and fatty liver, may be observed with a CT body scan.

KEY TERMS

Aneurysm—The bulging of the blood vessel wall. Aortic aneurysms are the most dangerous. Aneurysms can break and cause bleeding.

Contrast (agent, medium)—A substance injected into the body that illuminates certain structures that would otherwise be hard or impossible to see on the radiograph (film).

Gantry—A name for the portion of a CT scanner which houses the x-ray tube and detector array used to capture image information and send it to the computer.

Hematoma—A collection of blood that has escaped from the vessels. It may clot and harden, causing pain to the patient.

Hydrocephalus—A collection of fluid on or around the brain. The pressure from the spinal fluid causes the ventricles to widen.

Metastasis—Secondary cancer, or cancer that has spread from one body organ or tissue to another.

Radiologist—A medical doctor specially trained in radiology (x-ray) interpretation and its use in the diagnosis of disease and injury.

Spiral CT—Also referred to as helical CT, this method allows for continuous 360-degree x-ray image capture.

Thoracic—Refers to the chest area. The thorax runs between the abdomen and neck and is encased in the ribs.

CT of the aorta

CT provides the ability to see and measure the thickness of the aortal wall, which is very helpful in diagnosing aortic aneurysms. The use of contrast will help define details within the aorta. In addition, increased areas of density can identify calcification, which helps differentiate between acute and chronic problems. An abnormal CT scan may indicate signs of aortic clots. Aortic rupture is suggested by signs such as a hematoma around the aorta or the escape of blood from its cavity.

Chest scans

In addition to those findings which may indicate aortic aneurysms, chest CT studies can show other problems in the **heart** and **lungs**. The computer will not only show differences between air, water, tissues, and bone, but will

also assign numerical values to the various densities. Mass lesions in the lungs may be indicative of **tuberculosis** or tumors. CT will help distinguish between the two. Enlarged lymph nodes in the chest area may indicate lymphoma. Spiral CT is particularly effective at identifying pulmonary emboli (clots in the lung's **blood vessels**).

Cultural sensitivity

Definition

Cultural sensitivity begins with a recognition that there are differences between cultures. These differences are reflected in the ways that different groups communicate and relate to one another, and they carry over into interactions with health care providers. Cultural sensitivity does not mean, however, that a person need only be *aware* of the differences to interact effectively with people from other cultures. If health care providers and their patients are to interact effectively, they must move beyond both cultural sensitivity and cultural biases that create barriers. Developing this kind of culturally competent attitude is an ongoing process.

A culturally competent clinician views all patients as unique individuals and realizes that their experiences, beliefs, values, and language affect their perceptions of clinical service delivery, acceptance of a diagnosis, and compliance.

Description

Cultural competence is an important component of nursing care. This is especially true given America's increasingly diverse patient population and the disparities in the health status of people from different racial, ethnic,

socioeconomic, religious, and cultural backgrounds. To value this diversity a clinician must respect the differences seen in other people, including customs, thoughts, behaviors, communication styles, values, traditions, and institutions.

Recognizing differences among cultures is important, but the clinician should also be aware that differences also exist *within* cultures. The assumption that a common culture is shared by all members of a racial, linguistic, or religious group is erroneous. The larger group may share common historic and geographic experiences, but individuals within the group may share nothing beyond that.

Culture greatly influences how people view their health and the health care services they receive. Clinicians should be aware of these differences, respect them, and work within the parameters set by the patient's values. Clinicians must also recognize their own cultural values and draw parallels where possible; they should also identify any prejudices and stereotypes that prevent them from communicating effectively with patients from different cultures.

The language barrier

Language differences between the clinician and the patient are a further barrier to optimum health care. Where possible, hospital or local school translators should be used, since it's not always in the client's best interest to have a family member act as an interpreter. The client may feel uncomfortable discussing personal matters in front of a relative. In addition the interpreter may lack a medical vocabulary, or may reinterpret what the patient says in an effort to "help." Role conflicts may further hinder translation. For example, a child or a person of the opposite sex may be embarrassed by the information or feel it improper to convey the message intended.

When using an interpreter the clinician should:

- Try to find an unrelated interpreter of the same sex as the patient, who is able to translate medical information clearly.
- Schedule more time for the appointment, if possible. Discuss the focus of the session with the interpreter before the patient arrives; be clear about what the interpreter should convey to the patient.
- Have the interpreter meet with the patient before the session to assess his or her educational level. This will determine how complex the discussion can become. If the patient has already met the clinician, the interpreter should be presented as a member of the healthcare team.

- Speak in short sentences or phrases, to make translating easier for the interpreter. Make sure the patient understands what he or she has been told by asking for him/her to repeat the message in his/her own words.
- Remember who the patient is—keep the focus on the patient, not the interpreter.
- Be sensitive to cultural differences when using nonverbal communication. For example, a touch has many cultural meanings. Clinicians must be aware that personal space has different boundaries in different cultures.

Viewpoints

One of the biggest debates about cultural competence is whether the health care provider should be of the same culture or speak the same language as the patient. Many clinicians from racial, ethnic, or cultural minorities believe very strongly that providers should be of the same culture as the patient. Others believe this is unnecessary and wrongly maligns people who aren't members of that specific group.

Another area of disagreement is whether training programs, such as diversity workshops, affect cultural competence. The argument against them is that cognitive information does not necessarily change attitudes or behavior.

Professional implications

In order to be culturally competent clinicians need not possess full knowledge of every cultural practice and belief. Instead they should be sensitive to others' preferences and values, and should not assume that one person's preferences and values apply to everyone in that same group. Patients are often willing to share their customs with those who seek to understand them. Genuine concern about what is important to the client is the best way to insure that culturally competent care will be provided.

Cyanosis

Definition

Cyanosis is a physical state characterized by bluish discoloration of the skin and mucus membranes.

This elderly woman's lips turned purple due to central cyanosis, a condition most commonly due to slow blood circulation, leading to a bluish skin coloration. (Photo Researchers, Inc. Reproduced by permission.)

Description

Cyanosis is a physical sign, rather than a diagnosis. The abnormal coloring of a cyanotic patient is due to a low oxygen content of the circulating red **blood** cells. Typically the abnormal bluish coloring is most noticeable in the nailbeds, lips, ears, and cheeks.

Causes and symptoms

One of the many important functions of blood is to pick up oxygen from the air sacs of the **lungs** and deliver it to sites around the body in need of oxygen. To carry oxygen, red blood cells (RBCs) contain a pigment called hemoglobin. When hemoglobin is carrying its full capacity of oxygen, it will cause the RBC to appear bright red. After the oxygen has been delivered, the RBC has a darker, bluish cast. If the darker-colored RBCs predominate, this gives the skin and mucus membranes the characteristic blue appearance of cyanosis.

There are two basic types of cyanosis: central and peripheral. Central cyanosis means that the arterial blood simply does not contain normal levels of oxygen (hypoxemia). This can happen because of lung disease, **heart** defects, and certain problems with the hemoglobin itself. Peripheral cyanosis means that venous blood (or blood that has unloaded its oxygen) is contributing to skin color more than arterial (or oxygen-rich) blood. A patient may have normal oxygen levels in arterial blood, but still have the bluish color of cyanosis expressed in some part(s) of his body. With peripheral cyanosis the underlying condition may be exposure to the cold, or decreased output from the heart, or local disruptions in the flow of arterial or venous blood.

KEY TERMS

Hemoglobin—A colored substance (pigment) in the red blood cell that carries oxygen to tissues and gives blood its red color.

Pulse oximeter—A painless device which uses a beam of light directed through the patient's finger, toe or earlobe to assess oxygen saturation of the blood.

Patients may or may not have symptoms with cyanosis, depending on its cause. With central cyanosis patients are often short of breath, dizzy, or even unconscious. With a peripheral cause of cyanosis, patients may have complaints localized to the affected parts of the body.

Diagnosis

Cyanosis is a subjective observation, so there is no test to confirm it. A patient's skin pigmentation and the presence or absence of anemia can make cyanosis more or less obvious. But there are objective tests to verify the presence or absence of hypoxemia (or low oxygen content of the blood). A non-invasive **pulse oximeter** can be used by a nurse or respiratory therapist to give a fairly accurate approximation of arterial oxygenation, and arterial **blood gases** can be drawn by a physician or respiratory therapist if detailed information is needed. If the arterial oxygen level is low, the cyanosis is central; if the oxygen level is normal, the cyanosis is peripheral in nature. If the affected body parts regain normal color with massage and warming, the cause was peripheral. Occasionally cyanosis has both central and peripheral elements.

Treatment

Treatment of cyanosis is based on identifying and treating its cause, and restoring normal flow of oxygenated blood.

Prognosis

Prognosis is dependent on the disease process underlying the cyanosis. If the underlying condition (such as heart or lung disease) can be properly treated, the skin will return to its normal coloring.

Health care team roles

Health care team members should be alert to cyanosis as a warning sign, particularly as a new devel-

opment in a given patient. Prompt recognition and treatment could be very important to clinical outcome.

Cybermedicine

Definition

Cybermedicine, also known as e-health, involves the provision of health care services using the Internet for communication.

Description

The growth of the Internet since the early 1990s, from a small network used in academia and government to a global infrastructure, has radically affected the delivery of health care. The health care industry has begun the complex process of linking previously disparate computer databases and patient-management applications together via the Internet. It is also adopting Internet-ready technologies, such as hand-held computers, Web cameras, decision-support and voice-recognition software, and wireless-transmission technology. The loftiest hope for cybermedicine is that it will create a fertile ground for patient-clinician partnerships as well as allow for more efficient management of health-related information. However, many issues of concern remain before the benefits of cybermedicine can be maximized while closely protecting the privacy and confidentiality rights of patient and clinician.

The strongest advocates of cybermedicine currently are consumers who use the Internet as a health-research tool. As of 2001, nearly one-third of the 250 million annual searches on the Medline Web site managed by the National Library of Medicine were conducted by patients and the general public. Thousands of public- and private-sector health Web sites exist; some target specific diseases such as **prostate cancer**, while others provide general health information. Some of these sites allow individuals to conduct disease screenings, or lifestyle and

quality-of-life assessments. Government health organizations, such as the Centers for Disease Control and Prevention, take advantage of the Internet's large audience by using the Internet as a public-health information bulletin board. Similarly, the World Health Organization reports communicable-disease outbreaks on the Internet.

The Internet is also increasingly used for telemedicine, which is cybermedicine involving the provision of care over the Internet. Patients with access to computers and the Internet may consult with their physicians online, receiving a diagnosis, treatment plan, and drug prescriptions for relatively simple disorders without face-to-face meetings. Computer-based decision-support software and videoconferencing technology are also used to provide telemedicine to chronically ill patients at home, and to help people with chronic diseases to self-monitor their conditions. People with diabetes, for example, may download data from a blood-glucose meter, record information about their medications, diet, and symptoms, and transmit these data to their health care providers. Teleradiology has been in operation for years but has vastly improved with the ability to transfer large amounts of data quickly. Genetics specialists are using telemedicine for genetic evaluations and services in rural areas. The future of telemedicine is projected to include long-distance robotic surgeries and quick tests of patients' DNA.

Remote surgery is an application of interest. Using a Web camera, a live transmission is sent from the operating room, where the patient is, to the office of a specialist, in another location. The specialist guides the on-site surgeon through the procedure.

One of the fastest growing applications of cybermedicine is in health business-support services. For example, WebMD, Medscape, and the American Medical Association's Medem are gradually moving traditional, office-based medical practices to the Web by offering online services for physicians, including the electronic transmission and storage of patient information, claims processing, billing procedures, and access to medical databases.

Viewpoints

Since e-mail and other tools of cybermedicine are more impersonal than face-to-face communication, critics observe that cybermedicine may challenge the ability of patients and clinicians to make emotional connections, such as to foster trust; physicians may find it too easy to dehumanize patients, thereby lessening patients' involvement in decision making. As regards remote surgery, critics question what happens if the Internet service fails during a crucial transmission. Perhaps the major issue of

concern is how to protect patient privacy/confidentiality over the Internet.

Proponents of cybermedicine point out that the ability to improve the flow of information between patients and clinicians gives significant potential to improve patient health. E-mail allows patients and clinicians to transmit detailed medical information and may increase opportunities for clinicians to provide social support to patients. Cybermedicine offers the potential to empower patients because patients may access the same on-line medical information as clinicians, thereby making the clinician-patient relationship potentially more democratic. Patients armed with accurate medical information may not be able to treat themselves, but they will be better informed and better able to assist in treatment decision making.

Another concern about cybermedicine is the difficulty of ensuring that Internet health content is both accurate and unbiased toward any product brands, thus maintaining the integrity of the line between e-health and e-commerce. To address this issue, many health-information Web sites are establishing ethical guidelines addressing issues such as commercial advertising, privacy, and accuracy of information. The American Telemedicine Association and the American Medical Informatics Association have established ethical and clinical guidelines for health care Web sites, health-related e-mail, and home-based telemedicine.

Professional implications

All indications suggest that cybermedicine practices will only increase. Health care practitioners should learn how to take advantage of this technology while recognizing its potential drawbacks, including concerns about individual patients' ability to assess symptoms and relate status effectively and clearly via the Internet. There is research suggesting that patients with chronic diseases such as diabetes or **asthma** and other chronic obstructive pulmonary disease (COPD) tend to underestimate the severity of their symptoms and to overestimate the degree of control that exists. Patients with breathing difficulties, for instance, cannot be adequately or accurately assessed without physical evaluation of the **lungs** and trachea and without in-office pulmonary-function tests. People with diabetes may find ways to modify results or underplay symptom reports via e-mail, so medications will not be changed.

Practitioners will also need to stay abreast of legal developments in cybermedicine. One legislative development expected to play a role in cybermedicine is the Health Insurance Portability and Accountability Act of 1996 (HIPAA). This act calls for protection of patient

health information, and it allows patients to access their **medical records**, which in the context of cybermedicine will probably be done electronically. In December of 2000, the HIPAA Privacy Rule was issued. It gives patients greater access to their own medical records and allows them to control how personal health information is used.

Cystic fibrosis

Definition

Cystic fibrosis (CF) is an inherited disease that affects the **lungs**, **digestive system**, and sweat glands, and causes **infertility** in males. Its name derives from the fibrous scar tissue that develops in the **pancreas**, one of the principal organs affected by the disease.

Description

Cystic fibrosis affects the body's ability to move salt and water in and out of cells. This defect causes the lungs and pancreas to secrete thick mucus, an inflammatory response that blocks passageways—particularly airway passages—and therefore prevents proper functioning of the affected areas.

CF affects approximately 30,000 children and young adults in the United States, where approximately 3,000 babies are born with CF every year. CF primarily affects people of white northern-European descent. Rates of CF are much lower in nonwhite populations.

Many of the symptoms of CF can be treated with drugs or nutritional supplements. Close attention to and prompt treatment of respiratory and digestive complications have dramatically increased the expected life span of a person with CF. Several decades ago, most children with CF died by the age of two years. By the end of the twentieth century, about one-half of all people with CF lived past 31 years of age. That median age is expected to grow as new treatments are developed. It is estimated that a person born in 2001 with CF has a median expected life span of about 40 years.

Genetic profiles

Cystic fibrosis is a genetic disease, meaning it is caused by a defect passed on through the genes. Genes, found in the nucleus of all body cells, control cell function by serving as the blueprint for the production of **proteins**. Proteins carry out a wide variety of functions within cells. The cystic fibrosis transmembrane conductance regulator (CFTR) gene, when defective, causes CF. A simple defect in this gene leads to all the consequences of CF. There are more than 500 known defects in the CFTR gene that can cause CF. However, mutation delta F508 in exon 10 is present in about 70% of CF chromosomes worldwide.

Genes can be thought of as long strings of chemical words, each made of chemical letters called nucleotides. Just as rearranging its letters can change a word and changing a word can change a sentence, genes can be

mutated, or changed, by changes in the sequence of their nucleotide letters. The gene defects in CF are called point mutations, meaning that the gene is mutated only at one small spot along its length. In other words, the delta-F508 mutation is a loss of one “letter” out of thousands within the CFTR gene. As a result, the CFTR protein made from its blueprint is made incorrectly and cannot properly perform its function.

The CFTR protein helps to produce mucus. Mucus is a complex mixture of salts, water, sugars, and proteins that cleanses, lubricates, and protects many passageways in the body, including those in the lungs and pancreas. The role of the CFTR protein is to allow chloride ions to exit from mucus-producing cells. When the chloride ions leave these cells, water follows, thinning the mucus. In this way, the CFTR protein helps to keep mucus from becoming thick and sluggish, thus allowing the mucus to be moved steadily along the passageways to aid in cleansing.

In CF the CFTR protein does not allow chloride ions out of the mucus-producing cells. With less chloride leaving, less water leaves, and the mucus becomes thick and sticky. It can no longer move freely through the passageways, so they become clogged. In the pancreas, clogged passageways prevent secretion of digestive enzymes (including insulin) into the intestine, causing serious impairment of digestion, especially of **fats**, which may lead to malnutrition. Mucus in the lungs may plug the airways, preventing good air exchange and, ultimately, leading to **emphysema** or COPD. The mucus is also a rich source of nutrients for **bacteria**, leading to frequent infections such as sinusitis, bronchitis, and **gastritis**.

Inheritance factor

To understand the inheritance pattern of CF, it is important to realize that genes actually have two functions. First, they serve as the blueprint for the production of proteins. Second, they are the material of inheritance: parents pass on characteristics to their children by combining the genes in egg and sperm to make a new individual.

Each person actually has two copies of each gene, including the CFTR gene, in each of their body cells. During sperm and egg production, however, these two copies separate, so that each sperm or egg contains only one copy of each gene. When sperm and egg unite, the newly created cell once again has two copies of each gene.

The two gene copies may be the same or they may be slightly different. For the CFTR gene, for instance, a person may have two normal copies, or one normal and one mutated copy, or two mutated copies. A person with two mutated copies will develop cystic fibrosis. A person

with one mutated copy is said to be a carrier. A carrier will not have symptoms of CF but can pass on the mutated CFTR gene to children.

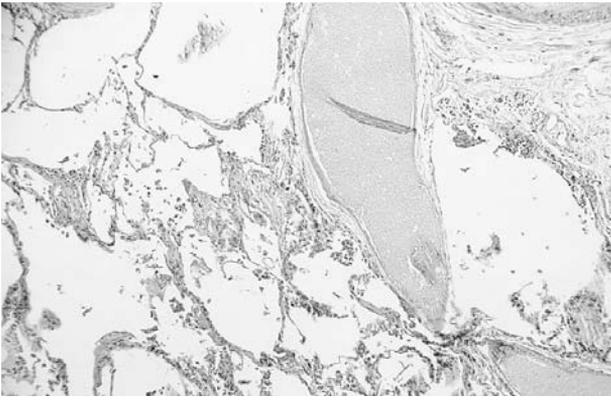

When two carriers have children, they have a one-in-four chance of having a child with CF each time they conceive, a two-in-four chance of having a child who is a carrier, and a one-in-four chance of having a child with two normal CFTR genes.

There are large differences in the frequency of mutated CF genes among different ethnic populations. For example, the frequency is highest in populations of northern-European descent—approximately one in every 25 Americans of northern-European descent is a carrier of the mutated CF gene, while only one in 17,000 African Americans and one in 30,000 Asian Americans are carriers. Since carriers are symptom-free, very few people know whether or not they are carriers unless there is a family history of the disease. Two white Americans with no family history of CF have a one-in-2,500 chance of having a child with CF.

It may seem puzzling that a mutated gene with such harmful consequences would remain so common. One might expect that the high mortality rate for CF patients before reaching childbearing age would quickly lead to the loss of the mutated gene from the population. It appears, however, that carriers may be protected from the intense **diarrhea** and eventual death by **dehydration** caused by cholera and typhoid **fever**. (This so-called “heterozygote advantage” is seen in some other genetic disorders, including sickle-cell anemia.) Some researchers believe that when these epidemics spread through early European populations, which were then much smaller, they would wipe out vast numbers in that population. However, people who carried one copy of the CF gene would have a greater chance of survival and so, therefore, would the defective gene. The incidence of the gene, then, would increase to a high level within that population. In hot climates, where dehydration from chronic excessive salt loss (perspiring) caused more deaths than occasional bouts of life-threatening diarrhea, the CF gene never gained the foothold it did in the colder European countries. Also, some researchers propose that CF heterozygotes are more resistant to **asthma**.

Causes and symptoms

The most severe effects of cystic fibrosis are seen in two body systems: the gastrointestinal (digestive) system, and the respiratory tract from the nose to the lungs. CF also affects the sweat glands and male fertility. Symptoms develop gradually; gastrointestinal symptoms are often the first to appear.

Lung tissue from a patient with cystic fibrosis. (Custom Medical Stock Photo. Reproduced by permission.)

Gastrointestinal system

Ten to fifteen percent of babies who inherit CF have meconium ileus at birth. Meconium is the first dark stool that a baby passes after birth. Ileus is an obstruction of the digestive tract. The meconium of a newborn with meconium ileus is thickened and sticky due to the presence of thickened mucus from the intestinal mucus glands. Meconium ileus causes abdominal swelling and vomiting, and often requires surgery immediately after birth. Presence of meconium ileus is considered highly indicative of CF. Borderline cases may be misdiagnosed, however, and attributed instead to a “milk allergy.”

Other abdominal symptoms are caused by the inability of the pancreas to supply digestive enzymes to the intestine. During normal digestion, as food passes from the **stomach** into the **small intestine**, it is mixed with pancreatic secretions (including insulin) that help break down the nutrients for absorption. While the intestines themselves also provide some digestive enzymes, the pancreas is the major source of enzymes for the digestion of all types of foods, especially fats and proteins.

In CF, thick mucus blocks the already inflamed pancreatic duct. Eventually, the duct becomes completely closed off by subsequent scar tissue formation, leading to a condition known as pancreatic insufficiency. Without pancreatic enzymes large amounts of undigested food pass into the **large intestine**. Bacterial action on this rich food source can cause gas and abdominal swelling. The large amount of fat remaining in the feces makes it bulky, oily, and foul-smelling.

Because nutrients are poorly digested and absorbed, a person with CF is often ravenously hungry, underweight, and shorter than expected for a given age. When CF is not treated for a longer period, a child may develop symptoms of malnutrition, including anemia, bloating, and—paradoxically—appetite loss. The rib cage

may eventually become barrel-shaped as the patient struggles with breathing and with the formation of emphysema-like symptoms.

Diabetes becomes increasingly likely as a person with CF ages. Scarring of the pancreas slowly destroys those pancreatic cells that produce insulin, producing type I, or insulin-dependent, **diabetes mellitus**.

Gall stones affect approximately 10% of adults with CF. **Liver** problems are less common, but can be caused by the buildup of fat within the liver. Complications of liver enlargement may include internal hemorrhaging, abdominal fluid (ascites), spleen enlargement, and liver failure.

Other gastrointestinal symptoms can include a prolapsed rectum, in which part of the rectal lining protrudes through the anus; intestinal obstruction; and rarely, intussusception (telescoping), in which part of the intestinal tube slips over an adjoining part, cutting off **blood** supply.

Somewhat less than 10% of people with CF do not have gastrointestinal symptoms. Most of these people do not have the delta-F508 mutation, but rather a different one, which presumably allows at least some CFTR-induced proteins to function normally in the pancreas.

Respiratory tract

The respiratory tract includes the nose, throat, trachea (or windpipe), main bronchus, bronchi (that branch off from the main stem bronchus within each lung), the smaller bronchioles, and the blind sacs called alveoli in which **gas exchange** takes place between air and blood through the capillaries feeding the alveoli.

Swelling of the sinus mucus membrane lining is common in people with CF. This usually shows up on x ray and may aid the diagnosis of CF. However, this swelling, called pansinusitis, rarely causes problems unless there is blockage and **infection**. Children with CF have a high rate of infection of the sinuses, requiring antibiotic therapy to prevent the infection from proceeding to the lungs.

Nasal polyps, or growths, affect about one in five people with CF. These growths are not cancerous and do not require removal unless they block nasal drainage enough to cause chronic sinus infections. However, they are usually treated medically before surgery is considered. While nasal polyps appear in older people without CF, especially those with **allergies**, they are rare in children without CF.

The lungs are the site of the most life-threatening effects of CF. The hyperinflammatory state of the membranes causes production of a thick, sticky mucus (that is actually the body’s attempt to soothe the affected area).

However, this mucus increases the likelihood of infection, decreases the ability to protect against infection, and causes further blockage of normal functioning in the airways. This blockage, in turn, exacerbates the inflammation and swelling. The functional capacity of the lungs is therefore severely compromised and may ultimately lead to emphysema. People with CF will live with chronic obstructive pulmonary disease (COPD) or bacterial residence in their lungs. Lung infection is the major cause of death for those with CF.

The bronchioles and bronchi normally produce a thin, clear mucus that traps foreign particles, including bacteria and **viruses**. Tiny hair-like projections, called cilia, on the surface of these passageways slowly move mucus out of the lungs and up the bronchus to the trachea and the back of the throat, where it may be swallowed or coughed up. This “mucociliary escalator” is one of the principal defenses against lung infection.

The thickened mucus of CF prevents ciliary movement of debris out of the lungs and increases the irritation and existing inflammation of airways and lung tissue. This inflammation swells the passageways, partially closing them down, further hampering the movement of mucus. A person with CF is likely to cough more frequently and more vigorously as their lungs attempt to clean themselves out.

At the same time, infection becomes more likely, since the mucus is a rich source of nutrients. Bronchitis, bronchiolitis, and **pneumonia** are frequent in CF. The most common infecting organisms are the bacteria *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*. A small percentage of people with CF have infections caused by *Burkholderia cepacia*, a bacterium that is resistant to most current **antibiotics** (*Burkholderia cepacia* was formerly known as *Pseudomonas cepacia*). The fungus *Aspergillus fumigatus* may infect older children and adults.

The body’s response to inflammation and infection is to increase mucus production; white blood cells fighting the infection thicken the mucus even further as they break down and release their cell contents. These white blood cell constituents serve as messengers to enhance the production of both inflammatory and antiinflammatory cells and mediators.

As mucus accumulates it can plug up the smaller passageways in the lungs, decreasing functional lung volume. Inhaling enough air (oxygen) can become difficult; fatigue, shortness of breath, and intolerance of **exercise** become more common. Because air passes obstructions more easily during inhalation than during exhalation, over time, air becomes trapped in the smallest chambers of the lungs, the alveoli. As millions of

alveoli gradually expand, the chest takes on the enlarged, barrel-shaped appearance typical of emphysema.

For unknown reasons recurrent respiratory infections or impairment lead to “digital clubbing,” in which the last joint of the fingers and toes becomes slightly enlarged and the distal fingernail edges curl around and over the enlarged fingertip.

Sweat glands

The CFTR protein helps to regulate the amount of salt in perspiration. People with CF have perspiration with a higher salt content than normal, and measuring the saltiness of a person’s sweat is a key diagnostic test for CF. Parents may notice that their infants taste salty when they kiss them. Excess salt loss is not usually a problem, except during prolonged exercise or heat. While most older children and adults with CF compensate for this extra salt loss by eating more salty foods, infants and young children are in danger of suffering its effects (such as heat prostration), especially during summer, and require electrolyte supplementation. Heat prostration is marked by lethargy, weakness, and loss of appetite, and should be treated as an emergency condition, especially in children and the elderly.

Fertility

Ninety-eight percent of men with CF are sterile due to complete obstruction or absence of the vas deferens, the tube carrying sperm out of the testes. While boys and men with CF form normal sperm and have normal levels of sex hormones, sperm are unable to leave the testes, and fertilization is not possible. Most women with CF are fertile, though they often have more difficulty conceiving than women without CF. In both boys and girls, **puberty** is often delayed, most likely due to the effects of poor **nutrition** or chronic lung infection. Women with CF who have good lung health usually have no problems with **pregnancy**, while those with ongoing lung infection often do poorly. The potential for digestive disruption from intestinal displacement may also pose problems, regardless of lung function.

Diagnosis

The decision to test a child for cystic fibrosis may be triggered by concerns about recurring gastrointestinal or respiratory symptoms, or salty sweat. A child born with meconium ileus will be tested before leaving the hospital. Families with a history of CF may wish to have all children tested, especially if one child has already manifested the disease. Some hospitals now require routine screening of newborns for CF.

Sweat test

The sweat test is both the easiest and most accurate test for CF. In this test, a small amount of the drug pilocarpine is placed on the skin. A very small electrical current is then applied to the area, which drives the pilocarpine into the skin. The drug stimulates sweating in the treated area. The sweat is absorbed onto a piece of filter paper and analyzed for its salt content. A person with CF will have salt concentrations that are one and one-half to two times greater than normal. The test can be done on persons of any age, including newborns, and its results can be determined within an hour. Virtually every person who has CF will test positively on it, and virtually everyone who does not have the disease will test negatively.

Genetic testing

The discovery of the CFTR gene mutation in 1989 allowed the development of an accurate genetic test for CF. Genes from a small blood or tissue sample are analyzed for specific mutations; presence of two copies of the mutated gene confirms the diagnosis of CF in all but a very few cases. However, since there are so many different possible mutations, and since testing for all of them would be too expensive and time consuming, it is important to remember that a negative gene test cannot rule out the possibility of CF.

Couples planning a family may decide to have themselves tested if one or both have a family history of CF. Prenatal **genetic testing** is possible through **amniocentesis**. Many couples who already have one child with CF decide to undergo prenatal screening in subsequent pregnancies and use the results to determine whether to terminate the pregnancy. Siblings in these families are also usually tested, both to determine if they will develop CF and if they are carriers. This aids in their own family planning. If the sibling has no symptoms, determining carrier status is often delayed until the teen years or later, when persons are closer to needing the information to make decisions.

Newborn screening

Some states now require screening of all newborns for CF using a test known as the IRT test—a blood test that measures the level of immunoreactive trypsinogen. Babies with CF generally have higher levels of IRT; however, this test is not an accurate predictor as it gives many false positive results immediately after birth. A second test is therefore required several weeks later for validation. A second positive result indicates the need to conduct a sweat test.

Treatment

There is no cure for cystic fibrosis. Treatment has advanced considerably since the mid-1900s, increasing both the life span and the quality of life for most people affected by CF. Early diagnosis is important to prevent malnutrition and infection from weakening a young child. With proper management, many people with CF may participate in the full range of school and sports activities.

Nutrition

People with CF usually require high-calorie diets and vitamin supplements. Height, weight, and growth of a person with CF are regularly monitored. Most people with CF need to take pancreatic enzymes to supplement or replace the inadequate secretions of the pancreas. Tablets containing pancreatic enzymes are taken with every meal; depending on the size of the tablet and the meal, as many as 20 tablets may be needed at a time. Because of incomplete absorption even with pancreatic enzymes, a person with CF needs to take in about 30% more food than a person without CF. Low-fat diets are not recommended, except in special circumstances, since fat is a source of both essential fatty acids and abundant calories, but the high calorie diet does not include increased fat intake (above normal).

Some people with CF cannot absorb enough nutrients from the foods they eat, even with specialized diets and enzymes. For these people, tube feeding is an option. Nutrients can be introduced directly into the stomach through a tube inserted either through the nose (a nasogastric tube) or through the abdominal wall (a gastrostomy tube). A jejunostomy tube, inserted into the small intestine, is also an option. Tube feeding can provide nutrition at any time, including at night while a person is sleeping, allowing constant intake of high-quality nutrients. The feeding tube may be removed or temporarily occluded during the day, allowing the patient to take food by mouth.

Respiratory health

The key to maintaining respiratory health in a person with CF is regular monitoring and early treatment. Pulmonary function tests are done frequently to track changes in functional lung volume and respiratory effort. Sputum samples are analyzed to determine the types of bacteria present in the lungs. Chest x rays are usually taken at least once a year. Lung scans are performed with the patient inhaling radioactive contrast gas that helps define areas on the lungs not visible with x rays. Pulmonary circulation may be monitored by injection of a radioactive substance into the bloodstream.

People with CF live with chronic bacterial colonization. This means that their lungs are constantly host to several species of bacteria. Good general health, especially good nutrition, may keep the **immune system** functioning well, decreasing the frequency with which the resistant bacterial colonies multiply and cause infection or attack lung tissue. Exercise is also important to promote pulmonary health, and people with CF are encouraged to maintain a regular exercise program.

Clearing mucus from the lungs also helps prevent infection, and mucus control is an important aspect of CF management. Bronchial drainage (postural drainage) allows gravity to aid the mucociliary escalator. For this technique the patient lies on a tilted surface with head downward (Trendelenburg); alternately on the stomach, back, or side, depending on the section of lung to be drained. An assistant performs respiratory percussion techniques with varying strokes, rhythms, and hand positions, moving systematically over the patient's chest, rib cage, and upper back to help loosen secretions. A device called a "flutter" offers another way to loosen secretions: it consists of a stainless steel ball in a tube. When a person exhales through it, the ball vibrates, sending vibrations back through the air in the lungs. Some special breathing techniques, such as diaphragmatic breathing, and rib cage expansion and locking that allows the diaphragm freedom of movement, may also help clear the lungs.

Several drugs are available to prevent the airways from becoming clogged with mucus. Bronchodilators can help open up the airways, steroids reduce inflammation, and mucolytics loosen secretions. Surfactants are used to reduce the surface tension of the mucus, like a detergent breaks the surface tension of water and oils. Acetylcysteine (Mucomyst) has been used as a mucolytic for many years but now is less frequently prescribed, while DNase (Pulmozyme) is a newer product gaining in popularity. DNase is an enzyme that helps break down the DNA from dead white blood cells and bacteria found in thick mucus.

People with CF may contract cross-infected bacteria from other persons with CF. This is especially true of *Burkholderia cepacia*, which is not usually found in people without CF. While the ideal recommendation from a health standpoint might be to avoid contact with others who have CF, this is not always practical (since CF is a familial disease and CF clinics are a major site of care), nor does it meet the psychological and social needs of patients. At a minimum, CF centers recommend avoiding prolonged close contact between people with CF, and the use of scrupulous hygiene techniques, including frequent hand washing. Some CF clinics schedule appointments

on different days for those with and without *B. cepacia* colonies.

Some doctors choose to prescribe antibiotics for patients with CF only during an infection, while others prefer long-term prophylactic antibiotic treatment against *S. aureus*. The choice of antibiotic depends on the particular organism or organisms found. Some antibiotics are given as aerosols directly into the lungs. Antibiotic treatment for patients with CF, by necessity, may be prolonged and aggressive.

Supplemental oxygen may be needed as lung disease in CF progresses. In some cases, **respiratory failure** episodes require the temporary use of a ventilator to perform the work of breathing until the patient can begin to regain control and be weaned from the machine.

Lung transplantation is another option for people with CF, although the number of people who receive them is still much lower than those who need them. Transplantation is not a cure, however, and has been likened to trading one disease for another because long-term immunosuppression is required, increasing the likelihood of contracting opportunistic infections. About 50% of adults and more than 80% of children with CF who receive lung transplants live longer than two years posttransplant. Liver transplants may also be required for people with CF whose livers have been damaged by fibrosis.

Long-term use of ibuprofen as an antiinflammatory agent has been shown to help some people with CF. Close medical supervision is necessary, however, since the effective dose for patients with CF is high and not everyone benefits. Ibuprofen at these higher doses interferes with kidney function and, if taken together with aminoglycoside antibiotics, may cause kidney failure.

A number of experimental treatments are under research. Some evidence indicates that aminoglycoside antibiotics may help overcome the genetic defect in some CF mutations, allowing the protein to be made normally. While promising, these results would apply to only about 5% of those with CF.

Gene therapy has become the most ambitious approach to curing CF. In this set of techniques, copies of the healthy CFTR gene are delivered to affected cells, where they are accepted and used to create the CFTR protein. While elegant and simple in theory, gene therapy has met with a large number of difficulties in trials so far, including immune resistance, very short life-cycle duration of the introduced gene, and inadequately widespread distribution.

KEY TERMS

Carrier—In CF, a person with one copy of a defective gene who does not have the disease it causes but can pass along the defective gene to offspring.

Chronic obstruction pulmonary disease (COPD)—A progressive disease process that commonly stems from smoking. COPD is characterized by difficulty breathing, wheezing, and a chronic cough.

Cystic fibrosis transmembrane conductance regulator (CFTR)—The protein responsible for regulating chloride movement across cells in some tissues. When a person has two defective copies of the CFTR gene, cystic fibrosis is the result.

Emphysema—A pathologic accumulation of residual air in organs or tissues. This term is especially applied to the condition when in the lungs.

Gastrostomy tube—A tube that is inserted through a small incision in the abdominal wall and that extends through the stomach wall into the stomach for the purpose of introducing parenteral feedings.

Jejunostomy tube—A tube inserted through the abdominal wall and into the small intestine for the purpose of introducing parenteral feeding.

Lung surfactant—A surface active agent that renders the alveolar surfaces hydrophobic and prevents the lung filling with water by capillary action.

Meconium ileus—Obstructed bowel due to impacted, tenacious, meconium (infant's first stool).

Mucociliary escalator—The coordinated action of tiny projections on the surfaces of cells lining the respiratory tract that moves mucus up and out of the lungs.

Mucolytic—An agent that dissolves or destroys mucin, the chief component of mucus.

Nasogastric tube—A tube inserted through the nose, extending through the pharynx and esophagus, and into the stomach for the purpose of introducing parenteral feeding.

Pancreatic insufficiency—Reduction or absence of pancreatic secretions into the digestive system due to scarring and blockage of the pancreatic duct.

Alternative treatment

In homeopathic medicine the primary goal is to address the symptoms of CF in order to enhance quality of life. It is not yet possible to treat the cause, owing to the genetic basis of the disease. Homeopathic medicine seeks to treat the whole person, however, and in cystic fibrosis, this approach may include:

- mucolytics to help thin the mucous
- supplementation of pancreatic enzymes to assist in digestion
- addressing respiratory symptoms to open lung passages
- hydrotherapy techniques (such as nighttime mist tents) to help ease respiratory symptoms and help the body eliminate mucus from the lungs
- immune enhancements (such as vitamin supplementation) to help prevent development of secondary infections
- dietary enhancements and adjustments to treat digestive and nutritional problems

Prognosis

Approximately half of all people with CF live past the age of 30 years; however, because of earlier intervention and enhanced treatment, a person born in 2001 with CF may be expected, on average, to live to 40 years of age.

People with CF may lead relatively normal lives. Careful consideration of the effects pregnancy may have on a woman with CF is essential before beginning a family. Issues of parental longevity and the potential for the child to be a carrier are also concerns. Although most men with CF are functionally sterile, new procedures for removing sperm from the testes are being attempted that may offer more men suffering from CF the chance to become fathers.

Health care team roles

A pediatrician usually makes the initial diagnosis of CF. Family physicians, internists, and pulmonologists can manage persons with CF. Radiologists take images to document the extent of CF. Nurses, respiratory therapists, physical therapists, and nutritionists provide symptomatic treatments and supportive services. Surgeons are needed if transplantation is required.

Prevention

As of 2001 there was no way to prevent the development of CF in a person with two defective copies of

the relevant gene from both parents. Adults with a family history of CF may obtain a genetic test of their carrier status for purposes of family planning. Prenatal testing is also available to determine the genetic status of the infant with regard to CF.

Cystometry

Definition

Cystometry is a test of bladder function in which pressure and volume of fluid in the bladder is measured during filling, storage, and voiding.

Purpose

A cystometry study is performed to diagnose problems with urination, including incontinence, urinary retention, and recurrent urinary tract infections. The urinary bladder stores urine produced by the **kidneys**. The main muscle of the bladder wall, the detrusor, relaxes to allow expansion of the bladder during filling. The ure-

KEY TERMS

Anticholinergics—Drugs that prevent the action of acetylcholine, a compound released by nerve endings.

Cholinergics—Drugs that mimic the action of acetylcholine, a compound released by nerve endings.

Detrusor—Muscle of the bladder wall.

Residual urine volume—Amount of urine remaining after voiding.

Sphincter—Ring of muscle between the bladder and the urethra that functions to close off the urethra.

Urethra—Tube which empties urine from the bladder to the exterior of the body.

thra, the tube through which urine exits, is held closed by a ring of muscle known as the urethral sphincter. As volume increases, stretching of the detrusor and pressure on the sphincter sends signals to the **brain**, indicating the need for urination, or voiding. Voluntary relaxation of the sphincter and automatic contractions of the detrusor allow successful and virtually complete voiding.

Urinary difficulties may occur because of weak or hyperactive sphincter or detrusor, or non-coordination of their two activities. **Infection** of the bladder or urethra may cause incontinence, as can obstruction of the urethra from scar tissue, prostate enlargement, or other benign or cancerous growths. Loss of sensation due to nerve damage can lead to chronic overfilling.

Precautions

The mild irritation of the urinary tract necessary for insertion of the catheter may occasionally cause flushing, sweating, and nausea. Cystometry is contraindicated in patients with urinary tract infection because of the potential for false results and the possibility of exacerbating the infection.

Description

The patient begins by emptying the bladder as much as possible. A thin plastic catheter is then gently inserted into the urethra until it reaches the bladder. Measurements are taken of the residual urine volume and bladder pressure. Pressure measurements may require a

rectal probe to account for the contribution of the abdominal muscles to the pressure recording.

The bladder is then gradually filled with either warm water, room temperature water, saline solution, carbon dioxide gas, or a contrast solution for x-ray analysis, depending on the type of study being done. The patient is asked to describe sensations during filling, including temperature sensations and when the first feeling of bladder fullness occurs. Once the bladder has completely filled, the patient is asked to begin voiding, and pressure and volume measurements are again taken, as well as flow rate. It is important to instruct the patient not to strain while voiding during the test. Straining can alter the test results.

Preparation

There are no special food or fluid restrictions needed to prepare for this test. The patient may be asked to stop taking certain medications in advance of the test, including sedatives, cholinergics, and anticholinergics.

Aftercare

Cystometry may be somewhat uncomfortable. Urinary frequency or urgency and some hematuria (reddish urine), may last for a day. Increasing fluid intake helps to flush out the bladder. Caffeinated, carbonated, or alcoholic beverages are discouraged, because they may irritate the bladder lining. A warm bath or sitz bath may be recommended to soothe the patient.

Risks

There is a risk of upper or lower urinary infection due to tearing of the urethral lining. Although extremely rare, in some male patients, infection of the epididymis (tubules at the back of the testis) can occur and lead to **infertility**. Damage to the urethra or bladder sometimes occurs but usually heals without treatment. Rarely an allergic reaction may occur due to the contrast dye or medications.

Patients should notify their health care provider if they develop any of these symptoms:

- blood in the urine beyond several voidings
- fever or chills
- lower back pain

Results

The normal bladder should not begin contractions during filling and should initially expand without resistance. A feeling of fullness occurs with a volume of 100-

200 ml. Adult bladder capacity varies dependent on gender. Normal adult female bladder capacity ranges between 250 to 550 ml, and normal adult male capacity ranges from 350 to 750 ml. The sphincter should relax and open when the patient wills it, accompanied by detrusor contractions. During voiding, detrusor contraction should be smooth and lead to a steady urine stream.

Inability of the bladder to relax during filling, or low bladder volume, may indicate interstitial cystitis, prostate enlargement, or bladder **cancer**. Contraction of the bladder during filling may be due to irritation from infection or cysts, obstruction of the bladder outlet, or neurological disease such as stroke, **multiple sclerosis**, or **spinal cord injury**. Diminished sensation may occur with nerve lesions, peripheral neuropathy, or chronic overfilling.

Health care team roles

A cystometry may be performed in the hospital, doctor's office, or outpatient facility by a physician or nurse.

Cystoscopy

Definition

Cystoscopy (cystourethroscopy) is a diagnostic procedure that uses an **endoscope** especially designed for urological use to examine the bladder, lower urinary tract, and prostate gland. It can also be used to collect urine samples, perform biopsies, and remove small stones.

Purpose

Cystoscopy is performed by urologists to examine the entire bladder lining and take biopsies of any questionable areas. Cystoscopy may be prescribed for patients who display the following:

- **blood** in the urine (hematuria)
- inability to control urination (incontinence)
- urinary tract **infection**
- signs of congenital abnormalities in the urinary tract
- suspected tumors in the bladder
- bladder or **kidney stones**
- signs or symptoms of an enlarged prostate
- **pain** or difficulty urinating (dysuria)
- disorders of or injuries to the urinary tract
- symptoms of interstitial cystitis

Blood and urine studies, in addition to x rays of the **kidneys**, ureters, and bladder, may be performed before a cystoscopy to obtain as much diagnostic information as possible. During the cystoscopy, a retrograde pyelogram may also be performed to examine the kidneys and ureters.

Precautions

Cystoscopy is a commonly performed procedure, but it is an invasive technique that involves small yet significant risk. If anesthesia is required, there is additional risk, particularly for people who are obese, smoke, or are in poor health. Those undergoing anesthesia must inform the doctor of any medications they are taking.

Description

A cystoscopy typically lasts from 10 to 40 minutes. The patient is asked to urinate before surgery. A well-lubricated flexible or rigid cystoscope (urethroscope) is inserted through the urethra into the bladder where a urine sample is taken. Fluid is then injected to inflate the bladder and allow the urologist to examine the entire bladder wall. The cystoscope uses a lighted tip for guidance and enables biopsies to be taken or small stones to be removed through a hollow channel in the cystoscope.

During a cystoscopy, the urologist may remove bladder stones or kidney stones, gather tissue samples, and perform x-ray studies. To remove stones, an instrument that resembles a tiny basket or grasper is inserted through the cystoscope so that small stones can be extracted through the scope's channel. For a biopsy, specially designed forceps are inserted through the cystoscope to

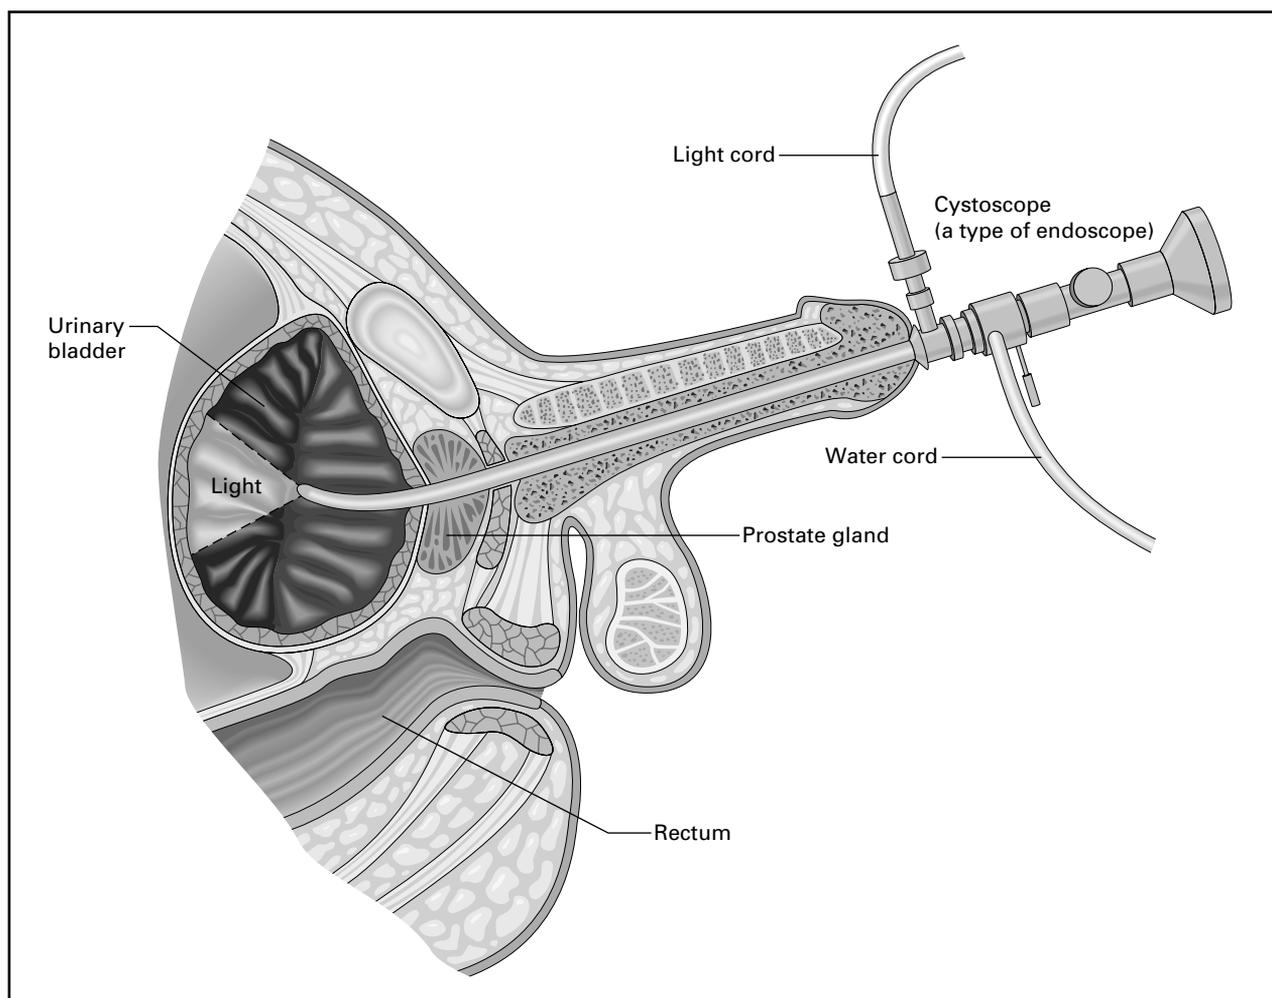

Illustration of cystoscopy procedure. (Delmar Publishers, Inc. Reproduced by permission.)

pinch off a tissue sample. Alternatively, a small brush-like instrument may be inserted to scrape off some tissue. To perform x-ray studies such as a retrograde pyelogram, a dye is injected into the ureters by way of a catheter passed through the cystoscope. After completion of all needed tests, the cystoscope is removed.

Preparation

Cystoscopy can be performed in a hospital, doctor's office, or outpatient surgical facility. Spinal or **general anesthesia** may be used for the procedure. Distension of the bladder with fluid is particularly painful, and if it needs to be done, as in the case of evaluating interstitial cystitis, general anesthesia is required. Cystoscopy is typically performed on an outpatient basis, but up to three days of recovery in the hospital is sometimes required.

Aftercare

Patients who have undergone a cystoscopy are instructed to:

- take warm baths to relieve pain
- rest and refrain from driving for several days, especially if general anesthesia was needed
- expect any blood in the urine to clear up in one to two days
- avoid strenuous **exercise** during recovery
- postpone sexual relations until the urologist determines that healing is complete

Patients may be prescribed pain relievers and **antibiotics** following surgery. Minor pain may also be treated with over-the-counter, non-prescription drugs such as acetaminophen.

Complications

As with any surgical procedure, there are some risks involved with a cystoscopy. Complications may include profuse bleeding, a damaged urethra, a perforated bladder, a urinary tract infection, or an injured penis.

Patients should contact their physician if they experience any of the following symptoms following the procedure: pain, redness, swelling, drainage or bleeding from the surgical site; signs of generalized infection, which may include headache, muscle aches, dizziness or an overall ill feeling and **fever**; nausea or vomiting; or difficult or painful urination.

Results

A successful cystoscopy includes a thorough examination of the bladder and collection of urine samples for cultures. If no abnormalities are seen, the results are indicated as normal.

Cystoscopy allows the urologist to detect inflammation of the bladder lining, prostatic enlargement, or tumors. If these are seen, further evaluation or biopsies may be needed. Cystoscopy with bladder distention can also evaluate interstitial cystitis. Bladder stones, urethral strictures, diverticula, or congenital abnormalities can also be detected.

Health care team roles

Cystoscopy is performed in a hospital operating room, cystoscopy suite, or urologist's office, depending on the condition of the patient and the anesthesia required. If general anesthesia is required, an anesthesiologist is necessary to administer the anesthesia and monitor the patient. The cystoscopy procedure is performed by a urologist, urologic surgeon, or urogynecologist, with assistance from nurses experienced in urologic procedures. If x rays are taken during the procedure, a uroradiologist or radiologic technologist is required to operate the x-ray equipment. Biopsy tissue samples are sent to the clinical laboratory for examination by a pathologist.

KEY TERMS

Diverticula—A pouch or sac occurring normally or from a herniation or defect in a membrane. Cystoscopy can detect diverticula in the urinary tract.

Endoscopy—A minimally invasive procedure that involves examination of body organs or cavities using an endoscope (a lighted optical instrument used to see inside body cavities). A cystoscope is a type of endoscope.

Interstitial cystitis—A chronic inflammatory condition of the bladder involving symptoms of bladder pain, frequent urination, and burning during urination. Diagnosis is confirmed by cystoscopy with the bladder distended by fluid.

Retrograde pyelogram—A pyelography or x-ray technique in which radiopaque dye is injected into the kidneys through the ureters.

Ureter—The tube that carries urine from the kidneys to the bladder.

Urethra—The tube that carries urine from the bladder to outside the body. In females, the urethral opening is between the vagina and clitoris; in males the urethra travels through the penis, opening at the tip.

Urogynecologist—A physician that specializes in female medical conditions concerning the urinary and reproductive systems.

Uroradiologist—A radiologist who specializes in diagnostic imaging of the urinary tract and kidneys.

Cytomegalovirus antibody screening test

Definition

Cytomegalovirus (CMV) is a common human virus. When first exposed to CMV, a healthy person’s **immune system** is triggered and quickly makes antibodies to fight the virus. Specialized screening tests can be done to document the presence or absence of antibodies specific to the cytomegalovirus. Antibodies to CMV can be evidence of a current or a past **infection**.

Purpose

Up to 85% of people have antibodies to CMV by the time they are 40 years old. In a healthy, nonpregnant person, CMV infection is almost never serious. Symptoms, if present, are mild, often resembling infectious mononucleosis caused by the Epstein-Barr virus. However, consequences of CMV infection can be devastating to the fetus, transplant patients, patients with human **immunodeficiency** virus (HIV) and other patients with suppressed immune systems. People with weakened immune systems are vulnerable to infection from several routes, including from another person, from a donated organ or transfused **blood**, or from reactivation of a past infection. CMV is related to the herpes simplex and varicella (chickenpox) **viruses** in that it remains dormant in the body but can resurface with or without symptoms.

Antibody screening helps control the infection risk for high risk groups. For instance, before a transplant, both the recipient and donor are usually tested for antibodies. A recipient who has never had CMV (negative for antibodies) should not receive an organ from a donor who has had CMV (positive for antibodies) because active infection could be acquired by the recipient. CMV infection in this context can be associated with organ rejection, or can cause illness such as **pneumonia**, hepatitis, or death. In some transplant patients, particularly after bone marrow transplantation, testing may be done as often as every week to screen for new or recurrent infection.

Women who do not have evidence of previous CMV infection (i.e. antibody screen negative) should try to avoid exposure to CMV in **pregnancy**. CMV infection is the most common congenital infection (existing at birth). The infection, passed from mother to baby, can cause permanent mental or physical damage, or death. However, CMV antibody screening is not routinely ordered as part of **prenatal care**.

Blood is usually screened for CMV antibodies before being transfused into a person with a weakened immune system. CMV infection can be very similar to illness due to Epstein-Barr virus. If there is a need to know the specific source of a patient’s symptoms, antibody screening distinguishes between these two infections.

Precautions

Tests for CMV are performed on serum or biopsied tissue. Blood is collected by venipuncture by a nurse or phlebotomist. When collecting blood or handling tissue the health care provider should observe **universal precautions** for the prevention of transmission of blood-borne pathogens. Tests for immunoglobulin M (IgM) antibodies to CMV may be falsely positive in persons with rheumatoid arthritis. It is important to remember that an antibody screening test may not be useful in a person without an intact immune system. People with weak immune systems may not generate antibodies against CMV. A suspected infection in a transplant patient or a person with **AIDS** is confirmed with other tests, such as a viral culture, examination of biopsied material for cytopathic effects, or a viral DNA assay such as the polymerase chain reaction.

Description

The most frequently used antibody test for CMV is an enzyme linked immunosorbent assay (ELISA). In this test, CMV antigens are attached to the bottom of the wells of a microtiter plate. An initial dilution of the patient’s serum is added to a well of the plate and incubated. If antibodies to the CMV virus are present they attach to the CMV antigens in the well. The plate is washed and antihuman immunoglobulin G (IgG) or IgM conjugated to alkaline phosphatase is added. This antibody will attach to any antigen-antibody complexes in the wells. The plate is washed again, and substrate (e.g., p-nitrophenylphosphate) is added. The plate is incubated to allow the enzyme to split the phosphate from the substrate, which results in production of a yellow color. After incubating, a reagent (strong alkali) is added to stop the enzyme reaction and the optical density of the wells is measured. The test is interpreted as positive if the optical density of the patient’s sample is equal to or high-

er than the low-level standard. Multiple calibrators can be used to quantify the amount of anti-CMV in the patient's sample. Tests that measure a specific type of antibody help differentiate between a current and a past infection. IgM antibodies appear at the beginning of an infection and last only weeks. IgG antibodies appear 10-14 days later and can last a lifetime. A person suspected of having a current infection should be tested at the beginning of the infection and again 10-14 days later. The CMV antibody screening test is also called the transplant reaction screening test.

Preparation

This test requires 5 mL of blood. Collection of the sample takes only a few minutes.

Aftercare

Discomfort or bruising may occur at the puncture site, or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Applying warm packs to the puncture site relieves discomfort.

Complications

The most common complication is a bruise at the site of the puncture or excessive bleeding. The patient can apply moist warm compresses if there is any discomfort.

Results

A person without previous exposure to CMV will test negative. A positive test for CMV antibodies means the person is infected or has been infected previously with the virus. An antibody titre that is significantly higher at the end of the illness than at the beginning, or the presence of IgM antibodies, indicates a recent or current first-time infection. A positive antibody test does not mean that the person has lifetime immunity. After an infection, this virus, like all members of the herpesvirus group, can stay dormant inside a person and cause infection if the person's immune system later weakens and antibody protection decreases. In fact, reactivation of such latent infection is not uncommon and usually occurs without symptoms.

KEY TERMS

Antibodies—Proteins made by the body to attach to foreign molecules called antigens and aid in their destruction.

Antigen—A marker on the surface of a molecule which stimulates an immune response and can be identified using the specific antibody formed against it.

Titre—A term denoting the concentration of an antibody. The titre is defined as the reciprocal of the highest dilution of the sample that gives a positive reaction.

Health care team roles

CMV antibody tests are ordered and interpreted by a physician. The sample is usually collected by a nurse or phlebotomist. Testing is performed by clinical laboratory scientists/medical technologists. Nurses, nurse practitioners, and physician assistants will educate patient about the purpose of the test, the nature of the CMV infection, and the consequences specific to the individual's situation.

Dance therapy

Definition

Dance therapy is a type of **psychotherapy** that uses movement to further the social, cognitive, emotional, and physical development of the individual. Dance therapists work with people who have many kinds of emotional problems, intellectual deficits, and life-threatening illnesses. They are employed in psychiatric hospitals, day care centers, mental health centers, prisons, special schools, and private practice. They work with people of all ages in both group and individual therapy. Some also engage in research.

Dance therapists try to help people develop communication skills, a positive self-image, and emotional stability.

Origins

Dance therapy began as a profession in the 1940s with the work of Marian Chace. A modern dancer, she began teaching dance after ending her career with the Denishawn Dance Company in 1930. In her classes, she noticed that some of her students were more interested in the emotions they expressed while dancing (loneliness, shyness, fear, etc.) than the mechanics of the moves. She began encouraging them by emphasizing more freedom of movement rather than technique.

In time, doctors in the community started sending her patients. They included antisocial children, people

with movement problems, and those with psychiatric illnesses. Eventually, Chace became part of the staff of the Red Cross at St. Elizabeth's Hospital. She was the first dance therapist employed in a formal position by the federal government. Chace worked with the emotionally troubled patients at St. Elizabeth's and tried to get them to reach out to others through dance. Some of them were schizophrenics and others were former servicemen suffering from **post-traumatic stress disorder**. Success for these patients meant being able to participate with their class in moving to rhythmic music. "This rhythmic action in unison with others results in a feeling of well-being, **relaxation**, and good fellowship," Chace said once.

Chace eventually studied at the Washington School of Psychiatry and began making treatment decisions about her patients along with other members of the St. Elizabeth's medical team. Her work attracted many followers, and the first dance therapy interns began learning and teaching dance therapy at St. Elizabeth's in the 1950s.

Other dancers also began using dance therapy in the 1940s to help people feel more comfortable with themselves and their bodies. These dancers included Trudi Schoop and Mary Whitehouse. Whitehouse later became a Jungian analyst and an influential member of the dance therapy community. She developed a process called "movement in-depth," an extension of her understanding of dance, movement, and depth psychology. She helped found the contemporary movement practice called "authentic movement." In this type of movement, founded on the principles of Jungian analysis, patients dance out their feelings about an internal image, often one that can help them understand their past or their current life struggles. One of Whitehead's students, Jane Adler, furthered Whitehead's work in authentic movement by establishing the Mary Starks Whitehouse Institute in 1981.

In 1966, dance therapy became formally organized and recognized when the American Dance Therapy Association (ADTA) was formed.

Benefits

Dance therapy can be helpful to a wide range of patients—from psychiatric patients to those with **cancer** to lonely elderly people. Dance therapy is often an easy way for a person to express emotions, even when his or her experience is so traumatic he or she can't talk about it. It is frequently used with rape victims and survivors of sexual abuse and incest. It can also help people with physical deficits improve their self-esteem and learn balance and coordination.

Dance therapists also work with people who have chronic illnesses and life-threatening diseases to help them deal with **pain**, fear of death, and changes in their body image. Many people with such illnesses find dance therapy classes to be a way to relax, get away from their pain and emotional difficulties for a while, and express feelings about taboo subjects (such as impending death).

Dance therapy is suitable even for people who are not accomplished dancers, and may even be good for those who are clumsy on the dance floor. The emphasis in dance therapy is on free movement, not restrictive steps, and expressing one's true emotions. Children who cannot master difficult dances or can't sit still for traditional psychotherapy often benefit from free-flowing dance therapy. Even older people who cannot move well or are confined to wheelchairs can participate in dance therapy. All they need to do is move in some way to the rhythm of the music.

Dance therapy can be useful in a one-on-one situation, where the therapist works with only one patient to provide a safe place to express emotions. Group classes can help provide emotional support, enhanced communication skills, and appropriate physical boundaries (a skill that is vital for sexual abuse victims).

Description

There are currently more than 1,200 dance therapists in 46 states in the United States and in 29 foreign countries. Like other mental health professionals, they use a wide range of techniques to help their patients. Some of the major "schools of thought" in dance therapy include the Freudian approach, Jungian technique, and object relations orientation. Many therapists, however, do not ascribe to just one school, but use techniques from various types of dance therapy.

The authentic movement technique is derived from the Jungian method of analysis in which people work with recurring images in their thoughts or dreams to derive meaning in their life. Instead of asking the patient to dance out certain emotions, the therapist instructs the patient to move when he or she feels "the inner impulse."

The moves are directed by the patient and the therapist is a noncritical witness to the movement. The moves are supposed to emerge from a deep level within the patient.

In Freudian technique, dance therapists work with patients to uncover feelings hidden deep in the subconscious by expressing those feelings through dance.

In object relations technique, the therapist often helps the patient examine problems in his or her life by considering the primary initial relationship with the parents. Emotions are expressed in a concrete, physical way. For instance, a patient would work out his fears of abandonment by repeatedly coming close to and dancing at a distance from the therapist.

Dance therapists sometimes use other types of therapy along with dance, such as art or drama. Therapists also discuss what happens during a dancing session by spending time in "talk therapy." Dance therapists use visualizations during sessions, too. For example, the therapist might instruct patients to imagine they are on a beautiful, peaceful beach as they dance.

In one frequently used technique, the therapist mirrors the movements of the patient as he or she expresses important emotions. This is especially powerful in private one-on-one therapy. It is thought that this device provides a sense of safety and validates the patient's emotions.

The underlying premise of dance therapy is that when people dance, they are expressing highly significant emotions. A fist thrust out in anger into the air or a head bent in shame has deep significance to a dance therapist. Through dance therapy, the theory goes, patients are able to more easily express painful, frightening emotions, and can progress from there. After experiencing dance therapy, they can talk about their feelings more freely and tear down the barriers they have erected between themselves and other people. The hope is that eventually they can go on to live more psychologically healthy lives.

Preparations

People who want to use dance therapy should find a qualified therapist. The ADTA provides lists of qualified therapists. The person should begin dance therapy with an open mind and a willingness to participate so he or she can get the most benefit.

Precautions

A qualified dance therapist should have completed a graduate program in dance therapy approved by the ADTA and should be registered with the ADTA. He or

she should not just be a dancer, but should also have extensive training in psychology.

Side effects

No known side effects.

Research and general acceptance

Dance therapy was once dismissed as simply an ineffective, “feel good” treatment, but it is now more respected. Many research studies have proven that dance therapy can be an effective tool to help people overcome psychological problems.

In a 1993 study, older people with cognitive deficits showed that dance therapy could significantly increase their functional abilities. Patients improved their balance, rhythmic discrimination, mood, and social interaction.

In 1999, a pilot study of 21 university students showed that those who took a series of four to five group dance therapy sessions in a period of two weeks significantly reduced their test **anxiety** as measured by a well-known exam called the Test Anxiety Inventory. Afterwards, the subjects reported that their dance movement experience was positive and provided them with psychological insight. The researchers concluded that dance therapy could be a viable method of treatment for students who suffer from overwhelming test anxiety, and should be researched further.

In another 1999 study presented at the ADTA national conference in November 1999, dance therapist Donna Newman-Bluestein reported success in using techniques of dance therapy with cardiac patients. In a **stress** reduction class, health professionals used dance therapy methods to teach body awareness, relaxation, self-expression, creativity, and empathy. According to Newman-Bluestein, the dance therapy techniques helped the patients deal with such stressful emotions as anger, increased their self-awareness, made them more relaxed, and helped them adjust emotionally to having **heart** disease.

Training and certification

Dance therapists should have dance experience and a liberal arts background with coursework in psychology for their undergraduate degree. Professional dance therapy training takes place on the graduate level. A qualified dance therapist has received a graduate degree from a school approved by the ADTA, or has a master’s degree in dance or psychology and has taken additional dance therapy credits.

KEY TERMS

Authentic movement—A type of movement that is influenced heavily by Jungian analysis, and works by analyzing the internal images of the patient. Patients are also urged to dance only when they feel the “impulse” to move.

Freudian analysis—A type of psychological treatment where the therapist seeks to help the patient resolve conflicts and traumas buried in the subconscious.

Jungian analysis—A method of psychological treatment where the patient strives to understand the internal, often mythic images in his or her thoughts and dreams.

Psychotherapy—A medical treatment that seeks to resolve psychological traumas and conflicts, often by discussing them and emotionally reliving difficult events in the past.

Test anxiety—A name for the stress and anxiousness that commonly occur in students before they take exams.

After graduation, dance therapists can become registered with the ADTA, meaning that they are qualified to practice. After two years they may receive an additional recognition when they become an Academy of Dance Therapist Registered. They can then teach dance therapy and can supervise interns.

Dance therapists can also obtain psychological credentials by taking a test and becoming registered by the National Board for Certified Counselors, Inc.

Death and dying

Definition

Death is the end of life, a permanent cessation of all vital functions. Dying refers to the body’s preparation for death, which may be very short in the case of accidental death, or can last weeks or months in some **cancer** patients.

Description

Quality and method of death differs between cultures, circumstances and degrees of preparation. For many years, the terminally ill did not have choices in their manner of death, often enduring excruciating **pain** before the inevitable end of life. In recent years changes have been made to allow for a better quality for end of life, such as hospice care and preparatory actions by the patient.

It is important to recognize the differences in the ways people grieve. Each culture socializes a person in a certain way to deal with death. Death affects a person cognitively, behaviorally and socially. The death and grieving attitudes of a person affect the subjects of death, dying, bereavement, suicide and **euthanasia**. While a person may be able to verbalize feelings about death, internal contradictory feelings of anxiousness are common. Each person handles the subject individually, and seeking appropriate assistance will help the person to come to terms with the event in his or her own time and way.

Hospice care

A diagnosis of terminal illness is a sad and traumatic circumstance. Hospice care provides quality, caring services for both the patient and his or her loved ones. Most communities have a variety of hospice providers. A physician or hospital patient services can assist with provider names. The yellow pages of the phone book, or referral services from United Way, the local council on aging, Visiting Nurse Association or the American Cancer Society are other information sources.

While the patient should be the one to choose hospice care, it is always appropriate to discuss all care options. Hospice staff are sensitive to concerns of both patient and family members and assist in the planning process as requested. Most physicians are aware of the services provided by hospice and will cooperate fully.

The hospice program will work closely with the physician to optimize the patient’s care. The patient will sign consent and insurance forms, which are similar to those signed for hospital admission. There is also a form that states the patient’s understanding that hospice care is aimed at pain relief and symptom control (palliative), rather than curative. Should a patient’s condition improve and hospice services are no longer necessary, or the patient is in remission, services can be discontinued and the patient may return to regular care options. There is no obligation to remain with hospice care if it is not necessary. Should the patient need readmission to the program, medical insurance and **Medicare** may allow additional funding for this purpose.

Once hospice services are approved, the provider will perform a needs assessment, then assist in locating the equipment necessary for the patient’s care. Quite often, the earlier needs are minimal, increasing as the illness becomes more serious. The purpose of hospice care is to make the home environment a comfortable haven for the patient.

The hospice team prepares a plan of care that is tailored to the patient. This will address the amount of care necessary to maintain the patient’s comfort and well-being. The staff visits the home regularly and provides instruction on patient care, as well as answers medical questions and supports the caregivers.

As the illness progresses, care becomes more difficult. Hospice plans provide staff around the clock to consult by phone or to make visits if deemed appropriate. Respite care is also available for exhausted caregivers, so that the home can remain functional.

Hospice patients are cared for by a team of doctors, nurses, counselors, social workers, clergy, and volunteers, among others. Each provides assistance based on

area of expertise. Additionally, **hospices** provide supplies, equipment, medications and other services related to the terminal illness. Hospice does not hasten nor does it delay the death process. However, hospices do provide specialized care that eases some of the **anxiety** and worry that accompany oncoming death.

The management of pain is very often an issue in terminal illness. The mission of hospice is to address all types of pain, not only the physical. Support is available to assist the patient in achieving the highest quality of life possible under individual circumstance. This may include physical and occupational therapists to keep the patient as self-sufficient and mobile as possible. Music therapy, **art therapy**, massage and diet counseling are available. The latest medications and devices for relief from pain and other symptoms is available. Also, counselors, some of whom are clergy members, assist both the patient and the family as needed/requested. However, hospice programs are not affiliated with religious groups and do not expect participants to adhere to any particular belief system.

The goal of the hospice program is to keep the patient both as pain free and alert as possible. Constant communication with the patient and caregivers assist in the high success rate of the hospice program. After the loved one's death, hospice programs provide both individual and group support for caregivers for at least one year, longer if necessary.

Preparing for death legally

An advance directive is a way to allow caregivers to know a patient's wishes, should the patient become unable to make a medical decision. People who are admitted to hospitals must be told about advance directives at the time of admission. Description of the type of care for different levels of illness should be in an advance directive. For instance, a patient may wish to have or not to have a certain type of care in the case of terminal or critical illness or unconsciousness. An advance directive will protect the patient's wishes in these matters.

A living will is one type of advance directive and may take effect when a patient has been deemed terminally ill. Terminal illness in general assumes a life span of six months or less. A living will allows a patient to outline treatment options without interference from an outside party.

A durable power of attorney for health care (DPA) is similar to a living will; however, it takes effect any time unconsciousness or inability to make informed medical decisions is present. A family member or friend is stipulated in the DPA to make medical decisions on behalf of the patient.

While both living wills and DPAs are legal in most states, there are some that do not officially recognize these documents. However, they may still be used to guide families and doctors in treatment wishes.

Do-not-resuscitate (DNR) orders can be incorporated into an advance directive or by informing hospital staff. Unless instructions for a DNR are in effect, hospital staff will make every effort to help patients whose hearts have stopped or who have stopped breathing. DNR orders are recognized in all states and will be incorporated into a patient's medical chart if requested. Patients who benefit from a DNR order are those who have terminal or other debilitating illnesses. It is recommended that this be discussed with a physician by a patient who has not already been considered unable to make sound medical decisions.

None of the above documents are complicated. They may be simple statements of desires for medical care options. If they are not completed by an attorney, they should be notarized and a copy should be given to the doctor, as well as a trusted family member.

Viewpoints

In the Hague, Netherlands, euthanasia was legalized in April 2001, and the country became the first in the world to allow doctors to end the lives of patients with painful, terminal illnesses. The Dutch Senate voted 46-28 in favor of the law, which took effect in the summer of 2001.

Prior to the vote, Health Minister Els Borst assured the legislators that euthanasia would not be abused by doctors because of the strict supervision that would accompany the measure. The practice has been discreetly practiced in the Netherlands for decades, and preliminary guidelines were established by the country's Parliament in 1993.

In the United States, Oregon has permitted doctors to perform assisted suicides since 1996.

Mourning and grieving among cultures

The death of a loved one is a severe trauma, and the grief that follows is a natural and important part of life. No two people grieve exactly the same way, and cultural differences play a significant part in the grieving process. For many, however, the most immediate response is shock, numbness and disbelief. Physical reactions may include shortness of breath, **heart** palpitations, sweating and dizziness. At other times, there may be reactions such as loss of energy, sleeplessness or increase in sleep, changes in appetite, or **stomach** aches. Susceptibility to

common illnesses, nightmares, and dreams about the deceased are not unusual during the grieving period.

Emotional reactions are as individual as physical reactions. A preoccupation with the image of the deceased, feelings of fear, hostility, apathy and emptiness, even fear of one's own death may occur. Depression, diminished sex drive and anger at the deceased, as well as extreme sadness may occur. Bereavement may cause short- or long-term changes in the family unit and other relationships of the bereaved.

It is important for the bereaved to work through their feelings and not avoid emotions. If this does not occur through family, friends, or primary support group methods, then a therapist should be consulted to assist with the process.

Various cultures and religions view death in different manners and conduct mourning rituals according to their own traditions. In the Christian faith, bodies of deceased are normally on view at a funeral parlor for one or more days before the actual funeral service. Specific hours are given for visitation or viewing.

Visitors come to express their condolences to the family and to bid farewell to the deceased. At times, funeral services are private. Various ethnic groups host a gathering after the funeral for those who attended. If it is held at the family's home, very often relatives and others will bring food and drink. Others choose to hold this event at a restaurant or some other public venue. It is common for these events to become a celebration of the life of the deceased, which also helps the bereaved to begin the mourning process positively. Memories are often exchanged and toasts made in memory of the deceased. Knowing how much a loved one is cherished and remembered by friends and family is a comfort to those who suffer the loss. Other methods of condolences include sending flowers to the home or the funeral parlor; sending a mass card (for Catholics); sending a donation to a charity that the family has chosen; bringing a meal to the family during the weeks after the death.

In the Jewish culture, bodies are buried as soon after death as possible, even as early as sundown of the day after death. For the Jewish population, this marks a sign of respect to the deceased. A seven-day period of mourning follows, which is called *Shiva* or sitting *Shiva*. Friends and community visit the family and often bring food, so that the family does not have to worry about meals. Normal activities are suspended for the family of the deceased at this time, so that the bereaved can focus fully on their grief, thus enabling them to re-enter life a bit easier after the period of mourning. The first meal that is served after return from the cemetery is called *seudat havrach*, prepared by friends and neighbors. Eggs and

other round objects are traditionally served. These are objects that are symbolic of life, hope and the full circle of life, which ends in death. Flowers are not traditional; however, donations to charities chosen by the family are acceptable in memory of the deceased.

In the Muslim faith, everyone accompanies the funeral procession to the gravesite. The permitted mourning period for a deceased Muslim is three days, except for a widow, who is permitted to mourn her spouse for four months and 10 days. Traditionally, people leave the gravesite after offering condolences and offering assistance. However, some families do hold gatherings at home. Friends and neighbors bring food and drink to alleviate the family from the worry of providing refreshments. Flowers are often sent after the funeral to the family's home.

Buddhists normally hold a funeral within a week after the death. Flowers or a donation to a charity in the deceased's name are appropriate signs of respect. Caskets are often open, and guests are expected to view the deceased and bow slightly toward it. Friends are invited to call at the deceased's home after the funeral service but not before. The funeral service itself is usually held within 24 hours after the death. Then the body is kept at home until the traditional cremation ceremony. Flowers are acceptable from visitors and are placed at the feet of the deceased. Fruit is also a customary gift to bring to the family.

Professional implications

The primary concern of health care workers in most cases is preserving the life and health of an individual. Severely ill patients may be given **nutrition** and fluids intravenously or have their breathing supported by a ventilator. In cases in which the heart stops, **CPR (cardiopulmonary resuscitation)** is performed. In the case of terminally ill, dying patients, the role of health care professionals is to provide palliative care, to ensure that proper arrangements are made for the person after death, and to address the concerns of family members.

Physical signs

The causes of death vary greatly. Injuries, illness and more violent deaths occur routinely. However, as the time of death grows near for the dying, certain signs are common as their bodies begin to shut down. The time variable is as much as a few days and as little as a few hours. There is no particular order of events and not everyone experiences all of them. Support and caring by those surrounding the dying person are essential to make the passing as comfortable and with as little **stress** as possible.

The health care professional should keep the patient comfortable. Eggshell mattresses or foam cushions can prevent bedsores, as can changing the patient's position in bed. Sheets should be changed at least twice a week. Helping the patient with mouth care often makes him or her feel better.

There will be less interest in eating and drinking. Refusal of food indicates a readiness to die. Fluid intake may be reduced to only as much as will keep the mouth from feeling dry. At this time it is important for caretakers to offer food, drink, and medications, but they should not be forced. Pain may not be an issue when the end is near, so the patient may not feel the need for the medication.

The patient will begin to sleep more and begin to detach from his or her surroundings. The caregiver should not interfere, except to make the patient as comfortable as possible. The caregiver's presence is the most important factor.

Mental confusion may occur as less oxygen reaches the **brain**. Loss of **hearing** and **vision** may occur. The patient may complain of strange dreams. The caregiver should gently remind the patient of the day and time, who is present, and where the patient is at the moment. This should be done in a conversational manner. The caregiver should speak louder than normal if that is necessary, but not draw attention to the patient's loss of senses.

The room should be kept at the light and temperature that the patient requests. All conversations should be carried on as if the patient were aware. Hearing is the last of the senses to leave entirely, even in the case of stroke victims who sometimes appear completely unaware. However, many patients are able to speak even just a few minutes before death and are reassured by loving words.

Secretions may collect at the back of the throat. This may cause a gurgling sound as the patient breathes and possibly tries to cough up mucus. A cool mist humidifier in the room may help. If not, it may be advisable to turn the patient on his or her side, propped up with pillows, so that secretions can drain out of the mouth. The caregiver can cleanse the mouth with glycerin-dipped swabs, mineral oil, or cool water.

Near the end, there may be periods of non-breathing or irregular breathing. As death comes nearer, breathing may resume regularity but become shallow and mechanical. The patient may become agitated, try to get out of bed, hallucinate or pull at the bed linens. The caregiver should calmly reassure the patient and try to prevent the patient from falling if an attempt is made to get out of bed. A massage or soothing music may help.

As circulation slows down, the patient may lose the ability to realize his or her body temperature. The arms will become cool and begin to turn a bluish color. The underside of the body may darken. The caretaker should provide additional blankets or remove them as necessary. The patient should be kept as comfortable as possible.

Loss of control of the bladder and bowel may occur at the time of death. Breathing and heartbeat will stop. The jaw may sag open slightly as it relaxes. The eyelids may close partially, but the eyes will be fixed.

After a patient dies, health care staff allow family members time to grieve with the body before starting post-mortem procedures.

Decompression sickness

Definition

Decompression sickness (DCS) is a dangerous and occasionally lethal condition caused by nitrogen bubbles that form in the **blood** and other tissues of scuba divers who surface too quickly. It also occurs in the blood of tunnelers or miners who work in conditions of increased pressure and return to normal atmospheric pressure too quickly.

A hyperbolic chamber is used to treat patients for decompression sickness, or “the bends.” (AP/Wide World Photos. Reproduced by permission.)

Description

According to the Divers Alert Network (DAN), a worldwide organization devoted to safe-diving research and promotion, fewer than 1% of divers fall victim to DCS or the rarer bubble problem called **gas embolism**, air embolism, or arterial gas embolism (AGE). A study of the U.S. military community in Okinawa, where tens of thousands of sport and military dives are made each year, identified 84 cases of decompression sickness and 10 instances of arterial gas embolism between 1989 and 1995. These numbers included 9 deaths. Translated, this provides an estimated incidence of one case of decompression sickness in every 7,400 dives and one death in every 76,900 dives. Since symptoms of decompression sickness can be quite mild, many cases go unnoticed by divers; thus this estimate is probably understated.

Different terminology is used in discussing decompression sickness and it can be confusing. Sometimes the term illness is used instead of sickness. Others treat decompression illness as a term that encompasses both decompression sickness and arterial gas embolism. An older term for decompression sickness is caisson disease.

This term was coined in the nineteenth century, when bridge construction crews working at the bottom of lakes and rivers in large pressurized enclosures (caissons) were found to experience joint **pain** (a typical symptom of decompression sickness on returning to the surface).

Causes and symptoms

The air we breathe is mostly a mixture of two gases, nitrogen (78%) and oxygen (21%). Unlike oxygen, nitrogen is a biologically inert gas, meaning that it is not metabolized (converted into other substances) by the body. For this reason, most of the nitrogen we inhale is expelled when we exhale, but some is dissolved into the blood and other tissues. During a dive, however, the **lungs** take in more nitrogen than usual. This happens because the surrounding water pressure is greater than the air pressure at sea level (twice as great at 33 ft [10 m], for instance). As the water pressure increases, so does the pressure of the nitrogen in the compressed air inhaled by the diver. Because increased pressure causes an increase in gas density, the diver takes in more nitrogen with each breath than would occur at sea level. But instead of being exhaled, the extra nitrogen safely dissolves into the tis-

sues, where it remains until the diver begins the return to the surface. Under some circumstances, the extra dissolved nitrogen can cause nitrogen narcosis, although this condition is different from decompression sickness. On the way up, decompression occurs; in other words, the water pressure drops. With the decrease in pressure, the extra nitrogen gradually diffuses out of the tissues and is delivered by the bloodstream to the lungs, which expel it from the body. If the diver surfaces too quickly, potentially dangerous nitrogen bubbles can form in the tissues and cause decompression sickness. These bubbles can compress nerves, obstruct arteries, veins, and lymphatic vessels, and trigger harmful chemical reactions in the blood. The precise reasons for bubble formation remain unclear.

How much extra nitrogen enters the tissues varies with the dive's depth and the duration of the dive. Dive tables prepared by the U.S. Navy and other organizations specify how long most divers can safely remain at a particular depth. If the dive table limits are exceeded, the diver must pause on the way up, to allow the nitrogen to diffuse out of tissues and into the bloodstream without forming bubbles. These pauses are called decompression stops and are carefully calibrated. Decompression sickness can occur, however, even when a diver obeys safe-diving rules. In such cases, the predisposing factors include fatigue, **obesity**, **dehydration**, hypothermia, and recent alcohol use. People who fly or travel to high-altitude locations without letting 12–24 hours pass after their last dive are at risk for DCS, because their bodies undergo further decompression. This is true even when flying in commercial aircraft, since the cabin pressure in commercial aircraft is set much lower than the pressure at sea level. At 30,000 ft (9,144 m), for instance, cabin pressure is usually equivalent to the pressure at 7,000–8,000 ft (2,133–2,438 m) above sea level, a safe level for everyone except people who have recently been diving. Exactly how long a diver should wait before flying or traveling to a high-altitude location depends on how much time has been spent diving. If there is uncertainty about the appropriate waiting period, the sensible course of action is to let a full 24 hours pass.

Since the nitrogen bubbles that cause decompression sickness can affect all body tissues, many different symptoms are possible. Symptoms can appear minutes after a diver returns to the surface. The appearance of symptoms occurs within eight hours in about 80% of cases. Pain is often the only symptom. This is sometimes called “the bends,” although many people incorrectly use that term as a synonym for decompression sickness. Pain, which ranges from mild to severe, is usually limited to the joints, but can be felt anywhere. Severe itching (pruri-

tus), skin rashes, and skin mottling (*cutis marmorata*) are other relatively common symptoms. All of these are sometimes classified as manifestations of Type 1 or “mild” decompression sickness. Type 2 or “serious” decompression sickness can result in **paralysis**, **brain damage**, **heart** attack, and death. Many persons with decompression sickness experience both Type 1 and Type 2 symptoms.

Diagnosis

Diagnosis is determined by taking a thorough medical history and conducting a **physical examination**.

Treatment

Decompression sickness is treated by giving the affected person oxygen and placement in a hyperbaric chamber. A hyperbaric chamber is an enclosure in which the air pressure is first gradually increased and then gradually decreased. This shrinks the bubbles and allows the nitrogen to safely diffuse out of the tissues. Hyperbaric chamber facilities exist throughout the United States. No matter how mild symptoms may appear, immediate transportation to a facility with a hyperbaric chamber is essential. Treatment is necessary even if the symptoms clear up before the facility is reached, because bubbles may still be in the bloodstream and still pose a threat. The Divers Alert Network maintains a list of facilities and a 24-hour hotline that can provide advice on handling decompression sickness and other diving emergencies.

Prognosis

People suffering from decompression sickness who undergo chamber treatment within a few hours of symptom onset usually enjoy a full recovery. If treatment is delayed, the consequences are less predictable, although many people have been helped even after several days have passed. A 1992 report on diving accidents indicated that full recovery following chamber treatment was immediate in about 50% of divers. Some people, however, suffer numbness, tingling, or other symptoms that last for weeks, months, or even a lifetime. In another study, 6 out of 94 (6.4%) persons experienced long-lasting symptoms even after repeated chamber treatments.

Health care team roles

Paramedics often make the initial diagnosis of decompression sickness. Physicians supervise treatment in a hyperbaric chamber, while RNs provide support and monitor the patient during the period of decompression.

KEY TERMS

Cutis marmorata—Skin that has a marbled appearance due to conspicuous veining of small vessels.

Gas embolism—The presence of a gas bubble in the bloodstream that obstructs circulation.

Hyperbaric chamber—A sealed compartment in which air pressure is gradually increased and then gradually decreased, allowing nitrogen bubbles to shrink and the nitrogen to safely diffuse out of body tissue.

Lymphatic vessels—Vessels that carry a plasma-like fluid called lymph from tissues to the bloodstream.

Nitrogen narcosis—Also called “rapture of the deep,” the condition is caused by increased nitrogen pressure at depth and is characterized by symptoms similar to alcohol intoxication.

Pruritus—The symptom of itching or an uncontrollable sensation leading to the urge to scratch.

Prevention

The obvious way to minimize the risk of decompression sickness is to follow the rules of safe diving and air travel after a dive. People who are obese, suffer from lung or heart problems, or are otherwise in poor health should not dive. Because the effect of nitrogen diffusion on the fetus remains unknown, diving while pregnant is not recommended.

Defibrillators, portable

Definition

A portable defibrillator is a device, often automated and generally weighing less than 5 lbs (2.2 kilograms), that is commonly used in non-hospital settings to administer a shock and re-establish a regular heartbeat to treat sudden cardiac arrest.

Purpose

Rapid defibrillation is the most significant factor in the survival of the abrupt disruption of the **heart** function known as sudden cardiac arrest (SCA). In non-hospital

settings, the most common method of administering such a shock is by using a portable defibrillator, also known as an automated external defibrillator (AED). AEDs are now common equipment in airports, malls, casinos, golf courses, businesses, hotels, schools, on airplanes, and through various emergency response groups such as the police, fire departments, and paramedic squads.

Contrary to the perception portrayed by television and movies, defibrillation is not effective in treating hearts showing a flat-line electrocardiogram (ECG). Instead, defibrillation is most effective in reversing arrhythmias (abnormal rhythms of the heart) such as those that can cause SCA. This condition is often characterized by ventricular fibrillation, a rapid, nonproductive contraction of the ventricles. To treat this problem, the shock stops the chaotic electrical activity and allows the natural pacemaker of the heart, the sinoatrial node, to regain control of the beat.

SCA is the cause of death of more than 350,000 Americans per year, striking persons of all ages and in both sexes equally. Unlike a heart attack, SCA often occurs without warning symptoms. The American Heart Association estimates that nearly 300 persons per day would be saved if everyone who suffered from SCA had access to treatment with an AED within 10 minutes. AED models are now available for treatment of adults, children, and infants.

Because many AEDs include an ECG display, the device can also be used during cardiac emergencies to monitor and record the heart's electrical signals before, during, and after any given treatment. This is true even when the person suffers from a heart condition that does not warrant administering a shock, as determined by the device's automatic analysis of the heart problem.

Description

AED devices include an ECG to monitor the heartbeat of the patient, software and voice prompting to guide the operator, other software to analyze the advisability of administering a shock, and a shock generator to administer a shock of set duration and power. The device itself is enclosed in a case that includes a display, a speaker, leads running to two pad-shaped electrodes, and two buttons (power and shock). More sophisticated versions of this device can include manual over-rides (for control by trained medical personnel of the power and duration of the shock) and pacing abilities.

Generally, defibrillators are available that produce two types of shocks, monophasic and biphasic. Monophasic shocks move from one electrode to the other, while biphasic shocks move from one electrode to the other, and then reverse direction. Biphasic shocking

A portable defibrillator is used in an attempt to revive a man who suffered a heart attack before he is transported to an emergency room. (Photograph by Adam Hart-Davis. Science Source/Photo Researchers. Reproduced by permission.)

is usually more effective than monophasic in taking a heart out of fibrillation and is associated with less post-treatment heart or **brain** dysfunction. Biphasic shocking, combined with pre-shock impedance measurements, is a method particularly successful in treating obese patients, a situation that can be a challenge to other types of defibrillation therapies.

The analysis of the heartbeat is done using an algorithm (a sequence of mathematical steps) that compares the electrical output of the patient's heart to known heartbeats to determine if a shock should be administered. The four characteristics of the output examined are rate, conduction, stability, and amplitude. Rate is measured in beats per minute (bpm), with normal being between 60 and 100. Increased rate is characteristic of many common arrhythmias. Conduction is evaluated by looking at the characteristics of the R wave of the ECG, which is the portion of the electrical signal of the heart where there is a tall, narrow spike. Rounded wide R waves can indicate problems with conduction.

Stability of the heartbeat is evaluated by comparing one heartbeat signal to the next. In healthy hearts, the beats repeat themselves with a regular pattern. Unhealthy hearts have varied beat signals, an indication of instability. Finally, the algorithm looks at the amplitude (height) of the electrical signal put out by the heart. Lowered amplitude is a characteristic of an unhealthy heart.

KEY TERMS

Algorithm—A sequence of mathematical steps used by an automated external defibrillator to evaluate whether a shock is appropriate treatment for the patient attached to the machine's electrodes.

Biphasic—A term to describe a defibrillation shock that travels from one electrode to another and back again.

Monophasic—A term to describe a defibrillation shock that travels from one electrode to the other.

Additionally, many AEDs have systems to filter out artifacts, electrical signals that do not come from the heart of the patient being evaluated and that may interfere with the evaluation process.

Operation

The operation of an AED is as straightforward as possible so a person can use the machine correctly even without training. When in automatic mode, the machine provides voice and display prompts to guide the operator through its use. Many models have only two buttons, a green power button and an orange or other brightly-colored shock button.

The use of a defibrillator to treat SCA is one part of a four-step program known as the chain of survival. The four critical steps include early access to emergency care (by calling 911 or another emergency number), early **cardiopulmonary resuscitation (CPR)**, early defibrillation, and early advanced cardiac support. Thus, before using an AED, the operator should have someone call 911 and then begin CPR, if possible.

AEDs should only be used on individuals who are unresponsive, not breathing, and have no pulse. On activation, the machine asks the operator to confirm that these conditions are present. Next, the operator is directed to place the electrode pads on the collapsed person. The two pads are placed on the chest, one on the patient's upper right chest area, and the other below the ribs on the patient's left side. Often, there is a diagram on the machine to aid in electrode placement. At this point, the machine directs the operator to plug in the electrodes, guided by a light. Some machines skip this step, as the electrodes are permanently attached.

The machine then directs everyone to stand clear of the patient so that the heartbeat can be evaluated. If the

condition can be treated with a shock, the operator is directed to both visually and verbally clear the area around the patient and then push the shock button. After the shock is delivered, the machine automatically checks the heartbeat for change and, if further shocks are needed, the machine directs their delivery.

Maintenance

Older AEDs require periodic maintenance and calibration by using external devices, sending the machine to the factory, or service contracts with outsource providers of maintenance. However, newer machines have internal maintenance programs that carry out the required routine performance checks and function adjustments. Many will check the ability of the machine's shock function on a daily basis. The internal maintenance functions, combined with heavy-duty, easy-to-carry external casings, facilitate the use of AEDs as emergency equipment in non-health care settings. Wall mountings such as those that are used for fire extinguishers are available to keep the equipment in sight but protected.

Health care team roles

AEDs are specifically designed to be used by people who have no medical training. Indeed, a study using AEDs showed that sixth grade students, without the benefit of training or ability to ask questions, took only 30 seconds longer to administer a shock than trained emergency technicians.

In a hospital setting, portable defibrillators are often available for use by hospital personnel in order to assure quick access to defibrillation equipment in intensive care units and other areas of the hospital where SCA might occur. The manual settings found on more sophisticated units can be used by health care providers such as doctors, nurses, paramedics, and **emergency medical technicians** who have training in advanced life support techniques. Their training allows them to identify specific abnormal rhythms that may require different energy settings for the most effective correction.

Training

When an AED program is implemented, for example, by a business, training for the employees is often accomplished using a four-hour course, with refreshers suggested every three months. Training programs are available from the company that manufactures the AED or from organizations such as the American Red Cross.

Dehydration

Definition

Dehydration is the excessive loss of water from body tissues accompanied by an imbalance in essential electrolytes, such as sodium, potassium, and chloride.

Description

Dehydration occurs when the body loses more fluid than it takes in. Dehydration can be caused by illness, injury, **infection**, prolonged exposure to sun or high temperatures, inadequate water intake, or overuse of diuretics or other medications that increase urination.

Water is distributed throughout three compartments in the body: inside the cells (intracellular), in the tissue (interstitial), and in the bloodstream (intravascular). Each compartment contains differing amounts of electrolytes that must remain in balance in order for body organs and systems to function correctly. Dehydration upsets this delicate balance. Total body water also varies in relation to age, gender, and amount of body fat. Adult males have approximately 60% water content, adult females have

50%, infants have an estimated 77%, and the elderly have 46% to 52%. An increase in body fat causes a decrease in the percent fluid content because fat does not contain significant amounts of water.

Causes and symptoms

Different types of dehydration have different causes. When managing patients with dehydration, the type of water loss must be determined to ensure appropriate treatment. In addition, water and sodium levels in the body are closely related; if one is abnormal, the other often is too.

Isotonic dehydration is an equal loss of water and sodium. Isotonic means that the number of particles contained on one side of a permeable membrane is the same as on the other side, thus there is no fluid shift in either direction. The amount of intracellular and extracellular water remains in balance. This can be caused by a complete fast, vomiting, and **diarrhea**.

Hypertonic dehydration occurs when water loss is greater than sodium loss. **Blood** sodium levels may be >145 mmol/l (normal range=135 to 145 mmol/l). Higher blood sodium levels combined with decreased water in the intravascular space increases the osmotic pressure in the bloodstream, which, in turn, pulls more fluid out of the cells. This type of dehydration is usually caused by extended **fever** with limited oral rehydration. Mortality is more likely to occur from hypertonic than from isotonic dehydration.

Hypotonic dehydration occurs when sodium loss is greater than water loss. Blood sodium levels may be less than 135 mmol/l; and the osmotic pressure is greater inside the cells, which pulls more fluid out of the intravascular space into the intracellular space. This type of dehydration occurs with overuse of diuretics, which causes excessive sodium and potassium loss. Potassium depletion affects respiration, increases nausea, and, if severe enough, may cause respiratory arrest or **central nervous system** (CNS) seizures. Potassium depletion may also cause arrhythmias (an alteration in the heart-beat). As a result, patients are told to take diuretics with orange juice or to eat a banana, both of which are high in potassium.

Strenuous activity, excessive sweating, prolonged time in the sun, and extended vomiting or diarrhea cause fluid loss. Elderly people who move to warm, dry climates frequently become dehydrated because of the climate change combined with a tendency to not drink enough water. Large amounts of fluid can also be lost from prolonged fever. Healthy people require about 1 milliliter of water for each calorie their body metabo-

lizes; but during a fever the metabolic rate increases by seven percent for each 1°F rise in body temperature. Fever also increases the respiratory rate, resulting in additional water loss from the **lungs**. Further causes of fluid loss that may be overlooked include **caffeine** and alcohol consumption, which increase urination and fluid excretion.

Decreased oral intake of fluids is a common cause of dehydration and often occurs during times of appetite loss from illness or after oral surgery or injury. The elderly are at high risk for decreased intake because their thirst mechanism may no longer function or they may be physically unable to get a drink. Infants, another high-risk group, are more likely to develop dehydration than adults because they have a higher metabolic rate and their immature **kidneys** have difficulty concentrating urine. Children who do not wet their diapers for three hours or more are dehydrated. Dehydration is also associated with disorders of the **adrenal glands**, which regulate water-electrolyte balance; **diabetes mellitus**; eating disorders; renal disease; and chronic lung disease.

Symptoms of dehydration at any age may include some or all of the following: cracked lips, dry or sticky mucous membranes, sunken eyes, lethargy, and/or confusion. Urine output is minimal and the skin loses its elasticity (turgor) and is slow to return to its normal position after being raised off the back of the hand (tenting). The **heart** rate and respiratory rate may be elevated. A dehydrated infant may not shed tears when crying and may have a depressed fontanel (soft spot on their head), although recent studies have shown that a depressed fontanel is not an accurate indicator of dehydration.

Diagnosis

The general diagnosis of dehydration can be made based on the patient's symptoms and medical history. **Physical examination** may reveal any of the symptoms mentioned above, along with **shock**, rapid heart rate, and low **blood pressure**. Blood tests are required to determine what deficiency exists (or what is elevated) so that therapy for electrolyte replacement can be planned. Blood tests to check electrolyte levels and urine tests such as urine specific gravity are used to evaluate the severity of the fluid loss. Other laboratory tests may be ordered to determine if an underlying condition (e.g., diabetes or an adrenal gland disorder) is the cause.

Treatment

Increased fluid intake and replacement of lost electrolytes are usually sufficient to restore **fluid balance** in patients who are mildly or moderately dehydrated. For

individuals who are mildly dehydrated, just drinking plain water may be all the treatment that is needed. Adults may replace lost electrolytes by drinking sports beverages, such as Gatorade or Recharge. Parents should follow label instructions when giving children Pedialyte or other commercial products recommended for the treatment of dehydration in children. Children who are dehydrated should be given only clear fluids for the first 24 hours.

A child who is vomiting should sip one or two teaspoons of liquid every 10 minutes. A child who is less than a year old and who is not vomiting should be given one tablespoon of liquid every 20 minutes. A child who is more than one year old and who is not vomiting should take two tablespoons of liquid every 30 minutes. A baby who is being breast-fed should be given clear liquids for two consecutive feedings before breastfeeding is resumed. A bottle-fed baby should be given formula diluted with water to half the formula strength for the first 24 hours after symptoms of dehydration are identified.

To calculate fluid loss accurately, weight changes should be charted every day and a record kept of how many times a patient vomits or has diarrhea. A record of fluid output (including sputum or vomit) and of fluid intake or replacement should be kept for at least 24 to 48 hours to see if balance is being accomplished. Parents should note how many times a baby's diaper must be changed. If dehydration continues, emergency department treatment or hospitalization to receive intravenous fluids and electrolytes may be necessary.

Children and adults can gradually return to their normal diet after they have stopped vomiting and no longer have diarrhea. Gelatin is often a welcomed substitute for additional water and does count as fluid replacement. Bland foods should be reintroduced first, with other foods added as the **digestive system** is able to tolerate them. Milk, ice cream, cheese, and butter should not be eaten until 72 hours after symptoms have disappeared.

When treating dehydration, the underlying cause must be addressed. For example, if dehydration is caused by vomiting or diarrhea, medications should be prescribed to resolve these symptoms. Patients who are dehydrated due to diabetes, kidney disease, or adrenal gland disorders must receive treatment for these conditions as well as for the resulting dehydration. If dehydration is being caused by diuretics, a dose adjustment made by the physician or a change to a different diuretic may be necessary.

Prognosis

Mild dehydration rarely results in complications. If the cause is eliminated and lost fluid is replaced, mild dehydration can usually be resolved in 24 to 48 hours. Vomiting and diarrhea that continue for several days without adequate fluid replacement can be fatal since more is lost than water and sodium. Severe potassium loss may lead to cardiac arrhythmias, respiratory distress or arrest, or convulsions (seizures). The risk of life-threatening complications is greater for young children and the elderly. However, dehydration that is rapidly recognized and treated has a good outcome.

Health care team roles

The nurse and the physician have the greatest responsibility in recognizing and treating dehydration. For hospitalized patients, the physician should order appropriate fluid and electrolyte replacement and the nurse should ensure that the correct fluids are given to the patient. The nurse should monitor the patient for signs that the dehydration (e.g., decrease in fever, increase in blood pressure, reduced heart rate) is resolving and should notify the physician if it is not.

Blood tests used to diagnose dehydration are collected by specially trained nursing assistants or by laboratory technicians. Outpatient samples in a physician's office may be taken by the nurse or a technician. In some institutions, the nurse collects the blood sample. Usually, urine samples are collected by the nurse, and results calculated by the laboratory technician.

Prevention

Patients who are vomiting or who have diarrhea can prevent dehydration by drinking enough fluid to keep their urine the color of pale straw. Infants and young children with diarrhea and vomiting can be given electrolyte solutions such as Pedialyte to help prevent dehydration, as well as suppository medication to stop the vomiting. People who are not ill can maintain proper fluid balance by drinking several glasses of water before going outside on a hot day. It is also a good idea to avoid coffee and tea, which increase body temperature and water loss.

Patients should ask a pharmacist whether or not any medications they are taking may cause dehydration and what to do to prevent it other than adequate fluid intake. Prompt medical attention should be sought to correct any underlying condition that increases the risk of dehydration.

KEY TERMS

Extracellular—Outside the cells.

Hypertonic—One solution having a greater amount of solute (dissolved substance in a solution) than another solution, thus it exerts more osmotic pressure than the second solution and the body will attempt to equalize pressure by passing fluid through the cell membranes.

Hypotonic—One solution having a lesser amount of solute than another solution, thus it exerts less osmotic pressure than the second solution.

Intracellular—Inside the cells.

Isotonic—Two solutions exerting the same amount of osmotic pressure on a cell membrane.

Osmotic pressure—The pressure exerted on a semipermeable membrane that separates two solutions and the particles they contain.

Dementia

Definition

Dementia is a condition characterized by a progressive, irreversible decline in mental ability, accompanied by changes in behavior and personality. There is commonly a loss of **memory** and skills that are required to carry out activities of daily living.

Description

Dementia is a group of symptoms caused by the gradual death of **brain** cells. The loss of cognitive abilities that occurs with dementia leads to impairments in memory, reasoning, planning, and personality. Dementia can occur at any age and may affect younger people as the result of disease such as **AIDS**, hypoxia (a deficiency of oxygen reaching the tissues of the body), or injury. However, it is primarily a disease of the elderly, affecting more than 15% of those over 65 years of age, and as many as 40% of those over the age of 80. The condition is somewhat more common among women than men. Some studies suggest that the risk for dementia is higher for African Americans and Hispanic Americans than it is for Caucasians. More than half of all nursing home admissions occur because of dementia.

While the overwhelming majority of people with dementia are elderly, it is not an inevitable part of aging. One of the challenges for health care professionals is to differentiate the early-stage cognitive deficits of dementia from normal age-related memory impairment. Persons with age-related memory impairment may tend to learn new information more slowly; but, if they are given additional time, their cognitive performance is usually adequate. Other problems that may be mistakenly labeled dementia include delirium, psychosis, depression, and the side effects of various medications.

Dementia presents a major health problem for the United States because of its huge impact on individuals and their families, the health care system, and society overall. The costs of dementia are considerable. While most people with the disease are retired and do not suffer income losses, the cost of care is often enormous. Financial burdens include lost wages for family caregivers, medical supplies and drugs, and home modifications to ensure safety. Nursing **home care** may cost several thousand dollars a month or more. As of 1998, the cost of caring for Alzheimer's dementia patients alone was estimated to be slightly over \$50 billion. The psychological costs are not as easily quantifiable, but can be even more profound. The person with dementia loses control of many of the essential features of life and personality, and loved ones lose a family member even as they continue to cope with the burdens of increasing dependence and unpredictability.

Causes and symptoms

Causes

Dementia is usually caused by degeneration in the cerebral cortex, the part of the brain responsible for thoughts, memories, actions, and personality. Death of

brain cells in this region leads to the cognitive impairment that characterizes dementia. Dementia may be caused by a variety of illnesses.

The most common cause of dementia is Alzheimer's disease (AD), accounting for half to three-quarters of all cases.

Vascular dementia accounts for 5–30% of all dementias in the United States. It occurs from a decrease in **blood** flow to the brain, most commonly due to a series of small strokes (multi-infarct dementia). Other cerebrovascular causes include vasculitis from syphilis, Lyme disease, or systemic lupus erythematosus; subdural hematoma; and subarachnoid hemorrhage. Because of the usually sudden nature of its cause, the symptoms of vascular dementia tend to appear more abruptly than those of Alzheimer's dementia. Symptoms may progress with the occurrence of new strokes. Unlike AD, the incidence of vascular dementia decreases after the age of 75.

Other conditions that may cause dementia include:

- AIDS
- Parkinson's disease
- Lewy body disease
- Pick's disease
- Huntington's disease
- Creutzfeldt-Jakob disease
- brain tumors
- hydrocephalus
- head trauma
- prolonged abuse of alcohol or other drugs
- **vitamin B₁₂** deficiency
- hypothyroidism
- hypercalcemia

Symptoms

Dementia is marked by a gradual decline of thought and other mental activities. The onset may be slow, occurring over months or years. The slow progression of dementia is in contrast with delirium, which involves some of the same symptoms, but has a very rapid onset and fluctuating course with alteration in the level of consciousness. However, delirium may occur along with dementia, especially since the person with dementia is more susceptible to the delirium-inducing effects of many types of drugs.

Symptoms of dementia may include:

- Memory losses: Memory loss is usually the first symptom noticed. It may begin with misplacing valuables

such as a wallet or car keys, then progress to situations such as forgetting appointments, where the car was left, or the route home. More profound losses follow, such as forgetting the names and faces of family members.

- **Impaired abstraction and planning:** The person with dementia may lose the ability to perform familiar tasks, to plan activities, and to draw simple conclusions from facts.
- **Language and comprehension disturbances:** The person may be unable to understand instructions, or follow the logic of moderately complex sentences. Later, the individual may not be able to understand his or her own sentences, and have difficulty forming thoughts into words.
- **Poor judgment:** The person may not recognize the consequences of his or her actions or be able to evaluate the appropriateness of behavior. Behavior may become ribald, overly friendly, or aggressive. Personal hygiene may be ignored.
- **Impaired orientation:** The person may not be able to identify the time of day, even from obvious visual clues; or may not recognize a location, even if familiar. This disability may stem partly from losses of memory and partly from impaired abstraction.
- **Decreased attention and increased restlessness:** These symptoms may cause the person with dementia to begin an activity and quickly lose interest, and to wander frequently. Wandering may cause significant safety problems, when combined with disorientation and memory losses. The person may begin to cook something on the stove, then become distracted and wander away while it is cooking.
- **Personality changes and psychosis:** The person may lose interest in once pleasurable activities, and become more passive, depressed, or anxious. Delusions, suspicion, paranoia, and hallucinations may occur later in the disease. Sleep disturbances may occur, including insomnia and sleep interruptions.

Diagnosis

Since dementia usually progresses slowly, diagnosing it in the early stages can prove difficult. However, as the elderly population grows and the prevalence of dementia increases, the importance of recognizing the early symptoms has become imperative.

Dementia may be suspected by the health care professional if memory deficits are exhibited during an examination or assessment. Information from the family members, friends, and caregivers may point to dementia as well. Diagnosis begins with a thorough physical exam

and complete medical history. A family history of either **Alzheimer's disease** or cerebrovascular disease may provide clues to the cause of symptoms. Simple tests of mental function, including word recall, object naming, and number-symbol matching, are used to track changes in the person's cognitive ability. If dementia is suspected, a complete review of medications and an assessment for chronic disease processes are indicated. If the patient shows no improvement after eliminating unnecessary medications and treating the chronic disease, then other tests are warranted. **Physical examination** and a variety of laboratory tests may rule out potentially treatable causes of dementia. These may include **hearing** or visual deficits, hypothyroidism, vitamin B₁₂ deficiency, and depression. Some of the laboratory tests that might be performed include a complete blood cell count and **urinalysis** (to rule out **infection**), serum electrolytes, glucose and **calcium** levels, and kidney and **liver function tests**.

The use of computed tomography (CT) or **magnetic resonance imaging** (MRI) to rule out vascular disease is somewhat controversial, since even if a cause is discovered, less than 11% of patients with cognitive decline have partially or fully reversible disease.

Treatment

Treatment of dementia starts with treatment of the underlying disease, where possible. The underlying causes of nutritional, hormonal, tumor-caused, and drug-related dementias may be reversible to some extent. Treatment for stroke-related dementia begins by minimizing the risk of further strokes, including smoking cessation, aspirin therapy, and treatment of **hypertension**. There are no known therapies that can reverse the progression of Alzheimer's disease.

Early intervention may allow the patient to compensate for the alterations in functioning, help to minimize complications, and have an improved quality of life. It may also allow the patient and family to plan for the future and to identify resources.

Periodically, new drugs are studied for the treatment of dementia. The only drugs currently approved for the symptomatic treatment of AD are tacrine (Cognex) and donepezil (Aricept). These drugs act by slowing down the degradation of neurotransmitters. They may provide temporary improvement in cognitive functioning for about 40% of patients with mild-to-moderate AD. However, drug therapy can be complicated by forgetfulness, especially if the drug must be taken several times a day.

Psychotic symptoms, including paranoia, delusions, and hallucinations, may be treated with **antipsychotic**

KEY TERMS

Amyloid plaques—Abnormal structures composed of parts of nerve cells surrounding protein deposits, found in the brains of persons with Alzheimer’s disease.

Neurofibrillary tangles—Abnormal structures composed of twisted masses of protein fibers within nerve cells, found in the brains of persons with Alzheimer’s disease.

drugs such as haloperidol, chlorpromazine, risperidone, and clozapine. Side effects of these drugs can be significant. Anti-anxiety drugs such as Valium may improve behavioral symptoms, especially agitation and **anxiety**, although BuSpar has fewer side effects. The anticonvulsant carbamazepine is also sometimes prescribed for agitation. Depression is treated with antidepressants, usually beginning with selective serotonin reuptake inhibitors (SSRIs) such as Prozac or Paxil.

In general, medications should be administered very cautiously to demented patients, in the lowest possible effective doses, to minimize side effects. Supervision of taking medications is generally required.

The primary goals of treatment for progressive dementia are to preserve as much functioning and independence as possible, and to maintain quality of life as long as possible. It is important that the patient and caregivers are aware that caring for a person with dementia can be difficult and complex. The patient must learn to cope with functional and cognitive limitations, while family members or other caregivers may need to assume increasing responsibility for the person’s physical needs. The patient and family should be educated early on in the disease progression to help them anticipate and plan for inevitable changes.

Behavioral approaches may be used to reduce the frequency or severity of problem behaviors such as aggression or socially inappropriate conduct. Problem behavior may be a reaction to frustration or over-stimulation. Understanding and modifying the situations that trigger it can be effective; strategies may include breaking down complex tasks such as dressing or feeding into simpler steps, or reducing the amount of activity in the environment to avoid confusion and agitation. Pleasurable activities such as crafts, games, and music can provide therapeutic stimulation and improve mood.

Modifying the environment can increase safety and comfort while decreasing agitation. Home modifications

for safety include removal or lock-up of hazards such as sharp knives, dangerous chemicals, and tools. Childproof latches may be used to limit access as well. Bed rails and bathroom safety rails can be important safety measures. Confusion may be reduced with the use of simpler decorative schemes and the presence of familiar objects. Covering or disguising doors may reduce the tendency to wander. Positioning the bed in view of the bathroom can decrease incontinence.

Long-term institutional care may be required for the person with dementia, as profound cognitive losses often precede death by a number of years. Early planning for the financial burden of nursing home care is critical. Useful information about financial planning for long-term care is available through the Alzheimer’s Association.

Family members or others caring for a person with dementia are often subject to extreme **stress**, and may develop feelings of anger, resentment, guilt, and hopelessness, in addition to the sorrow they feel for their loved one and for themselves. Depression is an extremely common consequence of being a full-time caregiver for a person with dementia. Support groups can be an important way to deal with the stress of caregiving. Contact numbers are available from the Alzheimer’s Association; they may also be available through a local social service agency.

Prognosis

The prognosis for dementia depends on the underlying disease. On average, people with Alzheimer’s disease live eight years past their diagnosis, with a range from one to 20 years. Vascular dementia is usually progressive, with death resulting from stroke, infection, or **heart** disease.

Health care team roles

Any member of the health care team may work with patients with dementia. The physician normally makes the diagnosis. Laboratory technicians may obtain laboratory tests, and radiology technicians may perform imaging studies, if ordered. Nurses assess patients and how dementia affects their functioning. **Patient education** is very important in managing dementia and is a nursing responsibility.

Prevention

There is no known way to prevent AD, although several drugs under investigation may reduce its risk or slow its progression. The risk of developing multi-infarct

dementia may be avoided by reducing the overall risk for strokes.

Dental abscess

Definition

A dental **abscess** is a localized collection of pus in a cavity formed by the disintegration of tissues from a bacterial **infection**.

Description

Dental abscesses occur when a small area of tissue becomes infected and the body is able to “wall off” the infection and keep it from spreading. White **blood** cells, the body’s defense against some types of infection, migrate through the walls of the **blood vessels** in the area of the infection and collect within the damaged tissue. During this process pus forms, which is an accumulation of fluid, living and dead white blood cells, dead (necrotic) tissue and **bacteria**, or any other foreign invaders or materials; popcorn hulls, calculus, etc. This pus pocket is the abscess, characterized by swelling, redness, and **pain**.

The swollen area can rupture, allowing the pus to drain, but it will return if the cause of infection is not removed. As an abscess develops, the bacteria and host cells cause rapid destruction of connective tissues around the tooth and into the jawbone. Abscesses can be acute or chronic, with the acute abscess being the most painful. A chronic abscess may produce a dull pain with intermittent swelling, but can develop into an acute abscess at any time.

The most common types of dental abscesses are:

- Periapical abscess: located at the apex of an infected tooth surrounding the roots.
- Periodontal abscess: located in the periodontal ligament (PDL) surrounding the tooth.

Studies by the American Academy of Periodontology (AAP) find that periapical abscesses can occur on any tooth that has severe decay or is broken or chipped, but periodontal abscesses commonly involve the mandibular and maxillary first molars, maxillary incisors, and cuspids, followed by maxillary second molars.

Causes and symptoms

Periapical abscesses usually result from **dental caries** that allow bacteria to infect the center area of the tooth (pulp). But they can also occur after a traumatic injury to the tooth resulting in necrosis (death) of the pulp. This infection may spread out from the root of the tooth to the bones supporting the tooth, causing an abscess. This type of abscess is extremely painful and very sensitive to cold and hot, and to the touch. Acute inflammation of the apex commonly occurs with the tooth seeming to be slightly extruded from its socket. The patient may also have a **fever** and redness of the cheeks and gum tissue. The abscess itself may feel hot and hard to the touch. The bigger the abscess gets, the more painful it becomes.

A periodontal abscess occurs where pre-existing **periodontitis** is present. This infection occurs in the walls of the periodontal pocket as a result of bacterial invasion into the periodontal tissue. While abscesses usually spontaneously occur in patients with untreated periodontitis, they are more common in periodontitis patients with a systemic disease, in which there is a reduced ability to combat infections, such as individuals with diabetes or HIV, or patients on **chemotherapy**.

Periodontal abscesses are generally not sensitive to heat, and the pain is not as severe as with a periapical abscess, but the discomfort level is constant. They appear red, edematous (swollen), shiny, and very sensitive to the touch.

Other symptoms of a dental abscess include:

- earache
- general ill feeling
- bad breath or foul taste in mouth
- fever
- continuous or throbbing pain

Diagnosis

When a patient has swelling and pain it is necessary to locate the exact region causing the pain. X rays greatly aid in locating the tooth or teeth in question. Hot and cold tests may be performed by touching the teeth with ice or heated instruments. This helps to pinpoint the exact location of the pain and to determine the type of abscess. Percussion tests may also be done by tapping the teeth in question lightly with the small end of an explorer. After diagnosis, the general dentist may choose to treat the abscess, but may also refer the patient to an endodontist or periodontist. The entire treatment may take a number of visits to complete depending on the severity of the abscess.

The cost for treatment of a periapical abscess is normally covered under dental insurance at 80%. The cost is usually a few hundred dollars or more if the patient is referred to an endodontist because of the specialty field. The insurance then only covers a certain amount of the usual and customary charge (UCR), commonly about 50%. A patient has to consider whether to have a general dentist treat the abscess, or whether to pay the extra cost to have a specialist perform the treatment. Usually having a specialist treatment the abscess is worth the extra cost in the long run.

For a periodontal abscess, a dental hygienist may perform the necessary scaling and root planing required to treat this condition. The cost for periodontal abscess treatment is commonly covered by dental insurance at 80%. Even when treated by a periodontist, insurance normally covers the treatment at 80% because a periodontal abscess is considered part of the periodontal disease for which the patient is already being seen by the specialist.

Treatment

The goal of treating a dental abscess is to eliminate the infection while preserving the teeth and to prevent any complications. Releasing the direct pressure of the infection build up is the first step in the treatment.

With a periapical abscess, the pus is drained through an incision in the gum tissue, or by enlarging the hole in the tooth. This alleviates the pain and the tissue swelling.

During this process the patient is given a local anesthetic to minimize the pain. Often with a periapical abscess, the infection is severe and pain is so intense that the anesthetic is injected into the tooth or infected area for immediate relief. Extraction of the tooth is sometimes required, especially if an injury to the tooth has fractured through the bifurcation area and saving the tooth is not possible.

The principle treatment for a periodontal abscess is to establish drainage of the inflammation and to eliminate the infective agent. Anesthetics are required because of the pain involved and the discomfort caused by scaling and root planing. Careful insertion of a dull probe into the pus pocket along the tooth will usually produce the drainage needed and the symptoms normally dissipate. Scaling and root planing through the periodontal pocket to rid the area of the cause of the infection is necessary.

If necessary, surgical procedures may be undertaken. Surgery aims at pocket reduction if not elimination. An incision into the gum tissue and the laying open of a flap of tissue may be necessary in order to reach the infection more easily. Surgery must be gentle and efforts are made to avoid damage to the remaining periodontal attachment. As soon as the etiologic factors have been eliminated the swelling is reduced.

The healing process is usually uneventful and regeneration frequently occurs. The abscess will recur unless the cause of the infection is removed and the depth of the pocket is reduced. Extraction of the tooth is indicated after the acute symptoms have subsided, but in some cases, normal tissue contours cannot be developed and maintained.

In cases where the periodontal destruction approaches the periapical region of the tooth (the apex) the patient may develop pulpitis. Treatment may cause the patient to experience pain and discomfort following the root planing treatment and treatment for pulpitis will need to be completed, usually with **root canal therapy**.

Antibiotics are vital in ridding the system of any infection for both periapical and periodontal abscesses. If the infection is not eliminated the abscesses will recur with a stronger infection and more severe symptoms.

The types of antibiotics prescribed for acute abscesses include:

- Penicillin VK: an initial dose of 1000 mg followed by 500 mg four times daily for seven days.
- Amoxicillin (Augmentin): 250 mg three times daily for ten days.
- Erythromycin: 1000 mg first followed by 500 mg four times daily for seven days (for patients allergic to penicillin).

For chronic infections or infections with an inadequate response to penicillin, clindamycin is often prescribed (300 mg daily for seven days).

Warm salt-water rinses can soothe the gum tissue and help with the healing process. Over-the-counter medication can be taken for pain along with the antibiotics. Medications such as acetaminophen (Tylenol) reduce fever (if any) and pain. Anti-inflammatory medicines such as ibuprofen (Motrin and Advil) aid in reducing fever and also help reduce swelling and inflammation in the tissue.

Prognosis

While the loss of periodontal attachment is commonly rapid during an acute periodontal abscess, the potential for repair and healing is very high if the abscess is treated quickly and appropriately. The prognosis for a periapical abscess is similar, if it is treated quickly and appropriately with the elimination of the infection that is causing the abscess.

Health care team roles

The role of the dentist is vital in combating the infection of a dental abscess. The patient needs to be educated that abscesses and infections of the mouth do not subside on their own without recurrence. An endodontist should be consulted if a periapical abscess needs to be treated. A periodontist should be consulted if an existing condition of periodontitis is being treated. Each type of dentist needs to have a good working relationship with the patient.

The dental hygienist can complete the scaling and root planing of the abscessed area in the dental office or the periodontist's office. Dental assistants can aid in taking x rays of the area needing treatment and in sterilization of the instruments. The front desk is the first to greet a patient and the last to see a patient leave. Having a warm and courteous front office is vital to any dental office where treating disease, emergencies, and healing of patients is accomplished. All roles are important to the successful functioning of the health care team and good patient care.

Prevention

Dental abscesses can be prevented with regular dental care, including daily brushing and flossing, and regular dental check ups and cleaning. Wearing mouth guards during sports is one of the best ways to prevent an injury and trauma to the mouth.

KEY TERMS

Acute—Extremely sharp or severe, reaching a crisis rapidly.

Apex—The point at the end of the root of a tooth in the gum tissue.

Bifurcation—The area where the roots of the teeth separate into individual roots.

Calculus—Calcium deposits on teeth from the build up of plaque.

Chronic—Of long duration or frequent recurrence.

Cuspids—The teeth that are considered the cornerstone teeth of the mouth on the upper and lower jaws. More commonly known as the “eye” teeth.

Dental caries—Dental decay.

Edematous (edema)—An abnormal accumulation of serous fluid in the tissue.

Endodontist—A dentist who specializes in the diagnosis and treatment of disorders affecting the inside structures of the tooth.

Extraction—Surgical removal of a tooth.

Incisors—The teeth on the upper jaw right and left sides that sit next to the central front teeth.

Mandibular—Relating to the lower jaw region.

Maxillary—Relating to the upper jaw region.

Necrotic, necrosis—Pathologic death of tissue.

Periodontal—Tissue and structures that surround and support the teeth.

Periodontist—A dentist with specialized training for periodontal treatment and care.

Pulpitis—Inflammation of the pulp of a tooth involving the blood vessels and nerves.

Root canal—The space within a tooth that runs from the pulp chamber to the tip of the root.

Root canal therapy—The process of removing diseased or damaged pulp from a tooth, then filling and sealing the pulp chamber and root canals.

Root planing—Making the tooth smooth by removing built up calculus and tartar from below the gum tissue.

Scaling—The removal of food and debris from the portion of the tooth above the gum line.

Prosthodontist—A dentist with specialized training in crown and bridge treatment.

Dental anatomy

Definition

Dental anatomy is the study of the classification and morphology of teeth, as well as the study of the principles of occlusion.

Description

Dental anatomy may be considered the study of teeth at three different levels. First, teeth may be studied in terms of the elements of each individual tooth (for example, dentin and enamel). Second, teeth may be studied in terms of classification and numbering systems. Third, teeth may be studied in the larger context of the oral cavity, along with the principles of occlusion and structures that may display pathology such as the gingiva and the temporomandibular joint.

Teeth

The teeth are derived from the ectoderm and the mesoderm in the embryonic stages of development. Each tooth arises from either the maxilla (the bone that makes up the upper jaw) or the mandible (the bone that makes up the lower jaw). Teeth originating from the maxilla are considered to be in the superior dental arch, or the maxillary dental arch. Teeth arising from the mandible are considered to be in the inferior dental arch, also known as the mandibular dental arch.

Each tooth consists of:

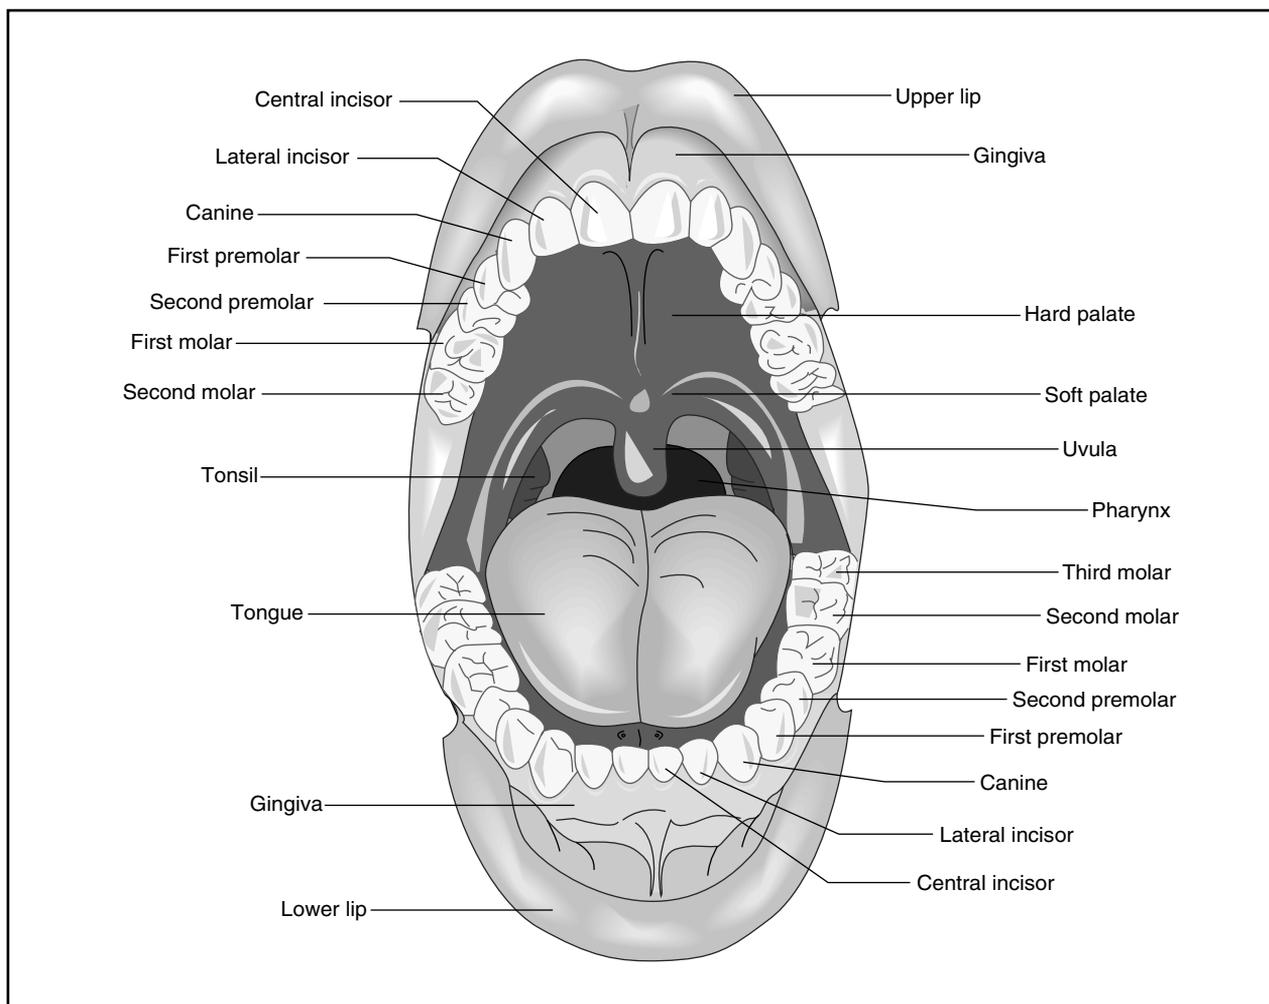

- **Crown:** The visible portion of a tooth.
- **Root:** The portion of the tooth embedded in the gum.
- **Pulp:** Located in the center of the tooth, it contains the arteries, veins, nerves and lymphatic tissue.
- **Blood vessels:** They carry nutrients to the pulp.
- **Root canal:** The canal in the root of the tooth is where the nerve and **blood** vessels travel with nutrients to the tooth from the mandible or the maxilla.
- **Ligament:** The connective tissue that surrounds the root of a tooth and connects it to the maxilla or mandible.
- **Bone:** Alveolar bone forms tooth socket and part of the teeth.
- **Cementum:** The layer of tissue covering the dentin on the root of the tooth. Serves the same role as enamel.
- **Dentin:** The calcified tissue underlying the enamel (on the crown) and cementum (on the root), making up the main bulk of the tooth.
- **Enamel:** The calcified outer layer of the crown of the tooth.

Although each tooth has the same basic structure, some variation exists. Different types of teeth have variation in their roots. Incisors and cuspids have only one root. Maxillary (upper) premolar teeth commonly have two roots, whereas the mandibular premolars commonly have one. The premolars may also have two roots fused to look as one. The molars on the maxillary arch have three roots, while, on the other hand, the molars on the mandibular arch have two roots.

Tooth types

Permanent teeth are divided into four groups based on their function and placement in the jaw. Teeth are given the same name whether they are in the upper or lower jaw. From medial (middle of the mouth) to lateral, the four types of teeth are listed below:

- **Incisors** cut the food. They are divided into central and lateral. They are the two most medial teeth on either

Major structures of the oral cavity. The maxillary third molars are missing in this adult dentition. (Delmar Publishers, Inc. Reproduced by permission.)

side (left and right) in the upper and lower jaw, for a total of eight.

- Cuspids also known as canines, cut and tear the food. They are the third teeth from the center, and there are a total of four (two upper, two lower).
- Pre-molars seize and shear the food. They are also known as bicuspid because they have two cusps, or projections on the surface of the teeth. There are eight total (four upper, four lower) between the cuspids and the molars.
- Molars grind the food. They are the most lateral teeth. There are a total of twelve, including the four “third molars” also known as wisdom teeth.

Children who still have their temporary teeth (also known as primary, deciduous, or “baby” teeth) have incisors (four upper, four lower), cuspids (two upper, two

lower), and molars (four upper and four lower), but lack pre-molars. There are 20 total primary teeth.

Tooth classification and numbering systems

Universal tooth numbering and classification allows health care professionals to discuss and identify teeth with a measure of certainty. Permanent dentition has a universal numbering system that begins by splitting the mouth into four quadrants; the upper right quadrant, the upper left quadrant, the lower right quadrant, and the lower left quadrant. Each quadrant contains eight teeth. The upper right quadrant consists of the eight teeth on the upper right side of the mouth from the third molar (wisdom tooth) to the right central incisor. The upper left quadrant is the same except on the left portion of the mouth from the third molar (wisdom tooth) to the left central incisor. The lower right quadrant consists of the

KEY TERMS

Gingiva—The gum tissue surrounding the teeth.

Mandible—The bone that helps make up the lower jaw of the mouth.

Mastication—Chewing and biting of the food in the mouth.

Maxilla—The bone that helps make up the upper jaw of the mouth.

Occlusal—Biting surface of the teeth.

teeth from the third molar on the lower left to the lower right central incisor. The same with the lower left quadrant from the third molar on the lower left to the lower left central incisor. Each quadrant can be named using acronyms; upper right (UR), upper left (UL), lower right (LR), lower left (LL).

General dentists generally number the teeth, beginning with the third molar in the upper right quadrant (number one), crossing to the upper left quadrant (the third molar is number 16), proceeding to the lower left quadrant (the third molar is number 17), and ending in the lower right quadrant with the third molar number 32 (third molars are known more commonly as the wisdom teeth). In contrast, orthodontists and oral surgeons use the acronyms of quadrants to help identify teeth, and number the teeth from medial to lateral (one to eight). Thus the upper right first (or central) incisor is also known as UR1, whereas the upper left third molar is known as UL8. LL5 would be the lower left second premolar and LR6 is the lower right first molar.

Primary, or temporary, teeth are systematically lettered in an alphabetical order beginning with A on the upper right quadrant, ending with J for the second molar in the upper right quadrant, proceeding with K for the second molar in the lower left quadrant, and ending with T for the second molar in the lower right quadrant. Primary teeth consist of twenty teeth total; ten on the maxilla and ten on the mandible

Occlusion

When discussing occlusion, one is essentially discussing the operation and conjunction of the teeth at rest and in the process of mastication (chewing). Two important elements in mastication are the muscles involved, and the temporomandibular joint.

MUSCLES. The four main mandibular muscles for dental anatomy are the:

- **Masseter:** The main muscle for the movement of the mandible for chewing.
- **Temporalis:** Maintains the position of the mandible at rest when a person is upright. During chewing it pulls the mandible back into the rest position.
- **Lateral pterygoid:** This muscle has a horizontal position and is the prime mover of the mandible into a protrusive position.
- **Medial pterygoid:** Works with the masseter muscle to aid in the elevation of the mandible. It is almost a mirror image of the masseter muscle—it gives extra aid in chewing.

TEMPOROMANDIBULAR JOINT. Also known as the TMJ, this is the connecting hinge between the lower jaw (the mandible) and the bone at the (lateral) base of the **skull** (the temporal bone). This joint is very fragile. A meniscus (piece of cartilage) separates the lower jawbone from the socket where it rests. Tendons, ligaments and muscles hold the TMJ in position. TMJ disorders can arise from **pain** because of muscle dysfunction (myofascial pain), pain because of degenerative bone disease (like arthritis), pain because of a broken bone, pain arising from dislocation of the meniscus, or pain arising from the dislocated joint. These dysfunctions can result in headaches, jaw soreness, neckaches and pain when chewing (often accompanied with a noise). Bite splints may be used to treat TMJ disorders caused by dislocation. Other therapies, ranging from isometric muscle exercises to oral surgery, may be required, based on the nature and severity of the TMJ disorder.

Gingiva

Normal, healthy gingiva may appear smooth or stippled. Known also as the gum tissue of the mouth, the gingiva shows the first signs of periodontal disease. Daily brushing and flossing help keep the gingiva healthy.

Function

Dental anatomy serves the important function of mechanical disruption and processing of food.

Role in human health

Properly functioning dental anatomy is essential for one of the first stages of food digestion—chewing. Chewing is essential for human health because (most) food is not prepared in a readily digestible form. Chewing increases the total surface area of the food by breaking it into smaller pieces, which allows more food to be digested. Chewing also breaks down any less-digestible barriers which may hinder absorption of food

in the gastrointestinal tract. For example, even after an orange is peeled, thin membranous tissue still surrounds the juicy, fruity portion of the orange. Chewing breaks down that barrier, making the nutrients inside much more accessible.

Common diseases and disorders

The most common childhood disease of the dentition is tooth decay. The **bacteria** demineralizes the enamel and dentin of the teeth, causing pain and swelling of the surrounding tissue if left untreated. Periodontal disease is a common disease among older adults associated with infectious bacteria affecting the tissues that support the teeth. Temporomandibular joint (TMJ) disorders cause pain to patients upon talking or chewing. TMJ disorders are commonly found in patients with physical, emotional, and social problems, as well as in individuals who experience work-related **stress**. Many types of TMJ have an excellent prognosis if treated.

Dental and periodontal charting

Definition

Dental and periodontal charting provide a graphic description of the conditions in a patient's mouth, including caries (i.e., decay), restorations, missing or malposed teeth, clinical attachment levels, furcation (root) involvement, mobility, pocket depths, bleeding sites, and other deviations from normal. Other conditions that may be charted include erosion, abrasion, developmental anomalies and use of prostheses.

Purpose

Thorough charting of both visual and radiographic findings allows dental practitioners to collate information needed to assess the patient's level of dental and periodontal health or disease. Charting should be updated with each visit to follow the patient's progress with **home care**, monitor disease progression, and to track completed dental procedures.

Description

Dental charting is part of both initial and periodic dental examinations, and is included in the cost of care. Exams are normally covered by dental insurance.

Charting begins with tooth naming and numbering. The maxillary, or upper arch, and the mandibular, or lower arch, each contain 16 teeth in a full adult dentition. Teeth are paired right and left by size, shape, and function. Beginning at the midline, each arch includes two central incisors side by side. Continuing outward to right and left are pairs of lateral incisors, canines (cuspids), first premolars (first bicuspid), second premolars (sec-

ond cuspids), first molars, second molars, and third molars (wisdom teeth).

In a primary, or deciduous, dentition there are no premolars or third molars. From the midline, pairs are central incisors, lateral incisors, canines, first molars, and second molars. As the adult dentition erupts, first and second primary molars are replaced by adult premolars. Adult molars erupt behind the primary molars in space created by the lengthening maxilla and mandible.

The widely used universal system, adopted in 1974, assigns the permanent teeth numbers from 1 to 32. Primary teeth are assigned letters from *a* to *t*, regardless of their position in the mouth. In the permanent dentition, 1 is the third molar of the maxillary (upper jaw) right quadrant. Numbering continues sequentially around the upper arch to 16, the third molar of the maxillary left quadrant. Number 17 is the third molar of the mandibular (lower jaw) left quadrant, and numbering again continues sequentially around the lower arch to 32, the third molar of the mandibular right quadrant. Teeth may drift due to factors including other missing teeth, **malocclusion**, malpositioning, or congenital abnormalities.

Lettering of primary teeth is similar. An *a* is assigned to the second molar of the maxillary right quadrant, and lettering continues sequentially around the upper arch to *j*, the second molar of the maxillary left quadrant. The letter *k* is the second molar of the mandibular left quadrant, and lettering continues sequentially around the lower arch to *t*, the second molar of the mandibular right quadrant.

An older system, sometimes used by orthodontists, is Palmer's Notation. In that system, teeth are numbered 1 through 8 or lettered *a* through *e* by quadrant, beginning at the midline. Permanent maxillary canines, for instance, would be referred to as "upper right 3" and "upper left 3" instead of 6 and 11. Primary mandibular first molars would be referred to as "lower right *d*" and "lower left *d*" instead of *s* and *l*. When written down, the numbers or letters are enclosed in half boxes to denote upper or lower, left or right.

A dental chart can be anatomically correct, showing several views of each tooth, or it can be stylized, showing two rows of 16 circles each. Small boxes are usually placed above and below the rows to allow coded notations for each tooth. Each circle represents a tooth, and is divided to show a smaller round center and four outside surfaces. The round center represents the occlusal (i.e., biting surface) of posterior teeth, or the incisal (i.e., biting edge) of anterior teeth. The four surfaces surrounding the center, noted clockwise from the top, are buccal (i.e., outside surfaces of posterior teeth) or facial (i.e., outside surfaces of anterior teeth; mesial (i.e., proximal surface of a tooth closest to the midline); lingual (i.e., inside sur-

face of a tooth); and distal (i.e., proximal surface of a tooth farthest from the midline).

For the purposes of communication, tooth surfaces are referred to by their first initial. For instance, a restoration on the mandibular left first molar that covers the mesial and occlusal surfaces would be called an MO on 19. A carious lesion that extends from mesial to facial to incisal surface of the maxillary right lateral incisor would be an MFI on 7.

Both restorations and lesions can also be classified according to location. The G.V. Black system of classification is as follows:

- Class I: Pits and fissures of the occlusal surfaces of posterior teeth, and lingual surfaces of anterior teeth.
- Class II: Proximal surfaces of posterior teeth.
- Class III: Proximal surfaces of anterior teeth.
- Class IV: Proximal surfaces of anterior teeth that involve an incisal edge.
- Class V: Gingival third (i.e., closest to the gumline) of the facial, buccal, or lingual surfaces of anterior and posterior teeth.
- Class VI: Cusp tips.

A carious lesion on the proximal surface of the maxillary left canine could therefore be referred to as a Class III lesion on 11.

Missing teeth are normally charted first, marked out with an X or a single vertical line. Unerupted teeth may be completely circled, with the circle altered if necessary to show partial eruption. Both carious lesions and restorations are marked by coloring the portion of the tooth affected, usually in different colors. For more precise charting, shadings, colors or coded letters may be used to differentiate between types of restorations. Amalgam (i.e., silver) restorations might be colored blue, for instance, while composite (i.e., white) restorations might be outlined in blue. Gold crowns might be marked with a "G" (or designated with a blue outline and oblique lines), and porcelain crowns with a "P." Additionally, full-coverage crowns are usually marked by circling just the crown of the tooth on the chart in blue. Areas of decay or defective restorations are marked in red.

Endodontic (i.e., root canal) restorations can be marked with a black line extending up the length of the tooth root. A periapical **abscess** (i.e., **infection** of the tooth nerve) is marked with a small circle at the apex of the root. Conditions such as erosion, abrasion, and congenital abnormalities can be identified with boxed notes. The directions of malpositioned, drifted, and super-erupted teeth can be indicated with arrows.

Implants can be drawn on the chart in their relative positions, with fixed bridgework noted by connected lines. Partial and complete dentures can be marked with brackets.

When a single clinician writes and draws findings on a dental chart, there are concerns about time, accuracy, and cross-contamination. Charting by hand is most efficient with two people, one performing the exam and the other recording the findings on the chart. If a computer is available in the treatment area, a clinician can use a headset microphone and voice-activated charting software for ease and convenience.

Once the teeth themselves have been charted, periodontal charting is indicated. The periodontium, or support structure for teeth, includes gingiva (i.e., gums), periodontal ligaments and membranes, and bone.

Baseline data, recorded as part of the initial examination, is a resource for treatment planning. During treatment, the chart offers direction for instrumentation, alerting the clinician to complex pocketing, mobility, and root furcation involvement. Later, periodically updated charts evaluate the success of home care and professional treatment. Further uses for periodontal charting are as legal evidence, to support a diagnosis and justify treatment, and as forensic evidence. The best defense in a **malpractice** suit is complete and accurate documentation.

For a periodontal chart, the clinician measures and records pocket depths surrounding the teeth. In a healthy mouth, each tooth is surrounded by a free collar of marginal gingiva. At a depth of 0–3 millimeters, the gingiva is attached to the cementum, the surface of the tooth root. The surrounding 0–3 mm. space within the free collar is referred to as the sulcus. In an unhealthy condition, sulcus depths can be much greater because of loss of attachment and are referred to as periodontal pockets.

Measurement is accomplished with a calibrated periodontal probe, inserted into the sulcus parallel to the long axis of the tooth. Depending on design, the probe may be marked at each millimeter up to 10. A more common design has the markings at four and six deleted for easier reading. Color-coded probes may be marked in blocks, with a green block up to 3 mm (i.e., indicating a healthy condition), and a red block up to 6 mm (i.e., indicating an unhealthy condition and the presence of periodontal disease). Probes are designed with blunt or ball-tipped ends to avoid puncturing the junctional epithelium at the base of the sulcus during probing. Electronic probes are also available that record pocket depths automatically on a computerized chart.

For a full periodontal chart, six readings are taken on each tooth and recorded in six boxes above and below teeth on the chart. Beginning with tooth number 1, a

measurement is taken at the mesio-buccal line angle, the midbuccal, the distobuccal line angle, the distolingual line angle, the mid-lingual, and the mesio-lingual line angle. The probe can be “walked” around the circumference of the tooth for complete exploration.

As the sulcus is probed, other conditions can be noted. Inflamed gingiva can bleed spontaneously from finger pressure or from probing, even though the probe does not puncture tissue. A bleeding index can be determined by dividing the number of sites bleeding by the number of sites examined. If 24 sites are probed, for example, resulting in 12 of those sites exhibiting bleeding, the patient has a bleeding index of 50%. Bleeding sites can be noted on the chart by a red dot or by the letter B.

A plaque index can be determined by the same method. A clinician counts the number of teeth where plaque, a biofilm, is present, and divides that by the number of teeth examined. A plaque index is a useful motivational tool for patients when measured at periodic intervals.

Other conditions that might be noted on a periodontal chart include the presence of exudate, tooth mobility, color and contour of the gingiva, recession, and the amount of plaque and calculus. All these conditions, when added together, provide the clinician a comprehensive picture of the patient’s periodontal status. Planning and treatment can only begin when these conditions have been fully documented.

Some clinicians prefer to assign standardized classifications to the patient’s degree of periodontal health. The five recognized classifications are:

- Case Type I: **Gingivitis** is present when inflammation is apparent and the gingiva is characterized by changes in color, form, position and appearance. Bleeding and/or exudate may be present.
- Case Type II: Slight **periodontitis** is present when inflammation has progressed from the gingiva to deeper periodontal structures and bone, with slight bone loss. Probing depths are 3–4 mm, and there is some loss of connective tissue attachment.
- Case Type III: Moderate periodontitis is a more advanced stage of Slight Periodontitis, with increased destruction and tooth mobility. There may be furcation involvement in multirrooted teeth.
- Case Type IV: Advanced periodontitis involves major loss of bone support and increased tooth mobility and furcation involvement.
- Case Type V: Refractory progressive periodontitis is diagnosed when there is rapid bone and attachment loss

KEY TERMS

Calculus—Calcified mass of bacteria, fungi, dequimated epithelial cells and food debris that forms on the surface of a tooth.

Caries—Tooth decay.

Cusp—Pointed projection on the crown of the tooth.

Deciduous teeth—Primary, or “baby” teeth.

Distal—Proximal surface of tooth farthest from the midline.

Facial—Outside surface of anterior tooth, adjacent to the face. The term includes buccal (cheek) and labial (lips) areas.

Gingiva—Gum tissue.

Incisal—Biting edge of anterior tooth.

Lingual—Inside surface of tooth, adjacent to the tongue.

Mesial—Proximal surface of tooth closest to the midline.

Occlusal—Biting surface of posterior tooth.

Periodontics—Study of the support structures of teeth, including gingiva, ligaments and alveolar bone.

Plaque—Collection of bacteria growing in a soft mass on surface of tooth or gingiva. Also called biofilm.

Sulcus—Normal 0–3mm space between the tooth and the junctional epithelium and the gingival margin.

or slow, but continuous, loss. Normal therapy is resisted, and there is gingival inflammation and continued pocket formation.

A simplified method of charting periodontal conditions was adapted in 1992 from a system in use in Europe called the Community Periodontal Index of Treatment Needs (CPITN). The CPITN is endorsed by both the World Health Organization and the Federation Dentaire Internationale for periodontal screening. The 1992 adaptation, called Periodontal Screening and Recording (PSR) TM, is endorsed by the American Dental Association (ADA) and the American Academy of Periodontology (AAP). It is best described as an early detection system for periodontal disease. PSR TM is not intended to replace full periodontal charting, but to serve as a simple and con-

venient screening tool. PSR TM can indicate to the clinician when a more comprehensive examination is needed. The ADA and AAP recommend using PSR TM at regular intervals as an integral part of oral examinations.

Pocket depths are scored in sections by codes, rather than individually by millimeters. For this system, the mouth is divided into sextants: maxillary right, anterior and left; and mandibular right, anterior and left. The PSR TM probe is ball-tipped and coded with a single colored marking from 3.5 mm to 5.5 mm. The clinician records a single sextant code according to the deepest probing depth found in that sextant. Where there are no teeth present in a sextant, an X is recorded.

Code 0 is used when the colored area of the probe remains visible in all the pockets of the sextant. The clinician detects no calculus and no defective margins on restorations. No bleeding is evident on probing.

Code 1 indicates nearly the same conditions as Code 0, but bleeding is detected on probing.

Code 2 is used when calculus, either above or below the gumline, is detected. It may also be used to indicate defective restorative margins. The colored area of the probe is still completely visible.

Code 3 is necessary when the colored area of the probe is only partly visible in at least one pocket of the sextant.

Code 4 is used when the colored area of the probe is not visible in at least one pocket of the sextant, indicating a program depth more than 5.5 mm.

An asterisk is added to a sextant score to indicate problems such as mobility, root furcation involvement, mucogingival abnormalities, or gingival recession greater than 3.5 mm. The sextant scores are recorded in a set of six attached boxes that can be drawn on the chart. Printed stickers are also available and can be added to the chart on the appropriate date.

Results

After dental and periodontal charting, a patient is found to be in good dental health if there is no decay, no restorations or replacements are needed, and the patient’s periodontal pockets are between 0–3 mm with no bleeding or abnormal conditions. A prophylaxis (i.e., cleaning) is usually the only treatment prescribed. The patient is placed on recall at 3- to 12-month continued care intervals for routine, preventive, and oral health maintenance care.

Any decay found, however, calls for treatment by elimination of active disease, restoration, or extraction. Endodontics may be necessary to preserve a tooth. Crowns, bridgework, implants or dentures may also be

indicated. If periodontal pockets deeper than 3 mm are found, they indicate the presence of periodontal disease, which must then be evaluated and treated appropriately.

Health care team roles

Any member of the dental team is equipped to perform dental charting, including the dentist, hygienist, expanded function dental auxiliary, or assistant. If no computer is available, charting is easier with two people. One performs the examination and calls out the findings while the other enters them in the chart.

Dental hygienists normally handle periodontal charting as part of the initial or periodic exam. Again, if no computer is available, charting is easier with two people. Periodontal screenings provide an excellent opportunity for **patient education**. While working, the dental hygienist can explain the meaning of any findings to the patient, and discuss their implications. During periodic exams, the patient can be told if scores have improved since the last visit.

Dental anomalies

Definition

Dental anomalies are craniofacial abnormalities of form, function, or position of the teeth, bones, and tissues of the jaw and mouth.

Description

Dental anomalies can range from missing or stained teeth to cleft palates. Many are expressions of other, more complex disorders. The National Institute of Dental and Craniofacial Research (NIDCR) estimates that in the United States a baby is born every hour with a craniofacial defect.

Causes and symptoms

Many dental anomalies are caused by inherited genetic defects or result from spontaneous genetic mutations. The Center for Biotechnology Information recognizes 1,250 gene loci for craniofacial diseases and disorders. Dental deformities may also have environmental, traumatic, or nutritional causes; these may develop or become clinically apparent at any time during an individual's life.

Genetic defects

The most common genetic craniofacial deformity is clefting of the lip and/or palate, a defect estimated by the NIDCR to occur once in every 500 births. A family history of clefting increases the chances of inheriting the disorder. Seen more often in boys than in girls, cleft lip is usually unilateral, appearing three times more frequently on the left side than on the right. Less common is a bilateral cleft, a condition formerly known as "harelip." An incomplete cleft stops short of the nostril; a complete cleft extends into the nostril. Both types frequently involve the palate as well. The typical patient with cleft palate and cleft ridge exhibits large defects in the roof of the palate with a direct opening into the nasal cavity.

Dentinogenesis imperfecta type II (DGI-II), another genetic defect, causes severely discolored teeth that break easily. Amelogenesis imperfecta produces only a soft, thin layer of tooth enamel. This lets the dentin show through, making teeth look yellow, and leaves them weak, easily damaged, and susceptible to decay.

Other genetic anomalies are less debilitating. **Malocclusion**, meaning bad or misaligned bite, is caused by crowding teeth, extra teeth, missing teeth, or jaws that are out of alignment. Most malocclusions are inherited genetically, although some can be caused by accidents, early or late loss of baby teeth, or prolonged thumb sucking. Orthodontia usually corrects this problem.

Relative microdontia is an inherited condition that produces smaller-than-normal teeth, usually in the upper jaw. To correct this condition crowns or veneers are applied to make the teeth the same size as the others. Microdontia is neither painful nor harmful; treatment is intended to improve the patient's bite and appearance.

Partial anodontia, or congenitally missing teeth, is a condition in which one or more permanent teeth fail to appear, although primary (baby) teeth usually erupt. Third molars are absent in as many as 35 percent of all subjects examined. Maxillary lateral incisors and maxillary and mandibular second premolars (bicuspid) also frequently fail to appear. When this happens, many dentists choose to leave the primary tooth in place to prevent the malocclusion that might otherwise occur. If this is not feasible, a dentist may extract the tooth and close the space with braces or cover it with a bridge.

Idiopathic anomalies

Stafne's bone cavity, also called static bone cyst or lingual mandibular bone concavity, is an anomaly of unknown etiology. A painless condition, it is an indentation of the jawbone that may contain muscle or salivary tissue. The skin covering this area is soft to the touch and feels concave. No treatment is required, although biopsies are often performed to rule out the presence of a malignant tumor.

Condylar hyperplasia, another idiopathic anomaly, affects the temporomandibular joint and surrounding tissues. The condition is characterized by unrestrained growth of the condyle, which deforms the face, jaw, and bite. Surgery is usually required to restore order, although once growth has stopped orthodontics are often helpful. Condylar hypoplasia occurs when one condyle is markedly shorter than the other, a condition that also causes facial and dental deformities. Surgery can restore balance, and orthodontics are indicated as well.

Environmental causes

Environmental anomalies are caused by external agents, including diet, that affect the teeth and gums. Extended use of the antibiotic tetracycline in young children, for example, can cause dark brown discoloration of the teeth. **Fluorosis**, an overabundance of fluorine in the diet, can create white or mottled spots on the teeth. This is most commonly seen in children who ingest greater-than-recommended amounts of fluoride by swallowing large quantities of fluoridated toothpaste. Teeth naturally darken with age, as the enamel thins and the dentin shows through. Coffee, tea, and red wine can also stain the teeth. Even children who swim an average of six hours or more a week in a pool may develop brown stains on their teeth.

Bulimia can cause severe decalcification of the teeth. Acid from constant regurgitation eats away at the enamel, especially in the molar region. This weakens the teeth, making them both susceptible to decay and highly sensitive. Unless the bulimia is arrested, sensitivity

increases until the nerve is exposed and **root canal therapy** is needed or extraction is required.

Poor **nutrition** can also cause dental anomalies. Scurvy, a disease caused by a lack of **vitamin C**, affects periodontal and other connective tissue, causing purple, swollen, bleeding gums and, if untreated, tooth loss. Anemia, caused by a lack of **iron** in the diet, causes fiery red gum tissues. Both of these anomalies can be corrected with proper nutrition and routine care.

Other anomalies

Concrescence is the fusion of teeth above and below the gum line, although each tooth has separate roots. The teeth are united by cementum only. It may be caused by crowding or injury. Most commonly it occurs with the second premolars (bicuspid). This is a painless anomaly and treatment is required only for cosmetic reasons.

Supernumerary teeth are extra permanent teeth that may or may not erupt and can be found anywhere in the mouth. The most common is the mesiodens, a small tooth with a cone-shaped crown and a short root situated between the maxillary central incisors. Heredity may play a role in the development of supernumerary teeth, but other factors are thought to contribute as well. Supernumerary teeth can be extracted with no harm to the patient.

Diagnosis

Dental anomalies can be evidence of systemic disease and may have more than one cause. After weighing the patient's symptoms, **pain** (if any), health risks, family history, aesthetic considerations, treatment costs, and insurance coverage, the dentist will decide whether to treat or simply monitor the condition.

Treatment

Treatment is intended to eliminate or diminish the defect, manage pain, and alleviate the patient's concerns. Treatment may progress in multiple phases, including a program of continuing care that allows the dentist or doctor to evaluate the treatment's effectiveness.

In most cases, surgery can correct the deformity. Cleft lips are usually repaired before the infant is a month or two old, with excellent cosmetic and functional results. Surgical repair of a cleft palate, however, is not usually performed until the patient is approximately eighteen months old, to minimize the risk of damaging important growth centers. Psychological services are often included as part of the treatment along with speech and **hearing** services.

Depending on the severity of the anomaly, treatment can be expensive, but medical and dental insurance can help limit out-of-pocket expenses for the patient. Sometimes treatment will be covered by medical insurance if procedures are performed by an oral surgeon or medical doctor instead of a dentist.

Prognosis

Although many orofacial anomalies are currently managed, rather than treated, the rapid advance of science—such as the ability to identify mutated genes—promise future cures and treatments that will eliminate or reduce the number of defects currently seen. **Gene therapy** may also someday be applied to the treatment of many craniofacial anomalies, both to repair congenital defects and to accelerate healing after trauma. Gene mapping may also help doctors know which patients are susceptible to what type of anomalies.

The NIDCR is the primary sponsor of craniofacial research and training in the United States. The institute supports a variety of projects, including basic studies of cell migration and differentiation, cell signaling, patterns of gene expression, growth factor effects, tooth formation and eruption, and bone formation. These studies explore the genetic and molecular mechanisms behind craniofacial abnormalities and are intended to prevent or correct the anomaly or improve the patient's ability to function with it.

Health care team roles

No one specialist can provide the range of treatment that is frequently needed for many dental anomalies. The most effective management is accomplished with a team of professionals who can render a comprehensive diagnosis, determine treatment needs and priorities, and supervise long-term planning. A list of physicians and specialists required to treat a craniofacial deformity might include: plastic surgeon, otolaryngologist (ear, nose, and throat specialist), audiologist, speech-language pathologist, oral/maxillofacial surgeon, orthodontist, pediatric/family dentist, dental hygienist, prosthodontist, geneticist/genetic counselor.

Prevention

The ADA advises dentists to discourage patients from using tobacco and illicit drugs, and to emphasize sound nutrition to maintain oral health and prevent nutritional anomalies. The NIDCR encourages clinical studies to diagnose genetic anomalies, decrease environmental risks, and improve treatment. **Genetic counseling**, map-

KEY TERMS

Anomaly—A deformity or abnormality.

Bridge—A dental prosthesis covering an open space in the mouth.

Cementum—A bony substance that covers the root of the tooth.

Condyle—The uppermost end of the mandible that sits in the zygomatic arch and allows the jaw to move.

Congenital—Present at birth; a nonhereditary condition acquired in utero.

Crown—1. The natural part of the tooth covered by enamel. 2. A restorative, protective shell that fits over a diseased or malformed tooth.

Decalcification—The wearing away of the enamel on the teeth.

Etiology—Cause or origin.

Extraction—Removal of the tooth.

Genetic—Inherited from the parents.

Mandible—Jaw, especially the lower jawbone.

Maxillary—Relating to the upper jaw region.

Maxillary central incisors—The front teeth on the upper jaw.

Maxillary lateral incisors—The teeth on the right and left quadrants of the upper jaw next to the front centrals.

Root canal therapy—Removal of the pulp of a tooth.

Veneer—A thin porcelain overlay that covers only the anterior surface of a tooth.

ping, and testing can help prevent dental anomalies in the next generation of children.

Dental assisting

Definition

Dental assistants are part of the dental health care team. They assist dentists in delivering oral health care to patients.

Description

The dental assistant uses interpersonal, administrative, and technical skills to perform a variety of tasks in the dental office. Dental assistants work with dentists when they perform dental treatments. Some of the tasks they perform before and during dental treatment include preparing patients for the treatment, passing dentists instruments and other materials, and keeping patients' mouths dry and clear using suction and other devices. They expose and develop x rays, or radiographs, as well as take impressions of teeth. Sometimes, dental assistants take patients' **blood pressure**, pulse, and medical histories. Dental assistants help comfort patients before, during, and after treatment. They also teach patients how to prevent oral disease and maintain their overall dental health. Administratively, a dental assistant may oversee an office's **infection control** practices, schedule patient appointments, answer phones, coordinate billing, and order supplies.

A dental assistant uses a suction tube while a dentist drills a patient's tooth. (Photograph by Francoise Sauze. Science Source/Photo Researchers. Reproduced by permission.)

The career offers variety of work, flexibility in scheduling, and direct contact with people. As of 1998, more than three in 10 dental assistants worked part-time. The median hourly wages in the profession was \$10.88 in 1998.

Work settings

Dental assistants work in general dental offices and all dental specialty settings, including orthodontics, pediatric dentistry, periodontics, endodontics, and oral surgery. They also work in solo practices or in **public health** dentistry, assisting in settings such as schools and community clinics. Dental assistants also work in hospitals to help treat bedridden patients and in dental school clinics, assisting dental students. Other opportunities for dental assistants exist in the insurance industry, as dental insurance claims processors; in vocational and other schools as instructors; and in dental product sales.

KEY TERMS

Oral and maxillofacial surgery—The dental specialty that focuses on the correction of orofacial deformities and removal of teeth.

Orthodontics—The dental specialty concerned with treating malocclusions, or bad bites.

Pediatric dentistry—The dental specialty concerned with the dental treatment of children and adolescents.

Periodontics—The dental specialty focused on treating diseases of the soft and hard tissues that surround and support the teeth.

Radiographs—X rays.

Education and training

While, in some states, dental assistants can work in the field without a college degree, dental assistants are usually trained at community colleges, vocational schools, technical institutes, universities, or dental schools. The Commission on Dental Accreditation of the American Dental Association is the agency that accredits dental assisting programs, of which there are over 200 in the United States. After completing a program that takes about nine to 11 months, plus an exam, dental assistants receive a certificate in dental assisting. To become a Certified Dental Assistant, or CDA, dental assistants must take the CDA examination after they have completed an accredited dental assisting program, or have at least two years of full-time on-the-job training as a dental assistant.

Advanced education and training

Associate or baccalaureate degrees are often required for dental assistants who want to go into teaching at colleges, technical institutes, vocational schools, or universities.

Future outlook

Job prospects in the field of dental assisting are expected to grow much faster than average, compared to other occupations. The job turnover is expected to be high, creating even more opportunity. Also, as the population ages and people keep their teeth, dental assistants will continue to be in demand.

Dental caries

Definition

Dental caries, also known as tooth decay, is the destruction of the outer surface (enamel) of a tooth. Decay results from the action of **bacteria** that live in plaque, which is a sticky, whitish film formed by a protein in saliva (mucin) and sugary substances in the mouth. The plaque bacteria sticking to tooth enamel use the sugar and starch from food particles in the mouth to produce acid. Tooth decay can result in tooth loss.

Description

Thanks to the benefits of fluoride and fluoridated water, dental caries, also called dental cavities, are not as prevalent as in the years before and including the 1980s. While the majority of senior citizens a generation ago lost all their teeth, the vast majority of the elderly today have some or all of their natural teeth.

Although anyone can have a problem with tooth decay, children and senior citizens are the two high-risk groups. While both groups experience a diminishing caries rate, senior citizens are getting more cavities than children. Since older adults are keeping their teeth longer, they have become more prone to root caries, or root decay. Other high-risk groups include people who eat a lot of starchy and sugary foods, people living in areas without a fluoridated water supply, and people who already have numerous dental restorations (fillings and crowns).

Dental caries charting: classification of cavities

Classification and location	Method of examination
Class I	
Cavities in pits or fissures	Direct or indirect visual
Occlusal surfaces of premolars and molars	Exploration Radiographs are not useful
Facial and lingual surfaces of molars	
Lingual surfaces of maxillary incisors	
Class II	
Cavities in proximal surfaces of premolars and molars	Early caries: by radiographs only Moderate caries not broken through from proximal to occlusal: Visual by color changes in tooth and loss of translucency Exploration from proximal Extensive caries involving occlusal: direct visual
Class III	
Cavities in proximal surfaces of incisors and canines that do not involve the incisal angle	Early caries: by radiographs or transillumination Moderate caries not broken through to lingual or facial: Visual by tooth color change Exploration Radiograph Extensive caries: direct visual
Class IV	
Cavities in proximal surfaces of incisors or canines that involve the incisal angle	Visual Transillumination
Class V	
Cavities in the cervical 1/3 of facial or lingual surfaces (not pit or fissure)	Direct visual: dry surface for vision Exploration to distinguish demineralization: whether rough or hard and unbroken Areas may be sensitive to touch
Class VI	
Cavities on incisal edges of anterior teeth and cusp tips of posterior teeth	Direct visual May be discolored

Baby bottle tooth decay

Baby bottle tooth decay is a dental problem that frequently develops in infants who are put to bed with a bottle containing a sweet liquid. Baby bottle tooth decay is also called nursing-bottle caries and bottle-mouth syndrome. Bottles containing liquids such as milk, formula, fruit juices, sweetened drink mixes, and sugar water continuously bathe an infant's mouth with sugar during naps or at night. The bacteria in the mouth use this sugar to produce acid that destroys the child's teeth. The upper front teeth are typically the ones most severely damaged, the lower front teeth receiving some protection from the tongue. Pacifiers dipped in sugar, honey, corn syrup, or

other sweetened liquids also contribute to bottle-mouth syndrome. The first signs of damage are chalky white spots or lines across the teeth. As decay progresses, the damage to the child's teeth becomes obvious.

Causes and symptoms

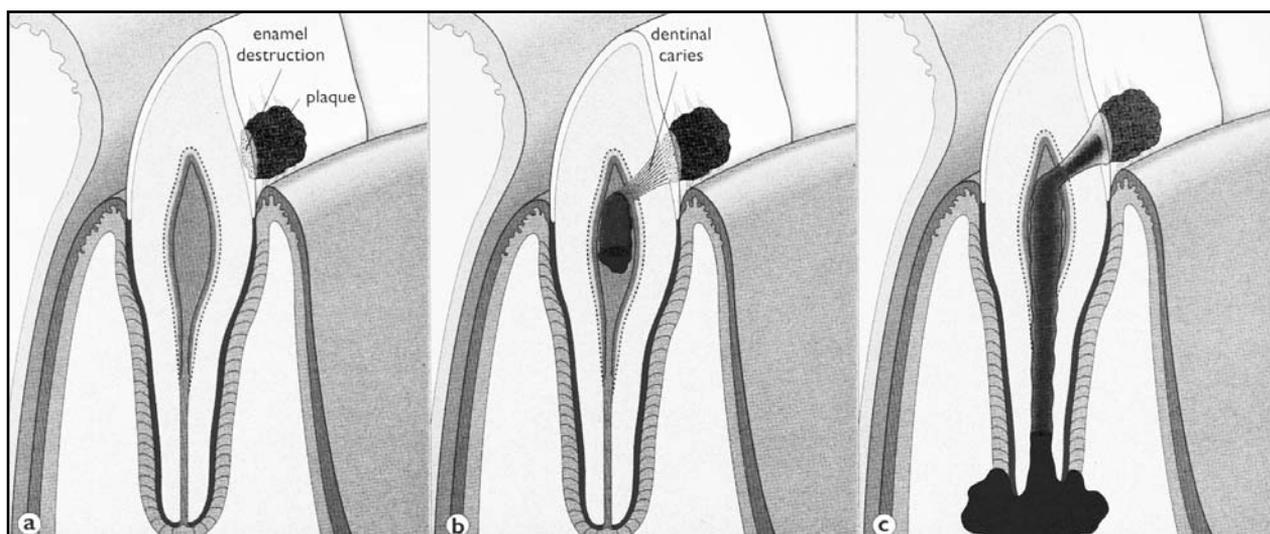

Tooth decay requires the simultaneous presence of three factors: plaque bacteria, sugar, and a vulnerable tooth surface. Although several microorganisms found in the mouth can cause tooth decay, the primary disease agent appears to be *Streptococcus mutans*. The sugars used by the bacteria are simple sugars such as glucose, sucrose, and lactose. They are converted primarily into lactic acid. When this acid builds up on an unprotected tooth surface, it dissolves the **minerals** in the enamel, creating holes and weak spots (cavities). As the decay spreads inward into the middle layer (the dentin), the tooth becomes more sensitive to temperature and touch. When the decay reaches the center of the tooth (the pulp), the resulting inflammation (pulpitis) produces a toothache.

The elderly are more prone to dental caries because more than 95% of senior citizens have lost some of the gum tissue that protects the tooth roots, exposing the roots to plaque and decay. It also is common to see decay around filling margins. Over time, fillings tend to weaken, fracture, and leak around the edges, which fosters the accumulation of bacteria. Another reason that the elderly get more cavities is that many take medications that reduce saliva, which naturally protects the teeth from caries.

Chewing tobacco is another culprit that increases the risk of tooth decay. A study showed that men who use chewing tobacco are four times more likely to have one or more decayed or filled root surfaces, compared to those who had never chewed tobacco.

Diagnosis

Tooth decay develops at varying rates. It may be found during a routine six-month dental checkup before the patient is even aware of a problem. In other cases, the patient may experience common early symptoms, such as sensitivity to hot and cold liquids or localized discomfort after eating very sweet foods. The dentist or dental hygienist may suspect tooth decay if a dark spot or pit is seen during a visual examination. Front teeth may be inspected for decay by shining a light from behind the tooth. This method is called transillumination. Areas of decay, especially between the teeth, will appear as noticeable shadows when teeth are transilluminated. X rays may be taken to confirm the presence and extent of the

Development of dental caries. (Photograph by Biophoto Associates. ScienceSource/Photo Researchers, .Inc. Reproduced by permission.)

decay. The dentist then makes the final clinical diagnosis by probing the enamel with a sharp instrument.

Tooth decay in pits and fissures may be differentiated from dark shadows in the crevices of the chewing surfaces by a dye that selectively stains parts of the tooth that have lost mineral content. A dentist can also use this dye to tell whether all tooth decay has been removed from a cavity before placing a filling.

Diagnosis in children

Damage caused by baby bottle tooth decay is often not diagnosed until the child has a severe problem, because parents seldom take their infants and toddlers for dental check-ups. Dentists want to initially examine primary teeth between 12 and 24 months. Children still drinking from a bottle anytime after their first birthday are likely to have tooth decay.

Treatment

To treat most cases of tooth decay in adults, the dentist removes all decayed tooth structure, shapes the sides of the cavity, and fills the cavity with an appropriate material, such as silver amalgam or composite resin. The filling is put in to restore and protect the tooth. If decay has attacked the pulp, the dentist or a specialist called an endodontist may perform root canal treatment and cover the tooth with a crown.

In cases of baby bottle tooth decay, the dentist must assess the extent of the damage before deciding on the treatment method. If the problem is caught early, the teeth involved can be treated with fluoride, followed by

changes in the infant's feeding habits and better **oral hygiene**. Primary teeth with obvious decay in the enamel that has not yet progressed to the pulp need to be protected with stainless steel crowns. Fillings are not usually an option in small children because of the small size of their teeth and the concern of recurrent decay. When the decay has advanced to the pulp, pulling the tooth is often the treatment of choice. Unfortunately, loss of primary teeth at this age may hinder the young child's ability to eat and speak. It may also have a bad effect on the alignment and spacing of the permanent teeth when they arrive.

Prognosis

With timely diagnosis and treatment, the progression of tooth decay can be stopped without extended **pain**. If the pulp of the tooth is infected, the **infection** may be treated with **antibiotics** prior to root canal treatment or extraction. The longer decay goes untreated, however, the more destructive it becomes and the longer and more intensive the necessary treatment will be. In addition, a patient with two or more areas of tooth decay is at increased risk of developing additional cavities in the future.

Scientists are working on several advances in the reversal and prevention of tooth decay. The advances under development include: *Smart* fillings to prevent further tooth decay, toothpaste to strengthen and restore tooth minerals, and mouthwashes and chewing gums that reverse early decay. Scientists are studying the use of **calcium phosphate cements (CPC)**, used to repair cranial defects, for **fractures** and bone loss from gum

disease. CPC might provide a successful drug delivery system in Smart fillings to prevent tooth decay from recurring around existing fillings and surrounding teeth. Other calcium phosphate-based technologies used in chewing gum and mouth rinses are being tested to remineralize hard tooth tissues or slow demineralization produced by caries. Scientists are researching controlled-release fluoride systems, placed between the teeth or in tooth pits and fissures, that deliver high fluoride concentrations to localized areas. Research is also being done on the use of filling materials to repair exposures of the tooth pulp, which could eliminate the need for **root canal therapy**.

Health care team roles

Dental assistants can provide patients and their families with education in caries prevention. This often includes instructions for **home care** and fluoride information. Dental assistants often participate in the treatment of dental caries, performing such tasks as taking x rays, assisting with materials during treatment, and setting up and maintaining treatment rooms. In some dental practices, dental hygienists assist with patient charting and taking x rays. Dental hygienists interpret findings and are often the first to see the decay during routine cleanings.

Prevention

It is easier and less expensive to prevent tooth decay than to treat it. The four major prevention strategies include: proper oral hygiene, fluoride, sealants, and attention to diet.

Oral hygiene

GENERAL CARE OF THE MOUTH. The best way to prevent tooth decay is to brush the teeth at least twice a day, preferably after every meal and snack, and to floss daily. Cavities develop most easily in spaces that are hard to clean. These areas include surface grooves, spaces between teeth, and the area below the gum line. Effective brushing cleans each outer tooth surface, inner tooth surface, and the horizontal chewing surfaces of the back teeth, as well as the tongue. Flossing once a day also helps prevent gum disease by removing food particles and plaque at and below the gum line, as well as between teeth. Patients should visit their dentist every six months for an oral examination and professional cleaning.

MOUTH CARE IN OLDER ADULTS. Older adults who have lost teeth or had them removed still need to maintain a clean mouth. Bridges and dentures must be kept clean to prevent gum disease. Dentures should be relined

and adjusted by a dentist whenever necessary to maintain a proper fit. These adjustments help to keep the gums from becoming red, swollen, and tender.

MOUTH CARE IN CHILDREN. Parents can easily prevent baby bottle tooth decay by not allowing a child to fall asleep with a bottle containing sweetened liquid. Bottles should be filled with plain, unsweetened water. A child should be starting to drink from a cup at around six months of age, and weaned from bottles at 12 months. If an infant seems to need oral comfort between feedings, a pacifier specially designed for the mouth may be used. Pacifiers, however, should never be dipped in honey, corn syrup, or other sweet liquids. After the eruption of the first tooth, parents should begin routinely wiping an infant's teeth and gums with a moist piece of gauze or soft cloth, especially before bedtime. Parents may begin brushing a child's teeth with a small, soft toothbrush at about two years of age, when most of the primary teeth have come in. They should apply only a very small amount (the size of a pea) of toothpaste containing fluoride. Too much fluoride may cause spotting (**fluorosis**) of the tooth enamel. As the child grows, he or she will learn to handle the toothbrush, but parents should control the application of toothpaste and do the follow-up brushing until the child is about seven years old.

Fluoride application

Fluoride is a natural substance that slows the destruction of enamel and helps to repair minor tooth decay damage by remineralizing tooth structure. Toothpaste, mouthwash, fluoridated public drinking water, and vitamin supplements are all possible sources of fluoride. It is important to note that bottled water and water from home purifiers often does not contain fluoride, so people who drink from these sources may have to supplement their fluoride use. Children living in areas without fluoridated water should receive 0.5 mg/day of fluoride (0.25 mg/day if using a toothpaste containing fluoride), from three to five years of age, and 1 mg/day from 6-12 years.

While fluoride is important for protecting children's developing teeth, it is also of benefit to older adults with receding gums. It helps to protect the newly exposed tooth surfaces from decay. Older adults can be treated by a dentist with a fluoride solution that is painted onto selected portions of the teeth or poured into a fitted tray and held against all the teeth.

Sealants

Because fluoride is most beneficial on the smooth surfaces of teeth, sealants were developed to protect the

irregular surfaces of teeth. A sealant is a thin plastic coating that is painted over the grooves of chewing surfaces to prevent food and plaque from being trapped there. Sealant treatment is painless because none of the tooth is removed, although the tooth surface is etched with acid so that the plastic will adhere to the rough surface. Sealants are usually clear or tooth-colored, making them less noticeable than silver fillings. They cost less than fillings and can last up to 10 years, although they should be checked for wear at every dental visit. Children should get sealants on their first permanent “6-year” molars, which come in between the ages of 5 and 7, and on the second permanent “12-year” molars, which come in between the ages of 11 and 14. Sealants should be applied to the teeth shortly after they erupt, before decay can set in. Although sealants have been used in the United States for about 25 years, one survey by the National Institute of Dental Research reported that fewer than 8% of American children have them.

Diet

Choosing foods wisely and eating less often can lower the risk of tooth decay. Foods high in sugar and starch, especially when eaten between meals, increase the risk of cavities. The bacteria in the mouth use sugar and starch to produce the acid that destroys the enamel. The damage increases with more frequent and longer periods of eating. For better dental health, people should eat a variety of foods, limit the number of snacks, avoid sticky and overly sweetened foods, and brush often after eating.

Drinking water is also beneficial by rinsing food particles from the mouth. Children can be taught to “swish and swallow” if they are unable to brush after lunch at school. Similarly, saliva stimulated during eating makes it more difficult for food and bacteria to stick to tooth surfaces. Saliva also appears to have a buffering effect on the acid produced by the plaque bacteria and to act as a remineralizing agent. Older people should be made aware that some prescription medications may decrease salivary flow. Less saliva tends to increase the activity of plaque bacteria and encourage further tooth decay. Chewing sugarless gum increases salivation and thus helps to lower the risk of tooth decay.

Resources

BOOKS

“Dental Caries and Its Complications—Tooth Decay.” In *The Merck Manual of Diagnosis and Therapy*, edited by Mark H. Beers, Robert Berkow, and Mark Burs. 17th ed. Rahway, NJ: Merck Research Laboratories, 1999.

KEY TERMS

Amalgam—A mixture (alloy) of silver and several other metals, used by dentists to make fillings for cavities.

Caries—The medical term for tooth decay.

Cavity—A hole or weak spot in the tooth surface caused by decay.

Dentin—The middle layer of a tooth, which makes up most of the tooth’s mass.

Enamel—The hard, outermost surface of a tooth.

Fluoride—A chemical compound containing fluorine that is used to treat water or applied directly to teeth to prevent decay.

Mucin—A protein in saliva that combines with sugars in the mouth to form plaque.

Plaque—A thin, sticky, colorless film that forms on teeth. Plaque is composed of mucin, sugars from food, and bacteria that live in the plaque.

Pulp—The soft, innermost layer of a tooth containing blood vessels and nerves.

Sealant—A thin plastic substance that is painted over teeth as an anti-cavity measure to seal out food particles and acids produced by bacteria.

Transillumination—A technique of checking for tooth decay by shining a light behind the patient’s teeth. Decayed areas show up as spots or shadows.

Dental casts

Definition

A dental cast is any dental prosthetic or device formed in a mold or used as a mold.

Purpose

Dental casts copy a patient's teeth and mouth structures for diagnostic purposes and are used as models for further casting of dental **prosthetics** such as bridges, crowns, implants, dentures, and partial dentures. Casts may also be used as education tools for dentists as they explain characteristics of a patient's bite or particular dental needs. Diagnostic casts can also show how a restoration will look when the work is complete.

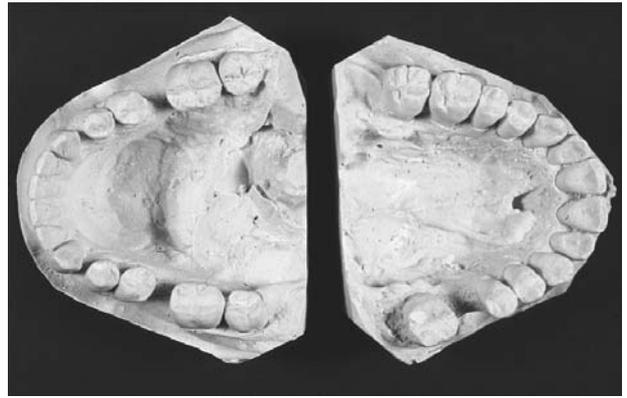

Description

Dentists are challenged to create solutions for problems that patients present from chipped or missing teeth, a collapsed bite, or teeth that are irregular or misshapen. A clear diagnosis of the condition often is made through the use of plaster-like dental casts of the patient's teeth and gums. These diagnostic casts allow the dentist to examine how the teeth fit together and what may be hampering the patient from chewing or speaking well. Often, the dentist will recommend replacement prosthetic devices for missing teeth. In the case of severely crooked teeth, the dentist may urge the patient to have the teeth realigned through braces or other **orthodontic appliances**.

From these initial casts, dental prosthetics are made that will fit into a patient's jaw structure and resemble the other teeth there. A variety of prosthetic devices can be cast from these initial casts: individual teeth for implants, crowns, bridges, dentures, and partial dentures.

The dentist first makes an impression of the patient's teeth and gums. A variety of impression materials are available, some are firm when used (waxes, plasters, putties, **zinc** oxide pastes) and some are more pliable (alginate and elastic silicones and polyvinyls). The elastic mediums are more stable and can stand longer before the casts are poured. Some impressions materials require that the cast be poured immediately or within a few hours. Some can wait several days or up to two weeks.

The impression produces a negative replica of the patient's teeth, which can then be cast in a variety of materials. Usually, plaster is used because it is inexpensive and sets up quickly. Other materials used include dental stone or special die stone. Both are very strong, but die stone is more abrasion resistant.

Dental casts are made from the impression of a patient's teeth, and may be used to help diagnose problems with bite, chewing, etc. (O.J. Staats, MD/Custom Medical Stock Photo. Reproduced by permission.)

From these casts, the dental technician can create wax diagnostic models of the proposed restoration. These wax models are finely-detailed sculptures of the mouth, showing how the restoration will look. From these, the prosthetics are cast.

Operation

The dental assistant prepares the impression medium and fills an impression tray that fits over the patient's mouth. The patient's teeth are dried either with gauze or a chemical product before the impression tray is fitted over the patient's teeth. The tray is held in place by the dental assistant for a brief time. The tray is removed in one motion, not rocked, in order to have a clean impression.

The impression is rinsed and disinfected and left to set. The dental assistant pours in the casting material. Sometimes this is only a few minutes after the impression is made; sometimes it can be several hours or days later.

Plaster-type casts are usually made first. These are used in diagnosis, **patient education**, and the creation of dental restorations.

The dental technician makes a single wax model of the prosthetic device to fit the patient's mouth, using the plaster cast as a guide. An investment mold is poured around the wax model and fired. The wax melts and drains out of the investment mold, leaving behind a durable mold into which the technician can pour a casting material. Restorative casting materials can be metals (gold, silver, amalgam), resins, or ceramics. These are poured into the investment mold to craft individual teeth, crowns, and other dental prosthetics. The mold is broken or opened, depending on whether the mold is reusable.

This technique is called lost wax casting and has been used for centuries to cast bronze sculptures or craft fine jewelry.

Maintenance

Alginate impressions are affected by water and can shrink or swell. This material often comes in powder form and should not be inhaled.

Casts made directly from impressions from plaster can be damaged through rough handling. Dental stone and dental die stone are more durable.

Dental prosthetics made from molds are long lasting and only require regular dental maintenance like tooth brushing and flossing. Dentures and partial dentures need to be rinsed and soaked to remove stains and odor. The dentist and dental assistant should inspect dental prosthetics often for any damage or wear, especially around the wires of partial dentures.

It should be noted that the impressions used to make plaster-like casts of the patient's mouth should be disinfected and dried before the casts are made. This protects dental personnel from any infectious agent attached to the impression when the cast was made and could be transferred to the cast.

Health care team roles

Dentists, dental assistants, and dental technicians work as a team to create and maintain dental casts. Dentists diagnose a particular problem in a patient's mouth and present solutions, depending on the specific nature of the case and the patient's comfort and budget. Sometimes, the exact solution is not fully determined until impressions of the patient's mouth are made and the dentist consults with the dental technician. Impressions are crucial to the problem-solving that the dentist and dental technician do. The dental assistant makes an impression of the patient's teeth and mouth structures and pours a hardened cast. The dentist examines this cast and sends it to the dental technician with recommendations for the creation of dental restorations. Dental technicians make wax diagnostic models from the mouth cast for various restorations (crowns, bridges, partial dentures, implants). These models are used by technicians to create metal frameworks and tooth structures in investment molds.

Training

Dental assistants and hygienists usually require some specialized training. Dental hygienists are often licensed. Dental technicians are trained at dental laboratories, though some dental schools offer coursework in dental restorations.

KEY TERMS

Bite—How the upper teeth and lower teeth fit together so that a person can chew and speak.

Bridge—A device that has at least one prosthetic tooth and two crowns. It is used to replace a missing tooth or teeth. The bridge is held in place when the adjacent crowns on the bridge are cemented over the two teeth on each side of the space left by the missing tooth or teeth.

Crown—A dental prosthetic that copies an existing tooth's shape (or ideal shape) and covers the tooth. It is cemented into place and feels like and is used as a normal tooth.

Denture—A dental prosthetic device consisting of a full set of teeth to fill the upper or lower jaw, or both. Also called false teeth.

Implant—A prosthetic tooth anchored permanently into the jaw bone by a post. It has the same strength and appearance as natural teeth.

Impression—An exact copy of the teeth and mouth using materials that will set sufficiently so that a more durable cast of the mouth can be made from plaster, dental stone, or other casting materials.

Investment mold—A plaster-like substance that is created around a wax model of an object that is to be cast in metal.

Lost wax casting—A process of casting metal that involves making a mold around a wax object that has been shaped exactly in the likeness of the intended finished object. The mold is then fired and the wax melts. The resultant mold is durable and capable of receiving molten metals which will be cast in the mold in the shape of the desired object.

Mold—A form or physical outline of an object used to hold a pliable material in order to copy the same shape or design.

Orthodontic appliances—Devices that help straighten the teeth; e.g. invisible braces, retainers, etc.

Partial dentures—A dental prosthetic of two or more teeth used to replace missing teeth.

Prosthetic device—A re-creation of a tooth or series of teeth to replace or improve the structure or appearance of a tooth or teeth.

Restoration—Any prosthetic device or process used to replace or improve the structure or appearance of a tooth or teeth.

Dental crowns, inlays, and bridges

Definition

Dental crowns, inlays, and bridges are prosthetic devices that replace missing teeth or part of a tooth. They are made of metal, porcelain, and resin, or a combination of these materials.

Purpose

Bridges, crowns, and inlays are created to restore a tooth's appearance, structure, or function. Inlays and crowns are intended to repair damage to individual teeth. They replace tooth structure lost by decay or injury, protect the part of the tooth that remains, and restore the tooth's shape and function. Bridges fill in a space in the jaw left by a missing tooth or teeth. They protect the shape of the mouth and restore function of the teeth and jaw.

Precautions

Some patients are allergic to the medications used for **local anesthesia** in dental restorations. In addition, many people are afraid of dental work. Most dentists in practice today can help patients with this specific fear.

Description

Crowns

The crown of a tooth is the portion that is covered by enamel. A restorative crown replaces this outer part to

protect and strengthen the tooth. This protection becomes necessary when a tooth cracks, has its entire structure weakened by decay, or becomes brittle after a root canal. Crowns can also cover dental implants or abutment (adjacent) teeth when fitting a bridge.

Crowns are also used to cover discolored or otherwise aesthetically displeasing teeth. **Cosmetic dentistry** does not use crowns as much as it once did, since crowns, though aesthetically pleasing, require more radical dental techniques. Dentists are opting for more conservative methods such as bleaching, bonding, or veneers to improve the aesthetic appearance of teeth.

The dentist first removes the decayed portion of the tooth. The tooth is then prepared for a crown. It may be tapered on the outside edges to a peg, reinforced with a cast metal core, or rebuilt with both a cast metal core and a post. An impression of the prepared tooth and the teeth next to it is made. A retraction cord is placed around the tooth in order to get the impression medium under the gum where the crown will be fitted.

The dental technician will create a new crown, using a cast made from this impression. The technique the technician uses is called lost wax casting. A wax model is made of the crown. Another mold is made around the wax model and both are fired in a kiln. The wax melts, leaving an opening into which a restorative material can be poured. The crown may be made of gold or stainless steel alone, metal with a veneer of tooth-colored porcelain or resin, or of porcelain or resin alone. The finished crown is then placed over the prepared tooth, adjusted, and cemented into place.

When a tooth has had a root canal and the root has been filled, the tooth may not be strong. Post crowns are used in these cases. The tooth is leveled at the gum line and a stainless steel or gold post is fitted into the root canal. This post can then receive the new crown and hold it in place.

For other patients, it may be necessary to implant the crown. In this case, a steel post is embedded in the patient's jawbone. It is left in place until the bone adheres to the post. The post is exposed and the crown is made and fitted.

New computerized techniques are making the restoration process faster and more comfortable. Chairside Economical Restoration of Esthetic Ceramics (CEREC) uses a computer system to allow the dentist to create ceramic crowns, inlays, and onlays, in one sitting. The tooth is prepared as usual but impressions are made digitally, using a hand-held camera. These photographs are converted to three-dimensional images on the computer screen, thus eliminating the need to take a physical impression of the patient's teeth. The dentist uses special 3D CAD/CAM software to design the crown. A milling

system attached to the CEREC machine is able to make a ceramic crown in 10-15 minutes.

Crowns can last 5-15 years or more, if they are well taken care of.

Bridges

Bridges are restorations that fill in a gap caused by missing teeth. They prevent the remaining teeth from shifting and provide a more stable surface for chewing. If the gap is not filled, the other teeth shift, affecting the patient's bite (occlusion), which sometimes produces **pain** in the jaw joint. As the teeth move and become crooked, they also become more difficult to keep clean. The risk of tooth decay and gum disease increases, also increasing the likelihood that additional teeth will be lost. A bridge is inserted to prevent this risk.

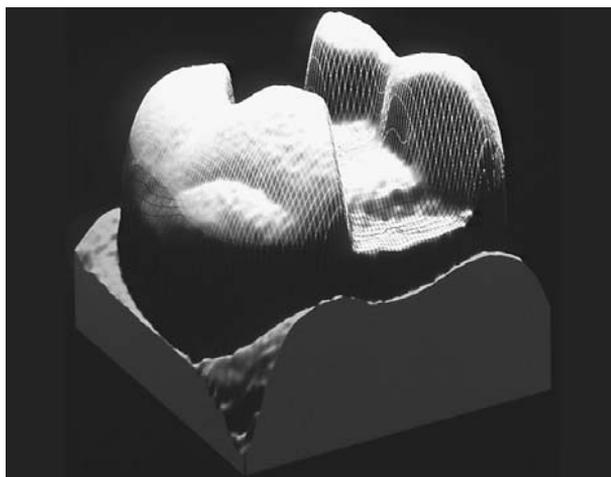

Bridges are appliances consisting of a metal framework and one or more artificial teeth (pontics) anchored to adjacent teeth. The abutment teeth carry the pressure when the patient chews food. Bridges can be removable or fixed (permanent). Removable bridges are attached to the abutment teeth by wires or precision attachments. Fixed bridges are attached to permanent crowns placed on abutment teeth. There are two types of fixed bridges—the crown-and-bridge design and the Maryland Bridge. A Maryland Bridge does not have crowns on it. The backs of the abutment teeth are reduced slightly and small wing-like appendages on the bridge are cemented to the back of the abutment teeth.

When the adjacent teeth are not strong enough to support a bridge, a two-implant bridge is required. This type of bridge takes longer for the permanent bridge to be fitted because of the necessity for the gums to heal. Posts are surgically implanted into the patient's bone and the gum closed. It takes several weeks for the bone to attach to the posts. The posts are re-exposed and the bridge is made to fit. It is then cemented in place.

Inlays

An inlay resembles a filling in that it fills the space remaining after the decayed portion of a tooth has been removed. The difference is that an inlay is shaped outside the patient's mouth and then cemented into place. After the decay is removed and the cavity walls are shaped, the dentist makes a wax pattern of the space. A mold is cast from the wax pattern. An inlay is made from this mold and sealed into the tooth with dental cement.

Inlays and their counterparts, onlays, are conservative alternatives to crowns. They don't require as much

tooth preparation and often are more durable than amalgam fillings. Inlays cover the grooves on the surface of the molar. Onlays wrap over the tooth, covering more of its surface.

Inlays used to be made entirely of gold for its durability. New inlay alloys of palladium, nickel, or chromium are frequently used. Metals have been the dentist's choice for inlays in molars. When inlays are required for teeth that will be seen when a patient smiles, tooth-colored composites and porcelains are used. Reinforced porcelain and Lucite porcelain are durable but still may not be suitable for patients who grind their teeth. Composites are also used in fillings.

Preparation

Before a restoration is placed in the mouth, the dentist removes all traces of decay or damage and shapes the remaining tooth structure for the restoration. When bridges or crowns are necessary, the tooth or teeth that are to receive the crowns are shaped into posts or pegs. Temporary crowns and bridges are installed until the permanent restoration is delivered by the laboratory.

Aftercare

Temporary crowns or bridges must stay in place until the permanent restorations have been fitted to the patient's mouth. Dentists and dental assistants should educate the patient about ways to keep the temporary in place; e.g. avoid hard foods, gum and other sticky or chewy foods. If possible, the dental assistant and dentist

KEY TERMS

Abutment tooth—A crowned tooth that stabilizes a bridge or partial denture.

Bridge—An appliance of one or more artificial teeth anchored by crowns on the adjacent teeth.

CAD/CAM—A computer-aided design and manufacturing package.

Complete denture—A full set of upper or lower teeth, mounted in a plastic base. Dentures are also called false teeth.

Crown—A protective shell that fits over the tooth.

Dental caries—A disease of the teeth in which microorganisms convert sugar in the mouth to acid that erodes the tooth.

Enamel—The hard outermost surface of a tooth.

Inlay—A filling that is made outside of the tooth and then cemented into place.

Occlusion—The way upper and lower teeth fit together during biting and chewing.

Pontic—An artificial tooth.

Pulp—The soft innermost layer of a tooth that contains its blood vessels and nerves.

should encourage the patient to avoid eating foods on the side of the mouth where the temporary is. Also, the patient should be reminded to call immediately if the temporary is loosened so that it can be re-cemented.

There can be some gum swelling or discomfort when a crown or bridge is fitted. If a bridge implant was completed, there is naturally some discomfort from the surgery. The dentist can recommend medications or oral rinses to mitigate the discomfort.

Patients may also experience sensitivity to cold foods or drinks for a few weeks after a crown, bridge, or inlay is in place.

Patients should be urged to maintain normal **oral hygiene** while they wear a temporary and after the crown or bridge is in place. Specialty brushes and floss threaders may be used to remove plaque and food from around crowns and bridges.

The patient should see the dentist for an adjustment if there is any discomfort or irritation resulting from a restoration. Otherwise, the patient should see the dentist at least twice a year for an oral examination.

Complications

Restoration procedures typically require local anesthesia. Some people may have allergic reactions to the medication. A very small number of people are allergic to one or more of the metals used in a dental restoration. In most cases, the dentist can use another material.

Results

A well-made restoration should feel comfortable and last a relatively long time with proper care. Artificial dental restorations only approximate the original tooth, however. It is better, therefore, to prevent the need for restorative dental work than to replace teeth. Restorations are expensive, may require many appointments, and still need careful cleaning and attention.

Health care team roles

The dentist is crucial in diagnosing a patient's particular dental needs and determining the correct remedy. The dentist will prepare a patient's teeth for restorative work. Often, this requires a great deal of skill and structural knowledge in order to remove enough tooth material for the restoration to fit and yet leave enough architecture within the tooth in order to stabilize the restoration.

The dental technician prepares the restoration so that it will fit the prepared tooth and fit in with the rest of the patient's mouth structure. The technician is part scientist and part artist in order to craft natural looking teeth that match the others in a patient's mouth.

The dental assistant prepares the patient and the patient's teeth for the dentist to do what is necessary to determine what restoration is best suited for this particular patient. The dental assistant takes impressions of the patient's teeth and gums and makes plaster-type casts to aid the dentist in diagnosis and the dental technician in creating life-like restorations that fit comfortably in the patient's mouth.

Dental emergency see **Dental trauma**

Dental examination

Definition

A dental examination is part of an oral examination: the close inspection of the teeth and tissues of the mouth using physical assessment, radiographs, and other diagnostic aids. Dental care begins with this assessment, and is followed by diagnosis, planning, implementation, and evaluation.

Purpose

The examination identifies tooth decay and evaluates the health of the gums and other oral tissues. The fit of dentures and bridges (if any) are evaluated. The patient’s bite and **oral hygiene** are also assessed. The dentist then recommends the best treatment options to the patient.

Precautions

Before a dental examination patients with heart-valve disease must take **antibiotics** to prevent **bacteria** that may spread into the bloodstream from causing **endocarditis**. Hypertensive patients may need to have their **blood pressure** measured. Many dentists prefer not to examine patients who have active herpes sores on or near the mouth. To maintain a sterile environment, dentists and their assistants don gloves and masks.

Description

A dental examination is part of a comprehensive oral examination to evaluate the mouth, jaw, and teeth. The American Dental Association (ADA) recommends that

patients seeing a dentist for the first time receive a comprehensive examination, and that established patients be thoroughly evaluated every three years, with professional oral care and periodontal maintenance between examinations. Comprehensive evaluations are usually combined with a dental cleaning, x rays, and other diagnostic tests. If a new patient presents with an emergency, the situation will be evaluated and treated first. Once the emergency is over, an appointment for a complete oral examination will be scheduled.

The examination begins with a review of the patient’s complete medical and dental history, which is usually a form or questionnaire completed by the patient. Once the dentist is familiar with any special conditions that may affect the patient during the exam—heart disease, relevant **allergies**, or the use of medications such as **blood** thinners—the examination and cleaning can proceed.

Teeth

The dentist or dental hygienist uses instruments such as a mouth mirror, periodontal probe, and explorer to examine the teeth. Every tooth is checked for cavities; the conditions and positions of the teeth, both erupted and impacted, are noted; previous treatments, such as crowns and other restorations, are evaluated. The dentist’s observations are recorded on a tooth chart. The jaw joint and bite are evaluated, since an irregular bite can lead not only to excessive wear on the teeth but other dental problems as well. The fit of dentures and bridges, if worn, are inspected. Dentists frequently order other diagnostic tests such as x rays, blood tests, and **dental casts** as well.

Gums

The dentist or hygienist evaluates the gingiva, or gum tissue, for periodontal disease by checking for loose teeth, bone loss, and bleeding, swollen, or receding gums. A periodontal probe measures the depth of the pocket around each tooth. If the gums are healthy the pocket will be less than three millimeters deep. Pockets of four millimeters or more indicate periodontal disease. The deeper the pocket, the greater the chance for tooth loss unless treatment is begun.

Tissues of the mouth

An **oral cancer** screening is part of the dental examination. The dentist feels the lymph nodes on the face and neck, and checks the entire oral cavity—including the hard and soft palates, tongue, cheeks, lips, and floor of the mouth—for irregularities. If caught early, many types of oral **cancer** can be treated successfully.

A dentist and assistant check a woman's teeth during a dental exam. (Photograph by Carolyn A. McKeone. Science Source/Photo Researchers. Reproduced by permission.)

Patient education

Oral exams often include instructing the patient in flossing and brushing techniques, the use of fluoride toothpastes, and the prevention of tooth damage from contact sports and other activities. Patient concerns can also be discussed during a counseling session.

Insurance

Oral examinations are covered by most dental insurance at 100%. Annual x rays are also covered. Panorax and full-mouth x rays are usually covered every three to five years, except for emergencies or third molar (wisdom tooth) surgery.

Preparation

The dental office prepares for an examination by sterilizing all the equipment that will be used during the examination. The patient prepares by having a complete medical and dental history available or alerting the dentist or hygienist to any health changes, and taking pre-treatment medication, if necessary.

Aftercare

The patient will be advised that the teeth may be tender after a thorough cleaning and examination, and ibuprofen (Advil, Motrin) or acetaminophen (Tylenol) may be recommended to alleviate the discomfort. This tenderness usually subsides within a day or two.

Complications

Complications from an oral examination are rare, although the tissues and teeth may be sore for a few days.

Results

An oral examination should give the dentist a good idea of the patient's oral health. Once this is established, a complete treatment program can be scheduled and maintained.

Health care team roles

The dental staff work as a team during the examination. The front office confirms the appointment with the patient a day ahead of time, and reminds the patient of

information that will be needed for medical and dental histories. The registered dental hygienist (RDH) assesses the patient's **health history**, takes x rays, and cleans the teeth. Next the registered dental assistant (RDA) and dentist chart the existing conditions of the mouth and teeth, and counsel or educate the patient. This helps the patient feel comfortable and knowledgeable about the treatment required for optimum health.

Dental filling materials see **Restorative dental materials**

KEY TERMS

Full-mouth x rays—A set of x-ray films that show all the teeth, consisting of 14 periapicals and two or four bitewings.

Panorex—Trade name for a single panoramic x ray taken by a camera that travels around the head, it shows all the teeth and both jaws in one film. It can reveal impacted teeth, cysts or tumors of the jaw, along with possible sinus infections and temporomandibular joint dysfunction.

RDA—Registered dental assistant, a licensed professional trained to assist the dentist at chairside, including preparation and maintenance of dental instruments, preparation of dental materials, taking impressions, etc.

RDH—Registered dental hygienist, a licensed professional. RDHs evaluate patient histories, clean teeth by removing deposits such as plaque and tartar, process dental x rays, and educate patients about oral hygiene.

Dental fillings

Definition

Dental fillings are metal amalgams or composite resins used to fill a cavity.

Purpose

Dentists use dental fillings to restore teeth damaged by **dental caries** (tooth decay). Dental caries are caused by microorganisms that convert sugars in food to acids which erode the enamel of a tooth, creating a hole or cavity. The dentist cleans out the decayed part of the tooth and fills the opening with an artificial material (a filling) to protect the tooth's structure and restore the appearance and utility of the tooth.

Precautions

As in any dental procedure, the dentist and dental assistant will need to use sterile techniques. Gloves and masks are essential as well as the sterilization of equipment and tools. This not only helps prevent the spread of infectious diseases like **AIDS** and hepatitis, but also the **common cold**.

The patient's reaction to anesthesia is the other main concern of the dentist and dental assistant when perform-

ing dental fillings. **Nitrous oxide** should be avoided with pregnant patients, and local anesthetics should be used with caution, though they are considered safe. Local anesthetics like Novocain and lidocaine have been in practical use for decades with few side effects reported. Some patients, however, are allergic to these drugs.

Description

Though dentists are encountering fewer and smaller cavities in their patients, there is still a need for dentists to fill cavities. Old fillings suffer wear and need to be replaced. Patients are demanding more restorative work on their teeth, sometimes opting for full mouth restorations that involve installing crowns, bleaching teeth or applying veneers, and replacing dark metal fillings with tooth-colored ones that create a monochromatic view in a patient's mouth.

Once the decay is removed and the tooth is prepared (see Preparation), the dentist has a wide choice of dental filling materials to choose from.

Amalgam fillings

The most common and strongest filling material is amalgam. It is a silver filling that is usually placed on the rear molars, which endure more stress during chewing. Amalgam fillings—used for large, deep cavities—are strong and very resistant to wear. Amalgam has been in use since 1833.

Amalgam is a mixture (an amalgam) of several metals, including liquid mercury (35% silver, 15% tin or tin and **copper**, a trace of **zinc**, and 50% mercury). When it is prepared, it has a malleable consistency which can easily be shaped to fit the prepared tooth. It hardens to a durable metal.

Despite its durability, many dentists and patients avoid amalgam fillings. Dentists have found that amalgam has a tendency to expand with time. As a result, teeth become fractured from the inside, often splitting the tooth. Patients often avoid amalgam for strictly aesthetic reasons. Amalgam fillings darken over time and make teeth look as if they are decayed.

The biggest reason amalgam has lost favor is a health concern due to its 50% mercury content. Although the American Dental Association (ADA) has pronounced amalgam safe in the quantity and composition of amalgam, some patients and dentists are disturbed by various reports of illness in relation to the mercury in amalgam fillings. Mercury is a toxic material. Some states are required to dispose of mercury waste as if it were a hazardous product. There is also an added risk of inhaling mercury particles when old fillings are removed.

Gold fillings

Gold fillings or inlays are created outside of the mouth by a dental technician and then cemented into place. They are also used to fill the back molars. Gold fillings are very durable. Like amalgam, however, they are not as aesthetically pleasing as tooth-colored fillings.

Composite fillings

Composite fillings, often called white fillings, are made of a plastic resin and finely ground glass. They must be applied to the tooth surface in thin layers. Dentists try to match the color of composites with neighboring teeth for a more natural look, making the filling appear invisible. Composite resin fillings often are made smaller than amalgam fillings and require less tooth preparation, thereby saving more natural tooth surface.

Composite fillings are bonded to the tooth so that the tooth becomes stronger than it was before. They are also less sensitive to temperature changes in the mouth that can damage the tooth; therefore there is less chance that the tooth will shatter because of the filling.

These fillings may not be suitable for large cavities in molars. Though composite durability increased in the 1990s, a porcelain inlay or crown may be the best choice for a durable, natural-looking restoration of a molar.

The major drawback of composite resin fillings is cost. They average one-and-a-half to two times more than the price of amalgam fillings. They also can be stained from drinking coffee and tea. Large composite fillings tend to wear out sooner than amalgam fillings.

Composite fillings can last seven to ten years, which is similar to the lifespan of amalgam fillings.

Resin ionomer

Resin ionomers are new, tooth-colored filling materials that contain a resin and fluoride. They are very suitable for children and for older adults who suffer from root decay that occurs as a person ages. These fillings seal the tooth and also protect it from future decay because of the fluoride that they release.

Preparation

During a routine checkup, the dentist may find a cavity in a tooth with a metal tooth probe. A new diagnostic tool, the DIAGNOdent, can detect evidence of cavities and pre-cavity conditions on the tooth's surface. A low-powered laser, the DIAGNOdent is able to detect decay so early that a dental cavity can be avoided. These pre-cavity areas can be protected with a sealant, thereby preventing further decay.

Cavities found since the 1990s are relatively small and not very deep, so there may be no need to anesthetize the area where the dental work will be done. High-speed drills often are able to clean out the decay quickly and with little discomfort. If the cavity is not very deep, the drill may not reach the sensitive nerves in the teeth which usually cause **pain**. Children and some adults may need anesthesia in any case. The dentist and the dental assistant need to be aware of the patient's history and if the patient reacts adversely to **local anesthesia**. (See Precautions and Complications.)

There are some dentists who use electronic dental anesthesia (EDA), a device that sends electrical charges to the gum through electrodes. Sometimes this is enough anesthesia for the procedure. At other times, EDA numbs the area where the anesthesia is administered, so that the patient doesn't feel the needle as it goes into the gum. Some dentists also provide soothing music to calm patients during the procedure. Other dentists will use local anesthesia in combination with nitrous oxide-oxygen analgesia to minimize discomfort through the drilling phase of a filling.

Dental lasers that generate a low-powered beam of light are being used to cut away decay, but without the whine of the drill and without using anesthesia. Though a bit slower than the conventional drill, lasers are very efficient at preparing a tooth to receive a filling. Unfortunately, lasers cannot yet remove old fillings or prepare a tooth surface to receive a crown.

Air abrasion is another way to remove decay without using anesthesia. Air abrasion machines produce a spray of air and powder. There is no vibration or heat. Because it has no vibration, it avoids microfractures in the tooth that sometimes occur with drills. Air abrasion removes only a small amount of the tooth's structure. Therefore, it is suitable for small cavities and the repair and replacement of old fillings. It also can repair chipped teeth and clean discolored or stained teeth.

After the cavity is cleaned of decay, the walls of the tooth are shaped and are ready to receive a filling material. If a composite resin filling is used, the tooth next needs to be etched so that the resin will adhere to the tooth. The tooth then is filled, shaped, and polished. The composite filling then must be hardened by shining a special light on it.

Aftercare

The dentist and dental assistant should advise the patient that the teeth, lips, and tongue may be numb for several hours after the procedure, if a local anesthetic was used. Some patients experience sore gums or a sensitivity to hot and cold in the tooth that has just been

filled. Normally, patients are advised to avoid chewing hard foods directly on new amalgam fillings for 24 hours. Composite fillings require no special caution since they set immediately. If patients experience continued pain or an uncomfortable bite, they should call their dentist.

Complications

Some patient's have allergic reactions to local anesthesia.

Results

Fillings restore a tooth's function and appearance. They permit the patient to continue to eat and chew properly and last for several years. Normal fillings will need to be replaced over a patient's lifetime. Since fewer dental caries have been observed since the last decade of the twentieth century, dentists are initially filling fewer teeth, but are replacing fillings as they fail and sometimes systematically, especially if the patient decides to cosmetically enhance his or her teeth. Since many of the initial cavities are quite small, patients are opting for more aesthetically pleasing filling materials even if they are not as durable.

Health care team roles

When the dentist discovers a cavity, filling options are discussed with the patient. The dental assistant prepares the dentist's workstation and lays out the specific instruments that are needed. The dental assistant prepares the filling material according to the manufacturer's directions and assists the dentist in preparing the tooth for filling and in the filling procedure itself. The dental assistant cleans the patient's mouth and returns the procedure room to order. All of the instruments that have been used are sterilized by the dental assistant.

KEY TERMS

Amalgam—A mixture of metals, primarily mercury used to make large, durable fillings. Also called silver fillings.

Anesthesia—A condition created by drugs that produces a numb feeling. General anesthesia produces unconsciousness whereas a local anesthesia produces numbness around the site where the drug was introduced.

Composite filling—A resin material that is tooth colored and is used to fill a tooth once decay has been removed. It is used most often in front teeth but may be used in any tooth for aesthetic reasons.

Crown—An artificial covering prepared by a lab technician to fit over a damaged tooth or one weakened by decay.

Dental caries—Tooth decay caused by microorganisms that convert sugars in food to acids which erode the enamel of a tooth.

Dental laser—A device that generates a low-powered beam of light that is used in place of a dentist's drill to cut away decay from a tooth or remove gum tissue.

Enamel—The hard outer surface of a tooth.

Dental hygiene

Definition

Dental hygiene is the profession of cleaning teeth and helping patients maintain oral health. Dental hygienists are licensed professionals—key members of the dental health care team who provide educational, clinical,

and therapeutic dental services, such as preventive care, dental examinations, and instruction about how patients can better care for their teeth and gums.

Description

Dental hygienists are trained to provide dental hygiene care for patients, they work with dentists to deliver oral care to patients, and they use their interpersonal skills to educate and motivate patients about how to prevent dental disease and maintain oral health. In the clinical setting, dental hygienists:

- Assess patients' teeth and gums and review oral histories.
- Educate patients about **nutrition** and self-care to prevent dental disease, teaching them how to clean the mouth using aids such as toothbrushes, interdental devices, and other efficacious products.
- Examine head, neck and dental areas for disease.
- Perform x rays and other diagnostic tests.
- Perform preventive dental services, such as removing calculus, stains and plaque from teeth, to keep the teeth and gums healthy.
- Screen for **oral cancer** and high **blood** pressure.
- Educate patients about oral health and its link to general health.
- Place and remove periodontal dressings or temporary fillings.
- Make impressions of teeth to use as models for dentists to evaluate treatment needs.
- Apply preventive agents such as sealants and fluorides to keep teeth healthy.
- Remove sutures.

In administrative roles, dental hygienists consult with dental health or insurance companies, market dental products, and initiate community dental health programs. Dental hygienists also hold positions at colleges and universities, where they teach dental hygiene or conduct clinical research. Another area of opportunity is in **public health**, where dental hygienists provide health policy, program administration and management; research community-based care methods; focus on oral health promotion and disease prevention; and help assess, develop, evaluate, and initiate oral health care delivery systems. In these capacities they often have little or no direct individual patient contact.

Dental hygiene is a profession that requires its practitioners to work closely with patients, earning their trust, maintaining a high level of oral care, and teaching them

Examples of services provided by dental hygienists

Types of services	Purpose	Individual	Family	Community
Preventive: Primary	To prevent disease occurrence	Sealants	Counsel parents on prevention of baby-bottle tooth decay	Promote water fluoridation
Preventive: Secondary	Early treatment to prevent disease progression	Plaque/calculus removal	Counsel on harmful oral habits	Oral screening and referrals
Educational	Guide to good health behaviors	Home care instruction	Nutritional counseling	Oral health units in schools
Therapeutic	Stop or control disease and maintain healthy oral tissues	Scaling/root planing Postoperative care	Smoking cessation, counseling	Sealant programs Fluoridation of water supply

SOURCE: Alvarez, K.H. *Williams & Wilkins' Dental Hygiene Handbook*. Baltimore: Williams & Wilkins, 1998.

the skills they need to stay healthy. Providing these valuable services usually fosters a tremendous sense of personal fulfillment. Dental hygiene is a highly skilled, prestigious discipline with room for advancement. Flexible hours and work environments make the work attractive. Dental hygienists have little problem finding full- or part-time work during daytime, evening and weekend hours in almost every area of the world. Many also enjoy the job security that dental hygiene offers. Rapid advances in **preventive dentistry** combined with an aging and growing population ensures that dental hygienists will be busy for the foreseeable future.

Work settings

Dental hygienists usually work in private dental practices. However, other employment settings include health maintenance organizations, long-term care facilities, schools, military bases, universities, research facilities, governmental agencies, dental supply companies, or in veterinary dental medicine.

Education and training

Dental hygienists are licensed oral health care professionals who have either a two-year diploma, certificate, or associate degree in dental hygiene or a four-year baccalaureate degree. They are educated through community college academic programs, technical colleges, dental schools, or universities. Dental hygienists should work well with others and have good manual dexterity and hand-eye coordination to use **dental instruments** in the small area of a person's mouth.

Students in dental hygiene programs receive laboratory, clinical, and classroom instruction in subjects such as anatomy, physiology, chemistry, microbiology, **pharmacology**, nutrition, radiography, histology, periodontology, pathology, dental materials, dental hygiene theory and practice, and social and behavioral sciences.

Dental hygienists must be licensed in the jurisdiction in which they practice. To become licensed, dental hygienists must have graduated from an accredited dental hygiene school and passed written and clinical examinations. Accredited dental hygiene programs require an average of 2,000 curriculum hours, including 585 hours of supervised clinical dental hygiene instruction. Two-year associate's degrees allow dental hygienists to take national, state, or regional license examinations.

Usually, an associate's degree is qualification enough for those who want to practice in a private dental office. High school students considering a career in dental hygiene should consider taking such courses as health, biology, psychology, chemistry, mathematics, and speech. Some baccalaureate degree programs require that applicants first complete two years of college before being accepted into dental hygiene programs. About half of the dental hygiene programs prefer applicants who have completed at least one year of college. Students or school counselors should contact individual programs for their requirements.

Advanced education and training

Dental hygienists who go into research, education, or administration usually need a master's degree in dental hygiene. Those oral hygienists who choose to go into public health dental hygiene usually must pursue graduate public health education at both schools of public health and dentistry.

Future outlook

Dental hygiene is projected to be among the 30 fastest growing occupations due to the increasing population and people's longer retention of their natural teeth.

Proper dental hygiene clinical attire

Outer garments (gowns, lab coats, scrub suits, uniforms) should adequately cover arms and street clothing. They should be disposable or laundered commercially (not taken home or worn outside the clinic).

The face mask should block out particles as small as microns and have a lining impenetrable to moisture. The mask should cover the nose and mouth and fit comfortably under glasses, if worn. Change the face mask before each patient and wear for no longer than 1 hour.

Protective eyewear should be worn by both the patient and client. The eyewear should be shatterproof, lightweight, easily disinfected, and provide wide coverage with side shields.

Gloves should be strong and durable, and impermeable to saliva, blood, and bacteria. The gloves should be nonirritating or harmful to skin and fit properly.

Jewelry should not be worn on hands and wrists to minimize areas for microorganisms.

SOURCE: Alvarez, K.H. *Williams & Wilkins' Dental Hygiene Handbook*. Baltimore: Williams & Wilkins, 1998.

In fact, the career path is expected to grow much faster than average through 2008. Salaries of dental hygienists are based on their responsibilities and specific positions, the geographic location of employment, and their type of work environment. They are similar to those of other health care personnel with similar education and experience. In 1998 dental hygienists earned median hourly wages of \$22.06. The middle 50% earned between \$17.28 and \$29.28 an hour. The lowest 10% earned less than \$12.37; the highest 10% earned more than \$38.81 an hour.

Calculus—A hard mineral deposit formed on teeth; tartar.

Histology—Study of tissue structure.

Periodontology—Study of gum disease.

Plaque—Colorless, sticky film composed of acid and bacteria, which causes tooth decay.

Dental indices**Definition**

Dental indices provide a quantitative method for measuring, scoring, and analyzing dental conditions in individuals and groups. An index describes the status of individuals or groups with respect to the condition being measured.

Description

Oral health surveys depend on dental indices, as do researchers and clinicians, to help in understanding trends and patients' needs. In epidemiological oral health surveys, an index is used to show the prevalence and incidence of a particular condition, to provide baseline data, to assess the needs of a population, and to evaluate the effects and results of a community program. Researchers use indices to determine baseline data and to measure the effectiveness of specific agents, interventions, and mechanical devices. In private practice, index scores are used to educate, motivate, and evaluate the patient. By comparing scores from the initial exam during a follow-up exam, the patient can measure the effects of personal daily care.

The first dental index, developed by Schour and Massler, was known as a Papilla, Marginal gingiva and Attached gingiva (PMA) Index. Each of those areas was examined and scored from 0 to 5, depending on the severity of inflammation. The PMA Index, largely of historic interest now, was primarily used in surveys of acute **gingivitis**.

Today, dental indices are used to assess both individual and group oral health and disease status. They can be simple, measuring only the presence or absence of a condition, or they can be cumulative, measuring all evidence of a condition, past and present. Irreversible indices measure conditions that will not change, such as **dental caries**.

A reversible index measures conditions that can be changed, such as the amount of bacterial plaque present.

The status of a patient's periodontal health or disease is commonly measured by an index in private practices. One of the most widely used is the Periodontal Screening and Recording (PSR)TM Index, adapted in 1992 from a system in use in Europe called the Community Periodontal Index of Treatment Needs. The PSRTM is an early detection system for periodontal disease. It is not intended to replace full periodontal charting, but to serve as a simple and convenient screening tool. (The PSRTM is more fully discussed in the entry on dental and periodontal charting.)

In addition to measuring a patient's periodontal status, dental indices can measure the amount of plaque and calculus present or not present in a patient's mouth, the amount of bleeding present in the gingiva, the amount of tooth mobility present at a given time, the amount of **fluorosis** present, and the number of decayed, missing, or filled teeth present. Some of the more widely known indices are:

Plaque index (PI)

The PI as developed by Silness and Loe assesses the thickness of plaque at the cervical margin of the tooth (closest to the gum). Four areas, distal, facial or buccal, mesial, and lingual, are examined.

Each tooth is dried and examined visually using a mirror, an explorer, and adequate light. The explorer is passed over the cervical third to test for the presence of plaque. A disclosing agent may be used to assist evaluation. Four different scores are possible. A zero indicates no plaque present; 1 indicates a film of plaque present on the tooth; 2 represents moderate accumulation of soft deposits in the gingival pocket or on the tooth that can be seen by the naked eye; 3 represents an abundance of soft matter within the pocket or on the tooth.

Each area of each tooth is assigned a score from 0 to 3. Scores for each tooth are totaled and divided by the four surfaces scored. To determine a total PI for an individual, the scores for each tooth are totaled and divided by the number of teeth examined. Four ratings may then be assigned: 0 = excellent, 0.1-0.9 = good, 1.0-1.9 = fair, 2.0-3.0 = poor.

Plaque control record

A similar system for measuring plaque is credited to O'Leary, Drake, and Naylor. This system measures plaque present, rather than plaque not present, but no attempt is made to differentiate in the quantity of plaque seen on each surface. The number of surfaces examined may be increased from four to six. When using six sur-

faces, they are facial (or buccal), mesio-facial, mesio-lingual, lingual, disto-lingual, and disto-facial.

To determine an individual's score, the clinician multiplies the number of surfaces with plaque by 100, and divides that by the number of tooth surfaces examined. For example, if an individual has 26 teeth, that equals 104 surfaces. If eight surfaces are found to have plaque, then 800 is divided by 104, leaving a plaque control index of 7.6%. A score under 10% is considered good.

Oral hygiene index (OHI)

The OHI, developed by Greene, Vermillion, and Waggener, has two components, the debris index and the calculus index, and is an indication of oral cleanliness. The scores may be used singly or in combination. For scoring, the clinician divides the dentition into sextants and selects the facial (or buccal) and lingual tooth surface in each sextant that is covered with the greatest amount of debris and calculus. Twelve surfaces, therefore, will be evaluated. For this index, a surface includes half the circumference of the tooth.

Greene and Vermillion have also developed a simplified OHI in which the clinician measures only one tooth surface in each sextant, equaling only six surfaces.

DEBRIS INDEX (DI). For this index, debris is defined as soft, foreign matter consisting of bacterial plaque and food debris. The criteria include 0, no debris or stain present; 1, debris covering not more than one-third of the tooth surface or extrinsic stain without debris; 2, debris covering between one- and two-thirds of the tooth surface; and 3, debris covering more than two-thirds of the tooth surface.

CALCULUS INDEX (CI). Calculus, a hard calcified deposit of inorganic salts, is scored for this index with four criteria. They are 0, no calculus present; 1, supragingival calculus present covering not more than one third of the tooth surface; 2, supragingival calculus covering between one- and two-thirds of the tooth surface, or scattered subgingival calculus; and 3, supragingival calculus covering more than two-thirds of the tooth surface, or a continuous heavy band of subgingival calculus around the tooth.

To arrive at an OHI score, one first calculates the DI and CI scores by dividing the total scores for each tooth by the number of sextants. The DI and CI scores are then added to determine an OHI score. A perfect score would be 0, and the worst score possible is 12. In the simplified OHI, the worst score possible is 6.

Gingival index (GI)

Also attributed to Loe and Silness, the GI assesses the severity of gingivitis based on color, consistency, and

Types of dental indices

Type	Purpose
Individual assessment	Evaluation and monitoring the progress and maintenance of oral health Measures effects of personalized disease control programs over time Monitors progress of disease healing Patient education, motivation
Clinical trial	Determines the effect of an agent or procedure on the prevention, progression, or control of a disease Comparison of an experimental group with a control group
Epidemiologic survey	Survey for the study of disease characteristics of populations Not designed for evaluation of an individual patient

SOURCE: Alvarez, K.H. *Williams & Wilkins' Dental Hygiene Handbook*. Baltimore: Williams & Wilkins, 1998.

bleeding on probing. Each tooth is examined at the mesial, lingual, distal, and facial (or buccal) surface. A probe is used to press on the gingiva to determine its degree of firmness, and to run along the soft tissue wall adjacent to the entrance to the gingival sulcus. Four criteria are possible: 0, normal gingiva; 1, mild inflammation but no bleeding on probing; 2, moderate inflammation and bleeding on probing; 3, severe inflammation and ulceration, with a tendency for spontaneous bleeding.

Each surface is given a score, then the scores are totaled and divided by four. That number is divided by the number of teeth examined to determine the GI. Ratings are 0, = excellent; 0.1-1.0 = good; 1.1-2.0 = fair; 2.1-3.0 = poor.

Periodontal index (PI)

Developed by Russell, the PI determines the periodontal disease status of populations in epidemiologic studies. Each tooth is scored according to the condition of the surrounding tissues. On examination, each tooth is assigned a score using the following criteria:

- 0: Negative. Neither overt inflammation nor loss of function caused by the destruction of supporting tissue is noted.
- 1: Mild Gingivitis. Overt inflammation in the free gingiva is present, but does not circumscribe the tooth.
- 2: Gingivitis. Inflammation surrounds the tooth, but there is no apparent break in the epithelial attachment.
- 6: Gingivitis with pocket formation. The epithelial attachment of gum to tooth is broken. There is no inter-

ference with normal function. The tooth is not loose or drifting.

- 8: Advanced destruction with loss of function. The tooth may be loose or drifting. It may sound dull on percussion and may be depressible in the socket.

Scores for each tooth are added, and the total divided by the number of teeth examined. Scores can be interpreted as follows:

- 0-0.2: Clinically normal supportive tissues.
- 0.3-0.9: Simple gingivitis.
- 0.7-1.9: Beginning destructive periodontal disease.
- 1.6-5.0: Established destructive periodontal disease.
- 3.8-8.0: Terminal periodontal disease.

Gingival bleeding index (GBI)

Unwaxed dental floss is used to measure a GBI, developed by Carter and Barnes. A full complement of teeth has 28 proximal areas to be examined. Floss is passed interproximally, first on one side of the dental papilla, then on the other. The clinician curves the floss around each tooth and passes it below the gingival margin, taking care not to lacerate the gingiva. Any bleeding noted indicates the presence of disease. The numbers of bleeding areas versus proximal areas scored is recorded and used for patient motivation.

Mobility index

The mobility index, developed by Grace and Smales, can be useful to track the amount of mobility in teeth over a period of time. Grade 0 indicates no apparent mobility. Grade 1 is assigned to a tooth in which mobility is perceptible, but less than 1mm buccolingually. Grade 2 mobility is between 1-2 mm, and Grade 3 mobility exceeds 2mm buccolingually or vertically.

Dean's Dental Fluorosis Index

Dean's is used to score the amount of dental fluorosis (discoloration) present on teeth. Fluorosis generally appears as a horizontal striated pattern across a tooth. Molars and bicuspids are most frequently affected, followed by upper incisors. The mandibular incisors are usually least affected. Fluorosis tends to be bilaterally symmetrical. Defects may appear as fine white or frosted lines or patches near the incisal edges or cusp tips.

A score is given based on the two teeth most affected. If the teeth are not equal in appearance, the less affected tooth is the one scored.

Scores used in Dean's Index are as follows:

- Normal (0): The enamel is smooth, glossy and translucent, usually a pale creamy-white color.
- Questionable (1): There are slight aberrations from the translucency of normal enamel. Lesions may range from a few white flecks to occasional spots.
- Very mild (2): Opaque paper-white areas are visible, involving less than 25% of the facial or buccal tooth surface.
- Mild (3): White opacity of the enamel is more apparent than for code 2, but still covers less than 50% of the surface.
- Moderate (4): Marked wear and brown stain, frequently disfiguring, is visible.
- Severe (5): Hypoplasia is so marked that the general form of the tooth may be altered. Pitted or worn areas and brown stain are widespread. Teeth often have a corroded appearance.
- Excluded (8): Used for crowned teeth.
- Not recorded (9): Used for missing teeth or teeth that cannot be scored.

Decayed, missing and filled teeth (DMFT) index

To assess dental caries in a population, a DMFT index is used. During a systematic examination with a mirror and explorer that includes the crown and exposed root of every primary and permanent tooth, each crown and root are assigned a number based on the result of that exam. The numbers are recorded in boxes corresponding to each tooth to provide a DMFT chart. It is recommended that care be taken to record all tooth-colored fillings, which may be difficult to detect.

Number are assigned as follows:

- 0: A zero indicates a sound crown or root, showing no evidence of either treated or untreated caries. A crown may have defects and still be recorded as 0. Defects that can be disregarded include white or chalky spots; discolored or rough spots that are not soft; stained enamel pits or fissures; dark, shiny, hard, pitted areas of moderate to severe fluorosis; or abraded areas.
- 1: One indicates a tooth with caries. A tooth or root with a definite cavity, undermined enamel, or detectably softened or leathery area of enamel or cementum can be designated a 1. A tooth with a temporary filling, and teeth that are sealed but decayed, are also termed 1. A 1 is not assigned to any tooth in which caries is only suspected. In cases where the crown of a tooth is entirely decayed, leaving only the root, a 1 is assigned to both crown and root. Where only the root is decayed, only the root is termed a 1. In cases where both the crown and root are involved with decay, whichever site is

judged the site of origin is recorded as a 1. These criteria apply to all numbers.

- 2: Filled teeth, with additional decay, are termed 2. No distinction is made between primary caries which is not associated with a previous filling, and secondary caries, adjacent to an existing restoration.
- 3: A 3 indicates a filled tooth with no decay. If a tooth has been crowned because of previous decay, that tooth is judged a 3. When a tooth has been crowned for another reason such as aesthetics or for use as a bridge abutment, a 7 is used.
- 4: A 4 indicates a tooth that is missing as a result of caries. Only crowns are given 4 status. Roots of teeth that have been scored as 4 are recorded as 7 or 9. When primary teeth are missing, the score should be used only if the tooth is missing prematurely. Primary teeth missing because of normal exfoliation need no recording.
- 5: A permanent tooth missing for any other reason than decay is given a 5. Examples are teeth extracted for orthodontia or because of periodontal disease, teeth that are congenitally missing, or teeth missing because of trauma. The 5 is assigned to the crown, the root is given a 7 or 9. Knowledge of tooth eruption patterns is helpful to determine whether teeth are missing or not yet erupted. Clues to help in the determination include appearance of the alveolar ridge in the area in question, and caries status of other teeth in the mouth.
- 6: A 6 is assigned to teeth on which sealants have been placed. Teeth on which the occlusal fissure has been enlarged and a composite material placed should also be termed 6.
- 7: A 7 is used to indicate that the tooth is part of a fixed bridge. When a tooth has been crowned for a reason other than decay, this code is also used. Teeth that have veneers or laminates covering the facial surface are also termed 7 when there is no evidence of caries or restoration. A 7 is also used to indicate a root replaced by an implant. Teeth that have been replaced by bridge pontics are scored 4 or 5; their roots are scored 9.
- 8: This code is used for a space with an unerupted permanent tooth where no primary tooth is present. The category does not include missing teeth. Code 8 teeth are excluded from calculations of caries. When applied to a root, an 8 indicates the root surface is not visible in the mouth.
- 9: Erupted teeth that cannot be examined—because of orthodontic bands, for example—are scored a 9. When applied to a root, a 9 indicates the tooth has been extracted. The crown of that tooth would be scored a 4 or 5.

KEY TERMS

Buccal—Surface of a posterior tooth closest to the cheek.

Caries—Tooth decay.

Cementum—Outer surface of the tooth root.

Disclosing agent—Tablet or liquid containing a red dye that is used to color and reveal plaque in a patient's mouth.

Distal—Surface of a tooth farthest from the midline.

Edentulous—Without teeth.

Facial—Surface of an anterior tooth closest to the lips.

Fixed bridge—Two or more prosthetic crowns covering teeth on either side of a missing tooth. A pontic, or artificial tooth, is suspended between the crowns to fill the space.

Fluorosis—Mottled discoloration of tooth enamel due to excessive systemic ingestion of fluoride during tooth development.

Hypoplasia—Incomplete or defective development of the enamel of a tooth.

Lingual—Surface of a tooth closest to the tongue.

Mandibular—Pertaining to the lower jaw.

Maxillary—Pertaining to the upper jaw.

Mesial—Surface of a tooth closest to the midline.

Papilla—Triangular pad of gum tissue filling the space between the proximal surfaces of two adjacent teeth.

Pontic—Artificial tooth suspended between two prosthetic crowns to fill a space left by a missing tooth.

Sealant—Composite resin applied to pits and fissures of teeth to prevent decay.

Sulcus—Groove between the surface of a tooth and the epithelium lining the free gingiva.

- T: Indicating trauma, a T is used when a crown is fractured, with some of its surface missing but with no evidence of decay.

The “D” of DMFT refers to all teeth with codes 1 and 2. The “M” applies to teeth scored 4 in subjects under age 30, and teeth scored 4 or 5 in subjects over age 30. The “F” refers to teeth with code 3. Those teeth coded 6, 7, 8, 9, or T are not included in DMFT calculations.

To arrive at a DMFT score for an individual patient's mouth, three values must be determined: the number of teeth with carious lesions, the number of extracted teeth, and the number of teeth with fillings or crowns. A patient who has two areas of decay, six missing teeth and 11 filled or crowned teeth for example, has a DMFT score of 19. Teeth that include both decay and fillings or crowns, are only given one point, a D. Thirteen teeth (based on a full dentition of 32) remain intact.

It is also possible to determine more detailed DMFS (decayed, missing, or filled surface) scores. As anterior teeth have four surfaces and posterior teeth have five, a full dentition of 32 teeth includes 128 surfaces. A patient with seven decayed surfaces, 20 surfaces from which teeth are missing, and 42 surfaces either filled or included in a crown, the DMFS score is 69. Fifty-nine surfaces are intact.

For primary dentition, scoring is referred to as “deft” or “defs” (decayed, extracted, or filled).

Significant caries index

In 2000, the World Health Organization developed the significant caries index (SiC) to be used when studying DMFT scores on a global basis. A single population may include a number of individuals with low DMFT scores, as well as those with high scores. A mean DMFT value would not accurately reflect the status of the population. The SiC Index isolates and highlights those individuals with the highest caries values in a particular population.

To calculate a SiC Index, individuals are sorted according to DMFT values. The third of the population with highest caries scores is isolated, and a mean DMFT for this subgroup is calculated. The resulting value is the SiC Index.

Viewpoints

Researchers all over the world develop dental indices to suit their particular needs, resulting in some duplication. There are at least six indices that measure the presence or absence of plaque. Indices have become flexible, able to be adapted, modernized, or simplified to fit different needs. They will continue to develop as those needs change again.

Professional implications

Dental professionals from the private practice clinician to the researcher use indices to benefit their patients. A dentist or hygienist might use a PI to impress upon a patient the need for better **oral hygiene**. A World Health Organization researcher might use the same index to assess the **home care** practices of a population. Indices

will continue to be important and necessary tools for dental professionals.

Dental instruments

Definition

Dental instruments are tools used in the assessment, diagnosis, and treatment of oral diseases.

Purpose

Dental instruments are designed to be used by the dentist and staff during dental care. Instruments aid in the assessment and treatment of dental disease. Each is designed for a specific purpose.

Description

There are many different dental instruments used by oral health care professionals in their different roles and specialties. Certain types of instruments are unique to various therapeutic procedures.

Assessment

During an examination by a general dentist the following diagnostic instruments may be used:

- Cotton pliers: used for placing cotton rolls or pluggets to dry up saliva.
- Mouth mirror: used to view hard-to-see areas such as the roof of the mouth, behind the molars, and behind the anterior teeth.

Dental drill. (Photograph by Randy Duchaine. *The Stock Market*. Reproduced by permission.)

- Probes: used to measure the depth of periodontal pockets or sulci.
- Explorers: used to detect **dental caries** in tooth grooves and pits.

Restorative procedures

During restorative treatment the following types of instruments may be used:

- Amalgam carriers: for transferring amalgam from the tray to the patient's mouth.
- Burnishers: for smoothing the amalgam filling.
- Composite: for use as an alternate filling material when silver fillings are not appealing.
- Excavators: for removal of small amounts of decay close to the nerve.
- High speed hand piece: for removal of tooth decay. It is commonly known as the drill.
- Slow speed hand piece: for removal of deep decay from the teeth. It is commonly known as the slow drill, and is also used in extrinsic stain removal.
- Spatulas: for mixing compounds, such as alginate, plaster, dycal, and cements.

- Brush holders: for holding tiny brushes and reaching far in to the mouth.
- Carvers: for carving the amalgam filling to the shape of the tooth.
- Pluggers: for placing amalgam filling deep in the excavated tooth.
- Syringes: for washing out excavated teeth with sterile water.

Periodontal procedures

During periodontal treatment (concerning tissues surrounding the teeth), the following types of instruments may be used:

- Gingival knives: small knives used to cut gum tissue in the area of treatment.
- Chisels: **surgical instruments** that aid in the removal of infected bone.
- Surgical burs: used in high speed hand drills to aid in the sectioning of the infected bone or roots.
- Bone files: surgical instruments that aid in the filing of infected bone in order to remove that portion of infected bone.
- Scalers/curets: used for the removal of bacterial toxins and calculus below the gum line.

Endodontic procedures

During endodontic treatment (concerning diseases of the pulp), the following instruments may be used:

- Explorers: used to assess the root canals of the tooth.
- Spreaders: used to spread the hot gutta percha into the individual root canals.
- Files: used to clean out the nerve of the infected tooth. Files come in different lengths and sizes.
- Reamers: used to ream out the nerve. Reamers are bigger than a file.
- Broach: used to remove hardened nerve tissue (dead nerve tissue) and enlarge the canal.
- Syringes: used to flush the canals with sterile water for cleaning.

Orthodontic procedures

During orthodontic treatment (concerning alignment of teeth), the following instruments may be used:

- Cutting instruments: used to cut the wires already placed in the mouth.
- Wire forming: used to curve the wire to the correct spere for the individual patient.

- Utility plier: used to cut thick wires before placement in the mouth.
- Debonding instruments: used to remove molar bands from the molars.
- Debanding instruments: used to remove brackets from the teeth.
- Ligature forceps: used to place ligature ties around the brackets.
- Mosquito forceps: used to place ligature ties around odd angled teeth.
- Explorers: used to the remove ligature ties around the brackets.

Surgical procedures

During surgical procedures heavy-duty steel instruments are needed for leverage and lifting. The instruments are used to remove diseased bone or the roots of teeth. The following instruments may be used:

- Elevators: used to raise gum tissue or bone.
- Hemostats: used to grasp tissue for removal or retraction.
- Root tip picks: used to remove sectioned-off root tips.
- Tissue forceps: used to remove or retract tissue.
- Bone files: used to file down and remove diseased bone.
- Retractors: used to hold the cheeks and tongue out of the way.
- Wire cutters and twistors: used to cut wire during wire surgery for better healing of the bone and tissue.
- Extraction forceps: used to remove teeth.
- Periosteal elevators: used to elevate the periosteal (external to bone) tissue for better viewing of the surgical site.
- Scissors: used to cut soft tissue and surgical sutures.
- Scalpel: used to incise gum tissue.
- Needle holders: used to hold the needle during suturing.
- Surgical sutures: made from silk or thread, used to suture tissue together.

Operation

Dental instruments have a variety of applications. Many of the instruments can be used repeatedly after the sterilization process. The life span of the instruments depends on their usage, care, and the method of sterilization. Sterilization prevents the spread of diseases like hepatitis B. Following guidelines set by the ADA and the

manufacturer for proper sterilization of non-critical, semi-critical and critical instruments is advised.

Non-critical instruments can be treated with disinfectants classified as high, intermediate, or low relative to their effectiveness against bacterial spores and **viruses**. Non-critical instruments, such as articulators and spatulas, have no contact with mucous membranes. They do not require sterilization.

Semi-critical instruments touch mucus membranes but do not break the barrier of the mucosal surface or skin. They require sterilization or high-level disinfection, depending on whether they are affected by heat. Sterilization is usually achieved through methods that use extreme heat. Semi-critical instruments include amalgam condensers, hand pieces, and plastic vacuum tips.

Critical instruments require sterilization. These instruments penetrate or touch broken skin or mucus membranes. Critical instruments include needles, scalpels, surgical instruments, dental explorers, dental burs, and endodontic instruments. They must be sterilized.

Endodontic instruments need to be checked daily to determine usability. Files, reamers and broaches become brittle after months of sterilization. The CDCP and ADA recommend critical instruments be cleaned, bagged and then fully sterilized after each procedure. Heavy-duty gloves worn by the dental assistants during cleaning, disinfecting and sterilizing of most dental instruments is advised.

Maintenance

The ADA recommends that the working parts of all instruments be checked monthly. It is also recommended that a sufficient supply of instruments be maintained in order to allow for proper sterilization.

Health care team roles

Ultimately, the dentist is responsible for the ordering of dental instruments, but many offices delegate that task to a supervising dental assistant. The entire office staff is responsible for instrument sterilization. Instrument sterilization prevents **disease transmission** and maximizes the longevity of the instrument.

Training

Following the guidelines set forth by the instrument manufacturer is the best procedure for instrument maintenance and recirculation. The ADA recommends purchasing instruments from reputable companies that have the ADA seal of approval.

KEY TERMS

Amalgam—The material used in silver fillings.

Endodontic—Referring to the nerve and pulp of a tooth.

Endodontist—Dentist specializing in the removal of the nerve and pulp of the teeth.

Gutta percha—Material used during root canal therapy to fill the canals after the nerve has been removed.

Orthodontic—Referring to the movement of the teeth.

Orthodontist—Dentist specializing in the field of tooth movement.

Periodontal—Gum tissue surrounding the teeth.

Periodontist—A dentist who specializes in treating the gum tissue and bones of the mouth.

Sulcus—An indentation in an anatomic structure.

Dental laboratory technology

Definition

Dental laboratory technology is the science and craft of creating **dental prostheses**. It involves artistic talent, aptitude for precision work, good eyesight, and a high degree of manual dexterity. Knowledge of CAD/CAM computer programs, digital cameras, and digital imaging systems is also required.

Description

Preventive education has decreased the incidence of **dental caries**. Better dental health means that the demand for dentures has declined, while the need for dental prostheses and cosmetic procedures has increased.

Dental laboratory technicians are sought by dental laboratories, private dental practices, and medical institutions. These skilled craftspeople are part scientist, part artist, and part engineer. They must have manual dexterity, good eyesight, and a penchant for detailed, precision work.

Dental laboratory technicians create a variety of dental prostheses including crowns, bridges, artificial teeth, partial dentures, and complete dentures. They also prepare inlays—ceramic or resin structures that are cemented into a prepared tooth. Technicians also create onlays from those same materials which fit over the tooth but do not cover the tooth completely like a crown. In large laboratories, dental technicians may specialize in a single type of restoration, such as crowns or partial dentures. Some laboratories have ceramists who specialize in creating ceramic restorations of every type.

In order to design and craft these prostheses, a dental technician prepares wax diagnostic models from patients' mouth impressions. These wax models are finely detailed sculptures of the mouth, showing how the restoration will look and how it will work. From these, the prostheses are cast in investment molds through an ancient bronze casting and jewelry method, called the lost wax technique.

The investment mold is poured around the wax model of the prosthesis and is fired. The wax melts and drains out of the investment mold, leaving behind a durable mold into which the technician can pour a casting material. Restorative casting materials can be metals (gold, silver, amalgam), resins, or ceramics. These are poured into the investment mold to craft individual teeth, crowns, and other dental prostheses.

New computer applications are making the restoration process faster, more accurate, and more comfortable.

Implant and crown design is often time consuming, requiring several appointments to ensure a proper fit. Duplication technology (e.g. Geomagic Studio from Raindrop Geomagic of Morrisville, NC) uses 3-D scanners to scan a patient's mouth. This duplicates the shape, thickness, and color of the natural teeth. This information is processed through CAD software and used to generate a digital prosthesis that is virtually inserted into the digital image of the patient's mouth to check for an accurate fit. The dental prosthesis is then crafted in real materials and fitted into the patient's mouth.

Work settings

Dental laboratory technicians work mainly in dental laboratories. These are usually independent businesses, with one technician out of five owning his or her own laboratory. Some laboratories may also be connected with a dentist or a team of dentists, to create a one-stop service for patients. Some technicians work in hospitals or institutions which provide dental services to in-house patients, e.g. VA hospitals.

Laboratory facilities are clean, well lit, and carefully ventilated. Workstations may be equipped with computers, grinding equipment, polishing machines, and a variety of tools for fine detailed work. Most dental laboratory owners keep their facilities equipped with state-of-the-art tools, equipment (including a dental kiln), and materials. They also provide continuing training for their technicians in current procedures, techniques, and material use.

Education and training

Though most dental laboratory technicians learn while working on the job in the laboratory, many are now seeking professional training at junior colleges, dental schools, and vocational/technical institutions before seeking employment. Some dental schools offer course work in dental laboratory technology. In any event, technicians will still need to train on the job in order to learn the techniques and styles of a particular dental laboratory.

Early tasks on the job may be relatively menial in contrast to the skills the technicians will display later for the laboratory. They may prepare dental impressions or fire already prepared crowns or dentures. After three or four years of training, technicians are then able to design and craft dental prostheses for patients.

The ADA Commission on Dental Accreditation has accredited 34 programs in dental laboratory technology. Classroom instruction includes oral anatomy, dental materials science, fabrication procedures, computer software applications, digital imaging, and ethics. Students

complete course work in two years and receive an associate's degree.

Certification is available in some states through the National Board. This is voluntary and not necessary to work in the profession. Five areas of certification are available; crowns and bridges, ceramics, partial dentures, complete dentures, and **orthodontic appliances**.

Advanced education and training

Most dental schools offer specialization in prosthodontics. A prosthodontist is a dentist who does only dental restorations. Usually, prosthodontists have three or more years of education beyond their DDS (doctor of dental surgery) degree. They may supervise full mouth restorations or single crowns. They are often able to oversee the manufacture and fitting of fixed bridges, dentures, implants, or a combination of these prostheses. Periodontists, specialists in gums and bones, and oral and maxillofacial surgeons may also fit implants into the jaw. They also are required to have three or more years of education beyond their DDS degree.

Future outlook

More people in their retirement years have full, (or almost full) sets of teeth and no longer require complete dentures in old age. They are, however, requesting more enhancements to their appearance and more prostheses to improve their ability to chew and enjoy their food. Employment for dental laboratory technicians is favorable and may increase as the demand for prosthetic and cosmetic services increases with the aging of baby boomers.

Dental patient preparation

Definition

Dental patient preparation is the process of preparing a patient mentally and physically to receive dental care.

Purpose

Good preparation helps patients form a positive attitude about dental health care. Ideally, this attitude will continue throughout life, enhancing optimal oral health. An important aspect of patient preparation is education about the risks and benefits of dental procedures. The patient should understand beforehand the reasons for any procedure and what to expect during and afterwards. The patient should have the opportunity to weigh the pros and cons of any procedure and make a knowledgeable decision based on accurate, honest, and timely information.

Precautions

Patients must be prepared in a manner that is understandable and appropriate. Groups that might need special preparation include the poor, the elderly, and people from different cultures. In addition, health care providers must give special attention in preparing children and mentally handicapped adults for dental care, and include a parent or caregiver in all decisions as well as information regarding aftercare.

Description

Undergoing dental care can be frightening to children and even to many adults. **Stress** and **anxiety** are reduced when a patient understands the reasons for procedures and what to expect. Risks of procedures must also be carefully explained, so that **informed consent** can be made.

Patient education is needed in cases of:

- dental benefits, insurance, and financial options
- initial examinations
- x rays
- crown preparation
- crown delivery
- implants treatment
- inlay preparation
- restorative therapy
- root canal therapy
- periodontal therapy
- oral and maxillofacial surgery

Time spent by the dental office staff for patient preparation is not billed separately to the patient or to insurance companies. Extra staff time in preparation and follow-up phone calls, as well as the cost of informational brochures, are usually well worth the relatively small

additional expense to achieve increased patient satisfaction and compliance.

Preparation

Using brochures and other written materials is one way to prepare patients. They have the advantages of giving patients time away from the office to consider new information and can answer common concerns without taking up staff time. It is also helpful to take a moment to explain procedures and answer questions when calling patients to confirm appointments.

Aftercare

A phone call from the dentist is common aftercare, especially following a surgical procedure. The dentist assesses patient comfort, answers questions, and reminds patients of what to expect during recovery. Good aftercare protocol builds the patient/doctor confidence and trust and can help detect medical complications before they become serious.

Complications

Poor patient preparation can lead to misunderstandings, including unwarranted fear about procedures or confusion about financial obligations. Rushing through explanations or using too much professional jargon, for example, might lead a patient to back out of treatment and neglect oral health care.

Results

Many people avoid visiting the dentist because of fear of discomfort or embarrassment about poor **dental hygiene**. Care in patient preparation can go a long way in making patients feel more at ease, making them more likely to maintain better oral health and visit their dentist regularly.

Health care team roles

The dentist or specialist prepares the patient and answers questions. The dental assistant plays a supportive role in patient education and preparation.

The front office staff can provide brochures as recommended by the dentist or dental assistant, and help the patient work out financial arrangements.

KEY TERMS

Crown delivery—Placement of a porcelain crown. Normally, the tooth is prepared two weeks prior to this procedure.

Crown prep—Preparing a tooth to receive a crown or cap.

Implant—A surgical procedure involving permanently placing a false tooth into the gum tissue.

Inlay—Preparing a tooth for a partial crown made out of porcelain or gold. This is similar to a crown, but only part of the tooth is involved.

Restorative treatment—Any type of dental procedure that restores a tooth's function. This is usually accomplished with silver (amalgam) fillings.

Root canal—Removal of the nerves and pulp of the tooth.

Tooth extraction—Surgical removal of a tooth.

Dental prostheses

Definition

Dental prostheses, artificially made devices resembling natural teeth, are used to replace missing or damaged teeth. These devices include inlays/onlays, crowns, bridges, dentures, partial dentures, and dental implants.

Purpose

Crowns and inlays/onlays are intended to repair damage to individual teeth. They replace tooth structure lost by decay or injury, protect the part of the tooth that remains, and restore the tooth's shape and function. Bridges, dentures, and partial dentures fill in a space in the jaw left by a missing tooth or teeth. They protect the shape of the mouth and restore function of the teeth and jaw.

Precautions

Some patients are allergic to the constituents in local or general anesthetic agents. In addition, many people are afraid of dental work and therefore may experience stress-related symptoms, even fainting, while in the dental office. Most dentists can help patients with this specific fear. Also, the dentist and dental assistant will need to be aware of any pre-existing conditions in the patient's history, e.g. diabetes, high **blood pressure**, **heart disease**, **hemophilia**, or HIV/AIDS.

Description

Inlays/onlays

An inlay resembles a filling in that it fills the space remaining after the decayed portion of a tooth has been removed. The difference is that an inlay is shaped outside the patient's mouth and then cemented into place. After the decay is removed and the cavity walls are shaped, the dentist makes a wax pattern of the space. A mold is cast from the wax pattern. An inlay is made from this mold and sealed into the tooth with dental cement.

Inlays and their counterparts, onlays, are conservative alternatives to crowns. They don't require as much tooth preparation and often are more durable than amalgam fillings. Inlays cover the grooves on the surface of the molar. Onlays wrap over the tooth, covering more of its surface.

Inlays used to be made entirely of gold for durability. New inlay alloys of palladium, nickel, or chromium are now frequently used. Metals are the dentists' choice for inlays in molars. When inlays are required for visible anterior teeth, tooth-colored composites and porcelains

are used. Reinforced porcelain and Lucite porcelain are durable but may not be suitable for patients who grind their teeth. Composites are also used in fillings.

Crowns

A prosthetic crown replaces the outer portion of the tooth to protect and strengthen it. This protection becomes necessary when a tooth cracks, has its entire structure weakened by decay, or becomes brittle after a root canal. Crowns can also cover dental implants or abutment (adjacent) teeth when fitting a bridge.

Crowns can also cover discolored or otherwise aesthetically displeasing teeth. **Cosmetic dentistry** does not use crowns as much as it once did. Crowns, though aesthetically pleasing, require more radical dental techniques. Dentists are opting for more conservative methods such as bleaching, bonding, or veneers.

The dentist first removes the decay, and the tooth is then prepared for a crown. It may be tapered on the outside edges to a peg, reinforced with a cast metal core, or rebuilt with both a cast metal core and a post. An impression of the prepared tooth and the teeth next to it is made. A retraction cord is placed around the tooth in order to get the impression medium under the gum where the crown will be fitted.

The dental technician will create a new crown, using a cast made from this impression. The technique the technician uses is called lost wax casting. A wax model is made of the crown. Another mold is made around the wax model and both are fired in a kiln. The wax melts, leaving an opening into which a restorative material can be poured. The crown may be made of gold or stainless steel alone, metal with a veneer of tooth-colored porcelain or resin, or of porcelain or resin alone. The finished crown is then placed over the prepared tooth, adjusted, and cemented into place.

When a tooth has had a root canal and the root has been filled, the tooth may not be strong. Post crowns are used in these cases. The tooth is leveled at the gum line and a stainless steel or gold post is fitted into the root canal. This post can then receive the new crown and hold it in place.

For other patients, it may be desirable to implant the crown. In this case, a steel post is embedded in the patient's jawbone. It is left in place until the bone adheres to the post. The post is exposed and the crown is made and fitted.

New computerized techniques are making the restoration process faster and more accurate. Chairside Economical Restoration of Esthetic Ceramics (CEREC) uses a computer system that allows the dentist to create

ceramic crowns, inlays, and onlays, in one sitting. The tooth is prepared as usual but impressions are made digitally, using a hand-held camera. These photographs are converted to 3-D images on the computer screen, thus eliminating the need to take a physical impression of the patient's teeth. The dentist uses special 3-D CAD/CAM software to design the crown. A milling system attached to the CEREC machine is able to make a ceramic crown in 10 to 15 minutes.

Provided they are well taken care of, crowns can last 5–15 years or more.

Bridges

Bridges fill in the spaces caused by missing teeth. They prevent the remaining teeth from shifting and provide a more stable surface for chewing. If the gap is not filled, the other teeth shift, affecting the patient's bite (occlusion), which sometimes produces **pain** in the jaw joint. As the teeth move and become crooked, they also become more difficult to keep clean. The risk of tooth decay and gum disease rises, increasing the likelihood that additional teeth will be lost. A bridge is inserted to prevent this from happening.

Bridges are made of a metal framework and one or more artificial teeth (pontics), which are anchored to adjacent teeth. The abutment teeth carry the pressure when the patient chews food. Bridges can be removable or fixed (permanent). Removable bridges are attached to the abutment teeth by wires or precision attachments. Fixed bridges are attached to permanent crowns placed on abutment teeth. There are two types of fixed bridges, the crown-and-bridge design and the Maryland Bridge. A Maryland Bridge does not have crowns. The backs of the abutment teeth are reduced slightly and small wing-like appendages on the bridge are cemented to the back of the abutment teeth.

When the adjacent teeth are not strong enough to support a bridge, a two-implant bridge is required. This type of bridge takes longer for the permanent bridge to be fitted because of the necessity for the gums to heal. Posts are surgically implanted into the patient's bone and the gum closed. It takes several weeks for the bone to attach to the posts. The posts are re-exposed and the bridge is made to fit. It is then cemented in place.

Implants

Dental implants are hard plastic or metal fixtures surgically embedded through the soft tissue into the jawbone that will act as artificial roots or anchors for a prosthetic tooth. Over time, bone will grow around these fixtures, firmly anchoring them. The implant posts are then surgically exposed and an artificial tooth is crafted and

fitted over these anchors. Implants may also serve as stable abutments for bridges, partial dentures, or over-dentures. Dental implants may be the best choice for patients who have denture intolerance or who cannot chew food properly with other prostheses.

Partial dentures

A partial denture is similar to a bridge in that it fills a gap left by missing teeth. It is a removable dental appliance consisting of artificial teeth fitted onto a metal frame, which attaches to an abutment tooth or teeth, with a metal clasp or precision attachment. A partial denture is often used at the end of a row of natural teeth, where there is only one abutment tooth. The pressure exerted by chewing is shared by the abutment tooth and the soft tissues of the gum ridge beneath the appliance.

Complete dentures

Complete dentures may be worn when all of the top or bottom teeth have been lost. A complete denture consists of artificial teeth mounted in a plastic base molded to fit the remaining oral anatomy. It may or may not be held in place with a denture adhesive.

Removable implant supported over-denture

Some people cannot wear dentures because they cannot tolerate having a foreign substance in their mouths. Others simply can no longer wear dentures because of serious bone loss. In response to this denture intolerance, a removal implant supported over-denture may be the best solution. Implant anchors may be installed in either the upper or lower dental arch or both. Five or six implants are anchored into the bone of the upper arch and four or five are placed in the lower arch. Each group of jaw implants is connected by a stabilizing bar. A custom-made over-denture is placed over the bar by means of a silicone gasket, which holds the denture in place and provides a cushion between the denture and the implants. For patients with **Parkinson's disease**, telescopic attachments are added to the over-denture that have the ability to adjust to varying pressures within the mouth, allowing these patients to chew better.

Preparation

Before a restoration is placed in the mouth, the dentist removes all traces of decay or damage and shapes the remaining tooth structure to receive the restoration. Impressions are taken of the mouth and models are created from which the dental prostheses are made. When bridges or crowns are necessary, the tooth or teeth that are to receive the crowns are shaped into posts or pegs.

False teeth. (AP/Wide World Photos. Reproduced by permission.)

Prostheses are made up in a laboratory using a model of the tooth structure. Temporary crowns and bridges are installed until the permanent restoration is delivered by the laboratory.

Aftercare

Temporary crowns or bridges must stay in place until the permanent restorations have been fitted to the patient's mouth. Dentists and dental assistants educate the patient about ways to keep the temporary in place, e.g. avoiding hard foods, gum, and other sticky or chewy foods. If possible, the dental assistant and dentist encourage the patient to avoid eating food on the side of the mouth where the temporary has been placed. Also, the patient is reminded to call immediately if the temporary is loosened so that it can be re-cemented.

There may be some gum swelling or discomfort when prostheses are fitted, or if surgery is performed. The dentist can recommend medications or oral rinses to reduce the discomfort.

Patients may also experience sensitivity to cold foods or drinks for a few weeks after a crown, bridge, or inlay is placed.

Patients are urged to maintain normal **oral hygiene** while they wear a temporary, and after the actual the crown or bridge is in place.

Dental prostheses, especially partial and full dentures, may take several weeks to adjust to. Inserting and removing dentures and other removable appliances takes practice. Speaking clearly may be difficult at first, but this usually passes with continued usage. Eating may also feel awkward. The patient should begin by eating small pieces of soft foods. Very hard or sticky foods should be avoided. Care should also be taken when eating hot food

or food with bones, since artificial prostheses may make the mouth less sensitive to hard objects and hot food.

Also, patients may experience a reduced sense of **taste**, since teeth act as taste sensors. Many patients will eat a lot of very spicy, salty, or sweet foods because they can taste them better. Since it is important to include a variety of foods in the diet so that proper nutritional needs are met, it may be necessary to adjust seasonings to counter the blandness patients may be experiencing.

Permanent prostheses should be cleaned as regularly as real teeth. Specialty brushes and floss threaders may be used to remove plaque and food from around crowns and bridges. Full or partial dentures should be removed and brushed daily with a specially designed brush and a denture cleaner or other mild soap. Optimally, full and partial dentures should be removed at night and soaked in a cleaning solution. This allows the soft tissues in the mouth to recover from the pressures of the prostheses. The solution will preserve the denture material, since it may shrink or warp if it dries out. At this time, patients should also clean their gums to increase **blood** circulation and maintain healthy bones and gums.

The patient should see the dentist for an adjustment if there is any discomfort or irritation resulting from a prosthesis. Otherwise, the patient should see the dentist at least twice a year for an oral examination. If the patient has had several teeth extracted before dentures were installed, these prostheses should be adjusted within the first six months after the dentures have been fitted. Patients should also expect to have their full dentures adjusted if they lose or gain ten pounds or more. Also, dentures may need to be relined or replaced every five to ten years.

Complications

Restoration procedures typically require **local anesthesia**. In some cases, the patient may require **general anesthesia** because the procedures involve gum surgery or the extraction of several teeth. Some people may have allergic reactions to either kind of anesthesia. A very small number of people are allergic to one or more of the metals or acrylics used in dental restorations. In most cases, the dentist can use another material.

Surgery is an invasive procedure. The risk of trauma or **infection** is always present, though it is often a minor risk. The patient may commonly experience swelling, nausea, pain, or bleeding. When these symptoms are prolonged or **fever** is present, there may be infection. Rarely, nerve disturbances or bone **fractures** may occur.

Some patients experience speech difficulties when they have dental prostheses, especially with full dentures

or several implants. Usually, this occurs during the first weeks after they have been fitted with prostheses for the maxillary or upper jaw bone. Once patients adapt to the prostheses, this problem disappears.

Results

A well-made dental prosthesis should feel comfortable and last a relatively long time with proper care. Artificial dental restorations only approximate the original tooth, however. They will never feel as comfortable or function as well as natural teeth. It is better, therefore, to prevent the need for dental prostheses to replace teeth. They are expensive, may require many appointments, and still need careful cleaning and attention.

Health care team roles

The dentist is crucial in diagnosing a patient's particular dental needs and determining the correct remedy. The dentist will prepare a patient's teeth for dental prostheses. Often, this requires a great deal of skill and structural knowledge in order to remove enough tooth material for the prosthesis to fit, yet leave enough architecture within the tooth in order to stabilize the restoration.

The dental technician prepares the dental prosthesis so that it will fit the prepared tooth and be compatible with the rest of the patient's mouth structure. The technician is part scientist and part artist and is able to craft natural-looking teeth that match the patient's mouth and facial features.

The dental assistant prepares the patient and the patient's teeth for the dentist. The dental assistant takes impressions of the patient's teeth and gums and prepares study models to aid the dentist in diagnosis and the dental technician in creating life-like prostheses that function comfortably in the patient's mouth.

KEY TERMS

Abutment tooth—A healthy tooth or a crowned one that stabilizes a bridge or partial denture.

Anesthesia—A condition created by drugs that produces a loss of sensation, particularly pain. General anesthesia produces unconsciousness, a local anesthetic only results in localized numbness.

Bridge—An appliance of one or more artificial teeth anchored by crowns onto the adjacent teeth.

Complete denture—A full set of upper or lower teeth, mounted in a plastic base. Dentures are also called false teeth.

Crown—A protective shell that fits over a prepared tooth in order to restore its function.

Inlay—A filling that is made outside the tooth and then cemented into place.

Occlusion—The way upper and lower teeth fit together during biting and chewing.

Onlay—A restoration that covers the upper surface of a tooth. It is bigger than a filling but smaller than a crown.

Pontic—An artificial tooth suspended between two prosthetic crowns to fill a space left by a missing tooth.

Dental specialties

Definition

There are nine dental specialties approved by the Council on Dental Education and Licensure of the American Dental Association (ADA). These are:

- **Dental public health:** Dental public health is the dental specialty devoted to promoting public dental health and preventing and controlling dental diseases through community and public education.
- **Endodontics:** Endodontics is the dental specialty focused on the morphology, physiology, and pathology of the periradicular (tooth root) tissues and human dental pulp.
- **Oral and maxillofacial pathology:** Oral and maxillofacial pathology deals with the nature, identification, and management of diseases affecting the regions of the mouth, jaw and adjacent parts of the face.
- **Oral and maxillofacial surgery:** Oral and maxillofacial surgery is the dental specialty that focuses on the diagnosis, surgical, and related treatment of diseases, injuries and deficiencies of the hard and soft tissues of the oral and maxillofacial regions. These specialists address functional and esthetic aspects of the areas treated.
- **Orthodontics and dentofacial orthopedics:** Orthodontics and dentofacial orthopedics is the specialty concerned with guiding and correcting children’s and adults dentofacial structures.
- **Pediatric dentistry:** Pediatric dentistry is the dental specialty that is devoted to providing primary and comprehensive preventive and therapeutic dental health care from infancy through adolescence. Pediatric dentists also provide dental care to children with special health care needs.
- **Periodontics:** Periodontics involves the prevention, diagnosis, and treatment of diseases affecting the tissues supporting and surrounding the teeth. The specialty also focuses on the maintenance of healthy gums and supporting dental tissues.
- **Prosthodontics:** Prosthodontics is the specialty concerned with the restoration of natural and replacement teeth, as well as contiguous oral and maxillofacial tissues.
- **Oral and maxillofacial radiology:** No definition has yet been approved by the ADA House of Delegates for this newly granted dental specialty. However, these specialists use imaging techniques to assist general dentists and other oral health specialists in the diagnostic assessment of diseases of the head and neck.

While there are overlapping responsibilities among the specialties, each focuses on an aspect of the oral cavity, maxillofacial area, or adjacent associated structures.

Description

According to the ADA, about 20% of all dentists practice a dental specialty, while the rest remain general dentists. Orthodontics and dentofacial orthopedics and oral and maxillofacial surgery make up nearly half of all specialties.

Dental public health specialists view the community, rather than the individual, as their patient. Their roles are to educate the public, using applied dental research, and initiate community-wide dental care and preventive programs.

Endodontics encompasses basic and clinical sciences of normal pulp biology and the causes, diagnosis, prevention, and treatment of diseases and injuries to the pulp and associated periradicular conditions. Endodontists specialize in root canal treatments to remove damaged tissue from inside tooth root canals. Root canal treatment, a nonsurgical endodontic treatment, treats the soft inner tissue of the tooth, called the pulp, when it becomes inflamed or infected. During a root canal, endodontists remove the damaged pulp, clean the area and fill and seal it to preserve the tooth. Surgical procedures performed by endodontists include apicoectomy, which removes **infection** or inflammation of the bony area surrounding the tooth's end.

Oral and maxillofacial pathologists research the causes, processes, and effects of diseases that affect the oral and maxillofacial regions, which include the head, face, mouth, teeth, gums, jaws, and neck. These specialists use clinical, radiographic, microscopic, biochemical, and other examinations to research and diagnose disease. The practice of oral and maxillofacial pathology includes research; clinical, radiographic, microscopic, biochemical or other disease diagnosis; and patient management.

Oral and maxillofacial surgeons treat patients who have problems with wisdom teeth, facial **pain** and misaligned jaws. They treat accident victims with facial injuries, perform reconstructive and dental implant surgery, offer treatments for tumors and cysts of the jaws, and specialize in functional and cosmetic conditions of the head, face, mouth, teeth, gums, jaws, and neck. Oral and maxillofacial surgeons also offer preventive care of the teeth, mouth, jaws, and facial structures.

These specialists offer a wide variety of surgical procedures performed in the office and hospital, including dentoalveolar surgery to treat impacted teeth and reconstructive surgery to address inadequate bone structure of

the upper or lower jaws, which can result from injury, some types of surgery, and dentures. They place dental implants, which are an option for replacing missing teeth, and treat facial infections, which can develop into life-threatening conditions if not addressed. Oral and maxillofacial surgeons are often called in to treat trauma of the face, jaws, mouth, and teeth, often from injuries such as **falls**, as well as facial pain from such things as temporomandibular joint (TMJ) disorders. Other conditions treated by oral and maxillofacial surgeons include deformities in skeletal growth between the upper and lower jaws, which can affect chewing and swallowing, and snoring or obstructive sleep apnea, a condition that can lead to excessive daytime sleepiness. Not all procedures performed by oral and maxillofacial surgeons are covered by dental or health insurance because they also offer some cosmetic procedures of the face, mouth, and neck.

Orthodontists and dentofacial orthopedic specialists specialize in diagnosing, preventing, and treating dental and facial irregularities, known as malocclusions. Orthodontists represent about 6% of all dentists. Orthodontists treat children and adults. The American Association of Orthodontists recommend that all children have an orthodontic screening no later than age seven.

Malocclusions are often inherited but can be caused by trauma, pacifier sucking, airway obstruction, dental disease, or premature loss of primary or permanent teeth. Orthodontists most commonly treat crowding of the teeth, overbites, open bites (when upper and lower incisor teeth do not touch when biting down), spacing problems, crossbite and underbites, or lower jaw protrusion. Orthodontic treatment, often involving the placement of braces, helps not only cosmetically, but also functionally.

Pediatric dentists provide primary and specialty oral care for healthy, normal children, as well as those with special needs. Much of what the pediatric dentist does involves educating parents and children. The pediatric dentist will advise parents about thumb sucking and pacifier habits, dental decay in the early years, proper brushing habits, bottle and breast-feeding, and more. In a child's later years, they'll advise children and their parents about protecting teeth during sports and other preventive dental issues. Pediatric dentists offer techniques that can protect children's teeth, such as dental sealants, which fill the crevices on the surfaces of the teeth to protect teeth from decay.

Periodontists specialize in preventing, diagnosing, and treating periodontal disease. Periodontal diseases are bacterial infections of the tissues around the tooth, which, if untreated, can result in tooth loss. Periodontists place dental implants, which replace missing teeth and look

and feel like natural teeth, and they perform periodontal surgery used to treat severe cases of periodontal disease. While simple procedures might suffice to remove the plaque and calculus below the gum line and remove **bacteria**, surgical procedures are often necessary if periodontal disease has caused deep pockets in the gums and loss of supporting bone structure. Cosmetic periodontal procedures include treatments to improve a gummy smile, as well as treatment to correct long teeth, or receding gums.

Prosthodontists understand dental laboratory procedures and work closely with dental technicians to create comfortable and attractive custom-made prostheses for patients. Prosthodontists offer patients options for replacing missing teeth. Sometimes this involves the placement of dentures or fixed bridges, while other patients prefer dental implants. Prosthodontists receive training in diverse dental conditions, including complex care management involving many specialties, post-oral **cancer** reconstruction, some children's dental problems, jaw joint conditions, traumatic injuries, and snoring and **sleep disorders**. Prosthodontists are also trained in some types of **cosmetic dentistry**, including bleaching techniques, tooth bonding, and veneers.

Oral and maxillofacial radiologists are dentists who specialize in the use of imaging and other technologies to diagnose and manage dental and associated diseases. They also advise state agencies and dental professionals about regulatory compliance in the use of and advances in **radiologic technology**.

Work settings

Dentists work in private practice offices, public hospitals and clinics, for the Federal Government, and in dental research.

Education and training

Most dentists go through three years or more of undergraduate school with an additional four years of dental school to become a general dentist. All dentists graduate from dental school with a degree in general dentistry, receiving either the DMD (Doctor of Dental Medicine) or DDS (Doctor of Dental Surgery) designation. While most schools today award DDSs, there is no difference in these degrees for general dentistry. Dental specialists must then undergo additional postgraduate training to become a dental specialist. About 17 states require dentists to achieve specialty licenses before practicing as specialists.

Dental public health specialists must successfully complete two years of academic study in a program

accredited by the Commission on Dental Accreditation leading to a graduate degree in public health, or complete two or more years of dental public health advanced education by a non-U.S. institution followed by completion of an accredited U.S. residency dental public health program.

Endodontists possess advanced surgical and nonsurgical skills that allow them to treat routine and complex cases. Endodontists attend two- or three-year advanced dental school endodontic programs.

Orthodontists and dentofacial orthopedic specialists must successfully complete a two- to three-year residency program of advanced education in orthodontics after graduating from a general dentistry program accredited by the Commission on Dental Accreditation of the ADA. Through their advanced training, orthodontists acquire the skills necessary to manage tooth movements and guide facial development.

Oral and maxillofacial surgeons undergo four years or more of postdoctoral, hospital-based surgical residency training after graduating from a four-year dental school program. Their education intensity is similar to that of internal medicine physicians and general surgeons.

Pediatric dentists need two to three years of specialty training following dental school to learn about children's dental problems and how to educate parents and children about avoiding these problems. They also learn about the care of special needs children, including hospitalized, handicapped, and chronically ill children.

Periodontists receive three years of periodontal training after graduating from dental school.

Prosthodontists receive three years of specialized training in an American Dental Association (ADA) accredited graduate education program after completing dental school.

Oral and maxillofacial radiology programs are between two and three years long.

Advanced education and training

All dental specialists can attend continuing education courses to keep up with research, clinical procedures, and technology. They can also apply to become board certified in their dental specialties.

Future outlook

While, the dental profession is expected to experience slower than average growth through 2008 because more people are avoiding problems associated with tooth decay, the demand for specialists could rise. Baby-boomers coming into middle age will require complicated work, including bridges. The elderly will be more

KEY TERMS

Calculus—Calcified deposits that have formed around teeth.

Dentition—The natural teeth.

Dentofacial—Relating to the dentition, or natural teeth.

Etiology—The science of disease origins and cycles.

Human dental pulp—The soft, moist, coherent solid tissue within the pulp cavity of the tooth.

Malocclusion—Bad bite.

Maxillofacial—The area of the jaws and face.

Morphology—The study of the configuration or structure.

Pathology—The study of the nature and cause of diseases and the changes produced by them.

Periradicular tissues—The tissue around the top of a tooth root.

Physiology—The science that looks at normal life processes (functions and activities) of organisms.

Temporomandibular joint (TMJ)—The joint of the lower jaw.

Dental trauma

Definition

Dental trauma is an injury to the mouth and teeth, including oral structures such as the lips, tongue and cheeks.

Description

Dental trauma can occur during contact sports, motor vehicle accidents, falling and hitting the face, fighting and/or from untreated tooth decay. It can be caused by physical abuse or domestic violence.

Causes and symptoms

Injuries to a broken or knocked out (evulsed) tooth can cause severe **pain**. If the lower jawbone is cracked or broken, the patient will be unable to move the jawbone without pain and discomfort. Broken fillings or old crowns are susceptible to decay. They can weaken and undermine the tooth structure, causing the tooth to break. This could result in sharp edges and corners that may damage the tongue tissue.

Diagnosis

X rays (taken to reveal the extent of dental trauma to hard tissue) together with a thorough examination, aid in finding the source of the trauma.

Treatment

Tooth movement

If the entire tooth is knocked out of the socket (evulsion), the tooth must be found and repositioned back in the socket. If this is done in the first 20 minutes, there is a 90% chance of tooth survival. Thirty to 60 minutes cuts the tooth survival rate to 75%.

- The tooth should be picked up gently and held by the crown, not the root.
- The tooth should be carefully rinsed with water; it should not be scrubbed.
- The tooth should be kept moist; it should not be dried.
- If possible, the tooth should be placed in the socket; if this is not possible, it should be placed in a cup of milk.

If a tooth is bumped and still in the socket, but in the wrong position (luxation), dental help should be sought immediately. The following steps should be followed, depending on the position of the tooth.

- An upper tooth hanging down or lower tooth raised up (extrusion) should be repositioned in the socket using firm pressure. The tooth should then be stabilized by having the patient bite down firmly, or bite on a piece of cloth or a handkerchief.
- A tooth pushed back toward the tongue or pulled forward toward the face (lateral displacement) requires repositioning by using firm pressure. This may cause severe pain and biting down on a piece of cloth or handkerchief will help alleviate some of this pain and help to stabilize the tooth.
- Teeth pushed into the gum tissue or teeth that look short (intrusion) require no intervention. Repositioning may damage both tooth nerve and tissue.

Broken and fractured teeth

The fractured area should be cleaned, and a cold compress outside the cheek area should be applied. Dental help should be sought promptly. If a piece of the outer tooth has chipped off, but the inner soft tissue core (pulp) is undisturbed, the rough edges may be smoothed by the dentist and a simple filling placed. If most of the tooth is missing, but the pulp is not damaged, the tooth will require a protective covering with a crown. If the pulp has been damaged, the tooth will require root canal

treatment and a crown. A tooth fractured below the gum-line will require root canal treatment and protective restoration. A tooth with little remaining structure to retain a crown may have to be removed (extraction).

Cuts, abscesses, and pain

Cut lips, gums, or tongue require mild rinsing with cold water to remove debris. A cold compress should be applied to the injured area. Most cuts and abrasions are minor; a dental visit is not required. Dental care, however, should be sought if bleeding does not stop and the cut is deep. Pain and swelling can be controlled by ibuprofen (e.g., Advil, Motrin), which is an anti-inflammatory and a painkiller.

Abscesses and swollen gums are due to **infection** in the gum tissue or bone; ice should be placed on the swollen cheek to alleviate discomfort. **Antibiotics** and painkillers are generally needed to fight infection. If left untreated, the local infection can enter the bloodstream, causing serious illness. It could become life threatening in some cases. Treatment for the cause of an abscess should also be addressed. A periodontal abscess requires therapeutic sealing and root planing. An endodontic abscess requires a root canal and sometimes an apicoectomy (surgical removal of the tooth root).

Severe pain is caused mainly by trauma, but can be caused also by gum abscesses, tooth infection, bone infection, and some dental procedures. Prompt dental care can alleviate worries and aid in pain control.

With jawbone injuries, the jaw should not be moved. A handkerchief or towel should be tied around the jaw and over the head to secure the jaw in place. Immediate dental care should be sought. Severe pain may stem from temporomandibular joint (TMJ) disorders or trigeminal neuralgia.

Prognosis

The key to a good prognosis for a dental trauma is taking quick steps, remaining calm and getting dental attention within the first 20 minutes. Prevention is the best method.

Health care team roles

The dentist may delegate treatment to other staff members (e.g., registered dental assistants), who can take x rays and comfort the patient, while the office manager takes care of all financial matters and billing questions. The registered dental hygienist may administer an anesthetic agent where needed. All team members can alleviate patient fears during a trauma.

KEY TERMS

Crown—1. The natural part of the tooth covered by enamel. 2. A restorative crown is a protective shell that fits over a prepared tooth.

Eruption—The process of a tooth breaking through the gum tissue to grow into place in the mouth.

Eulsion—The forceful, and usually accidental, removal of a tooth from its socket in the bone.

Extraction—The surgical removal of a tooth from its socket in the bone.

Intrusion—A condition in which a tooth is forced upward into the bone tissue by a force outside the mouth.

Lateral displacement—A condition in which a tooth is forced out of alignment forward or backward, but remains in its socket.

Luxation—The movement of a tooth still in its bony socket.

Pulp—The innermost soft tissue of a tooth containing blood vessels, lymphatics, and nerves.

Root canal treatment—The process of removing diseased or damaged pulp from a tooth, then filling and sealing the pulp chamber and root canals. Also known as endodontic therapy.

Prevention

According to the study by the American Academy of Sports Dentistry, most dental traumas can be avoided if mouthguards are worn. They recommend that athletes, regardless of their age or gender, use mouth guards where facial impact is possible.

The American Dental Association's February 2000 news press release recommended preventive measures for avoiding a dental trauma:

- Yearly dental exams (including x rays).
- Teeth should be brushed and flossed thoroughly at least once a day.
- A mouthguard and helmet should be worn while playing all contact sports (football, soccer, hockey, baseball, boxing, basketball).
- A seatbelt should always be worn when in a moving vehicle.
- Foreign objects (pencils, fingernails, pens) should be kept out of the mouth.

Dental x rays

Definition

Dental x rays are pictures taken of the mouth area using high energy photons with very short wavelengths. They show the teeth and surrounding bone.

Purpose

Dental x rays are effective in discovering tooth decay, broken fillings, fractured teeth, tumors, occlusal trauma, or impacted or ectopic teeth that would otherwise be unseen by the eye, in between the teeth and below the gum tissue.

Description

Dental x rays are part of the **dental examination** for aiding in the diagnostic process. X rays are vital in the diagnosis of root canal treatment on checking the apical of the tooth and the surrounding structures for abscesses or bone loss. Without the aid of dental x rays, 60% of dental decay would be missed. Diagnostic x rays are essential in providing accurate information. The most common x rays taken are:

- bitewing x rays (vertical and horizontal bitewings)
- panoramic x rays

- periapical x rays
- occlusal x rays

Each is used in its own respective degree of diagnosis, with the bitewing x ray being the most common. Bitewings are the most effective in discovering tooth decay in between the teeth and on adjacent teeth. A bitewing shows only the top crown portion of the tooth structure. It is called a bitewing due to the way the patient can bite down and hold the film securely in place. The bitewing is good in diagnosing and evaluating periodontal conditions and bone levels between the teeth. They are also good in detecting tartar buildup.

The panoramic (a type of film used), or panorex (brand name) is also commonly taken on the initial visit to the dental office. This type of x ray makes a complete circle of the head from one ear to the other, to produce a complete two-dimensional representation of all the teeth. This x ray will also show bone structure beneath the teeth and the temporomandibular joint (TMJ). The panoramic is the most commonly used x ray in the aid of diagnostic decisions regarding third molar extractions (wisdom teeth) for people who are edentulous (the tooth is not there/has not erupted). This special x ray, however, has its advantages and disadvantages.

One advantage of the panoramic is that a broad area is imaged, showing many structures. Furthermore, the exposure level emits low radiation. The panoramic is excellent for evaluation of trauma, tooth development, and certain anomalies. A 1999 study at the University of Buffalo School of Dental Medicine demonstrated that calcifications in the carotid arteries, which were exposed on standard panoramic x rays, served as predictors of death from cardiovascular disease.

The main disadvantage of panoramic x rays is that the image shown does not provide the fine detail of a bitewing x ray. The procedure for taking a panoramic x ray is also somewhat confining to the patient, as the x ray machine takes a minute or more to fully encircle the head for the complete picture. These films are not good in aiding the diagnosis of decay, bone level, and certain types of periapical pathosis.

A periapical x ray is similar to a bitewing. This type of x ray shows the entire tooth area, from crown to root, and the bone surrounding the root from a side view. This type of film will reveal any root anomalies, changes in the bone and surrounding tissue, cysts, bone tumors, and abscesses. The fine detail in the periapical film is necessary in diagnosis and treatment planning, and is commonly taken during root canal treatment and crown restoration procedures.

Dental x rays

Type	Purpose
Bitewing (interproximal)	Show tooth crowns, alveolar crest, and interproximal area Check for cavities, look at previous dental work, and determine any bone loss
Edentulous (toothless)	Check for residual pathologic conditions, or foreign bodies Detect retained teeth or root tips prior to denture construction
Full mouth series	Includes a number of periapical and bitewing x rays to identify conditions in the bones around the teeth and nerve tissue in the teeth Can be used as comparison for future problems
Occlusal	Shows large areas of the maxilla, mandible, or floor of the mouth Shows entire upper or lower bite and how primary or permanent teeth are developing
Periapical	View the entire tooth from root to crown and its periodontal supporting structures Evaluate bone loss, determine causes of toothaches, and assess existing dental work
Panoramic	Supplement to periapical survey but not a substitute View general tooth development, check for specific problems such as trauma or temporomandibular joint (TMJ) pain

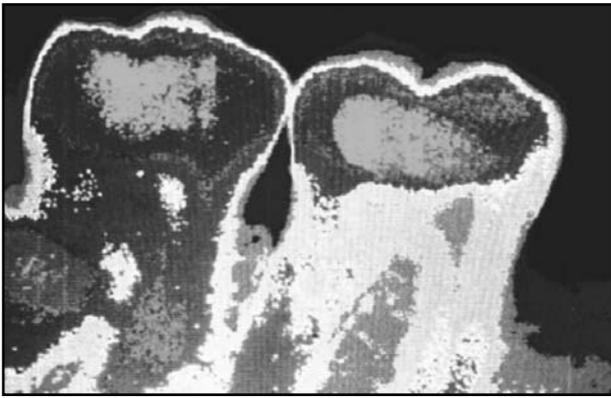

SOURCE: Alvarez, K.H. *Williams & Wilkins' Dental Hygiene Handbook*. Baltimore: Williams & Wilkins, 1998.

Occlusal films are least common. These films show the whole bite of the lower or upper jaw. Occlusal x rays, when taken, are mainly taken on children to show the eruption order of the permanent teeth.

X rays pass through hard and soft tissue in the mouth. The x ray beam is blocked by denser structures, such as teeth, fillings, jaws, and bones. Teeth appear lighter because fewer x rays go through the teeth to reach the film. Cavities and gum disease appear darker (shown by a dark spot in the tooth or loss of bone structure around the tooth) because of more x-ray penetration. On the film, the white images are the dense structures.

Operation

William Roentgen, a German scientist, discovered the x ray in 1895. He found that x rays are energy in the form of waves, similar to visible light. The only difference between light and x rays is that light does not have the ability to penetrate the body as x ray energy does. Light makes pictures of the outside of objects, while x rays have the ability to make pictures of the inside of objects. The name roentgen represents the amount of

A digitized x ray shows two molar teeth cavities. (Custom Medical Stock Photo. Reproduced by permission.)

exposure given off by one single energy photon. The amount of absorbed x ray in the body is a unit called a rad. A unit called “rem” accounts for the difference in biological effectiveness of different types of radiation, such as secondary radiation, or cosmic radiation. One rem equals one rad. One rad equals one R and one thousand milliroentgens, more commonly known as mrad; it is equal to one roentgen (R).

Research conducted in 2000 by the Idaho Radiation Network sets a maximum permissible x ray dose for one year at 5R (roentgens). A full mouth set of dental x rays consists of 18 to 20 films (bitewings, periapicals, occlusal and panoramic x rays). The amount of radiation for receiving the full-mouth set of x rays is 10 to 20 mrad (milliroentgens). The benefits derived from x rays greatly outweigh the radiation concerns. In 1999, the National Council on Radiation Protection reported that the amount of radiation an average person receives each year from background sources (e.g., outer space, materials in the earth, foods consumed, and naturally radioactive materials in the body) is 360 mrad.

Secondary radiation consists of the radiation waves left over after the source of radiation is stopped. Most secondary waves can penetrate tissue and are the most dangerous and damaging waves from radiation. Measures taken to prevent damaging rays are:

- setting radiation exposure to lower settings depending on the patient’s age, height, build and structure
- use of high-speed films to minimize exposure time
- use of lead-filled aprons to shield sensitive body parts, such as thyroid glands and gonads
- x ray badges worn by dental staff to monitor the amount of radiation exposure in the workplace

Maintenance

Dental x rays are essential in diagnosing and treating oral disease, abnormal tooth development, or trauma. At the initial dental examination, a full-mouth set of x rays may be taken (bitewings and panoramic). Thereafter, it is the dentist who should determine when and how often x rays will be required. Children are usually more cavity prone than adults; x rays may be taken with regard to degree of risk, or at the check-up examination every six months.

An adult presenting a **dental trauma** will need x rays to diagnose what the treatment should be. More x rays may be needed depending on the treatment plan and the extent of the injury.

The American Dental Association (ADA) recommends basic guidelines on taking dental x rays. On average, bitewing x rays should be taken approximately once a year. This is mainly to detect and treat any conditions early in their development. If the overall general health of the mouth is good, x rays can be taken every 18 to 24 months. The ADA also recommends that the type and frequency of dental x rays taken at an examination be based upon clinical judgment after the examination and consideration of the dental health and the general health of the patient.

Health care team roles

A registered dental assistant (RDA) or registered dental hygienist (RDH) commonly takes the x rays during a dental examination. They review the health and dental history, chart, and age of the patient to be x rayed. Adjustments are made to the x-ray unit depending on the size and age of the patient. The RDA then develops and mounts the x rays and presents them to the dentist. The dentist will interpret the x rays and complete the oral examination. A treatment plan will follow.

Training

An RDA and an RDH must have an x-ray certification in order to take and develop x rays. To become certified, full-mouth sets of x rays need to be taken. Knowledge of the x-ray machine unit is needed, as is the number of roentgens emitted from a variety of different x-ray machines. Furthermore, a working knowledge of angles and height of the x-ray unit is needed; this is necessary for taking fine-detailed images. Certification also requires knowledge of the principles of radiation safety.

Classes leading to certification as an RDA or RDH are available outside the work setting. Each state has dif-

KEY TERMS

Apical—Rounded end of the root of a tooth that is embedded in hard tissue (bone); toward the apex of the root.

Crown—1. The upper part of the tooth, covered by enamel. 2. A dental restoration that is a protective shell fitting over a tooth.

Eruption—The process of a tooth breaking through the gum tissue to grow into place in the mouth.

Pulp—The soft, innermost part of a tooth containing blood and lymph vessels, and nerves.

Root canal treatment—The process of removing diseased or damaged pulp tissue from a tooth, then filling and sealing the pulp chamber and root canals.

ferent bylaws regarding x-ray licensing for technicians. The rules of the state in which one is interested in working should be consulted.

Denture care

Definition

Denture care is the maintenance of removable artificial teeth. Full or complete dentures replace all teeth in the upper jaw (maxilla), lower jaw (mandible), or both jaws. Partial dentures replace some teeth.

Purpose

Dentures replace natural teeth lost because of a health condition or injury. The artificial teeth fit in the mouth, allowing a person to eat normally. Daily denture care by the patient helps prevent conditions such as plaque. Periodic dental appointments assure that dentures fit properly and that the patient's mouth is healthy.

Precautions

Dentures are fragile and can break if dropped. The American Dental Association (ADA) advises people to hold dentures over a towel or basin of water. The patient should not try to repair dentures.

Dentures should fit, so dental adhesive should be used only in an emergency. Extended adhesive use can conceal infections.

Sores

Dentures and partial dentures can cause sores in areas such as the jaw, below the tongue, and on the roof of the mouth (palate). Sores can swell slightly and are generally red. Poor **oral hygiene** and wearing dentures too long can lead to denture stomatitis (denture sore mouth). Symptoms often include an inflamed palate. The dentist may prescribe **antibiotics** or an antiseptic rinse.

Other causes of sores include poorly fitted dentures, an uneven bite, illness, and infections. Moreover, smoking, **alcoholism**, or **oral cancer** may cause sores. Furthermore, neglected sores could stimulate the growth of excess soft tissue. Tissue should be removed and a biopsy performed to detect malignant cells.

Description

People have worn dentures for thousands of years. Early material for artificial teeth included whale ivory. Today, most restorative teeth are made of plastic material such as acrylic resin.

Types of dentures

There are two types of complete dentures. Immediate dentures are placed in a patient's mouth after teeth are removed. These temporary dentures allow patients to have

Dental prostheses

Appliance type	Maintenance required for oral health
Orthodontic: fixed, removable, space maintainers	Specific plaque control instructions Orthodontic brushes Interdental aids: rubber tip, toothpick/holders, flossthreaders, proximal brushes, single tuft brushes Fluoride application: dentrifice, brush-on gel, gel trays Oral irrigation Store in water when not in use
Fixed partial dentures: natural teeth supported; implant supported	Toothbrushing instructions Oral irrigation Floss or yarn with threader Nonabrasive dentrifice with fluoride (do not use acidulated fluoride with composite and porcelain restorations)
Removable partial dentures, complete dentures, and overdentures	Power-assisted brush should not be used Use a separate toothbrush for dentures and natural teeth Immerse dentures in liquid cleanser after brushing Store in water when not in use

SOURCE: Alvarez, K.H. *Williams & Wilkins' Dental Hygiene Handbook*. Baltimore: Williams & Wilkins, 1998.

teeth while gums heal. Healing can take up to eight weeks. Conventional dentures are worn after gums heal.

Complete dentures rest on the dental ridge, the arch in the mouth that supports teeth roots.

For a partial denture, artificial teeth are attached to a base that fits on the gums. Clasps and attachments link the framework to the patient's other teeth.

An overdenture fits on the roots of natural teeth. Those teeth provide stability and support.

Costs for care

At-home denture care involves traditional oral hygiene and denture cleaning. In the spring of 2001, at-home denture products such as cleansers and toothpaste cost \$7 or less.

Denture care also includes dental appointments. In the United States in 2000, the average complete denture cost about \$874 for the upper arch and \$900 for lower arch, according to information compiled by <<http://www.bracesinfo.com>>. That information was based on statistics from sources including the ADA and the U.S. Bureau of Labor Statistics.

An acrylic partial denture cost averaged \$632, while a metal partial costs \$983.

Denture repairs averaged \$51 for an adjustment, \$91 for a broken denture with no teeth involved, \$90 for tooth replacement, and \$139 to reline dentures.

Dental plans may cover some costs. For example, the 2000 Delta Dental Plan of California assessed a patient co-pay of \$395 for the upper or lower complete denture, and \$495 for an immediate denture for one jaw. The co-pay for one partial was \$300 or \$395, with the higher cost for a metal framework.

Repair co-pays included \$20 for adjustments, \$50 for repairing the denture base, and \$25 for a tooth replacement. The plan allows one relining per denture in a year. The chairside reline cost was \$50 per denture and \$150 for laboratory relining.

Preparation

The process for making dentures generally starts with the dentist taking a wax impression of the patient's mouth. A material similar to plaster is poured into the impression to make a model of the teeth. The plaster model is sent to a lab, where a wax denture is made. The dentist fits this denture on the patient and then sends it to the lab where the permanent denture is created.

Aftercare

The dental team educates new denture wearers about how to adjust to restorative teeth and clean them.

Dentures should be rinsed to remove food particles. Then the patient brushes natural teeth and dentures to remove plaque and food. The ADA recommends using a toothbrush recommended for dentures or a soft bristle brush. Dentures can be cleaned with denture cleansers bearing the ADA Seal of Acceptance, mild liquid dish soap, or hand soap.

The new denture wearer is usually advised to wear the full denture most or all of the time. After an adjustment period, the dentist generally tells the patient to take the dentures out before bedtime. This gives the gums a chance to rest and promotes oral health, according to the ADA. When removed, dentures are soaked in water or a cleanser solution.

Complications

Bones and gums may shrink, especially during the first six months after teeth are removed. When shrinkage occurs, the dentist may need to rebase or reline the immediate dentures.

The new denture wearer may experience soreness. This is caused by the pressure of hard dentures on soft tis-

sue and is usually temporary. However, soreness is frequently a sign that dentures need adjusting.

The patient may also experience a temporary increase in saliva flow. If any symptoms persist, patients should contact their dentists.

Results

After a patient adjusts to new dentures, the person should have no trouble eating or speaking. Subsequently, modifications to dentures may be required because the shape of the mouth changes over time as gums recede or sink.

Dental adjustments include:

- Relining, adding material to reshape the denture.
- Rebasing, building a new base and placing the artificial teeth on it.
- Replacement of teeth.

A set of dentures may need to be replaced within five to 10 years.

Health care team roles

The dental team monitors the patient's mouth health during periodic check-ups.

In addition, the dental staff educates the new denture wearer about oral hygiene and how to adjust to wearing artificial teeth. Advice to new denture wearers includes:

- Eat soft foods and cut them into small pieces. After adapting to dentures, add other foods to the diet.
- Read aloud to adjust to speaking with dentures.
- Smiling, laughing, or coughing could cause dentures to slip. Gently biting down and swallowing will reposition the dentures.

Instruction for patients with dentures

Item	Important instruction
Dental hygiene	Thoroughly clean dentures twice each day by immersing dentures in chemical solution and brushing for plaque removal; rinse thoroughly. It is preferable to leave the dentures out while sleeping, or for 6–8 hours during the day. Brush and massage the gums to clean away plaque and debris and stimulate circulation.
Denture storage	After cleaning, store the dentures in water in a covered container when they are not being worn. Keep the container in a safe place inaccessible to children or house pets.
Eating	New denture wearers should cut food into small pieces, avoid foods that need incising, and avoid raw vegetables, fibrous meats, and sticky foods until experience has been gained. Practiced denture wearers may select a variety of foods, but should not expect the same efficiency as with the natural teeth. Use the canine and premolar area to bite food, and push back as the food is incised; do not pull or tear the food in a forward direction. Take small portions and try to chew with some food on each side at the same time to stabilize the denture.
Over-the-counter products	Consult the dentist for advice about all denture problems, and before buying self-reline materials, adhesives, or other additives. Never attempt to alter the denture for relief of discomfort.
Speaking	Speak slowly and quietly. Practice by reading aloud at home, preferably in front of a mirror, and repeat and practice words that seem the most difficult.

Depression see **Depressive disorders**

Depressive disorders

Definition

A depressive disorder is defined by the National Institute of Mental Health (NIMH) as an illness that involves the body, mood and thoughts. It encompasses feelings of overwhelming sadness and despair that persist or intensify over time.

Description

Occasional feelings of unhappiness or sadness are normal, but when such feelings dominate everyday life causing physical and mental deterioration, they are termed depressive disorders. In *Caring For The Mind, The Comprehensive Guide to Mental Health*, Dianne and Robert Hales state that comparing everyday blues to clinical depression is like comparing a cold to **pneumonia**. Nearly 19 million American adults, approximately 10% of the population, suffer from depression in any given year. Less than one of three of these will ever pursue, or receive, medical care. In a survey conducted by the National Mental Health Association, it was found that nearly half of those surveyed believed that depression was not an illness, but rather a personal emotional weakness. However depressive disorders are valid illnesses that require treatment and can literally be life-threatening: Fifteen percent of all people diagnosed as being depressed actually do commit suicide. Thirty percent may make unsuccessful attempts.

Categories of depression include:

- major depression
- seasonal affective disorder
- **bipolar disorder**
- dysthymia
- depression due to a general medical condition
- **postpartum depression**
- substance-induced depression

Major depression

Major depression can be mild, moderate or severe, and the rating of its severity is based upon the number of symptoms the person has, and how seriously these symptoms affect their lives. Typical symptoms are:

- lack of interest in once-enjoyable activities
- loss or gain of weight
- difficulty concentrating or making decisions
- feelings of worthlessness and hopelessness
- changes in sleep patterns, either insomnia or hypersomnia

People with major depression may be preoccupied with death or suicide. In children, it may manifest itself as irritability or *acting out*. According to the National Comorbidity Survey, major depression is the single most common mental illness in the United States, affecting one in ten Americans, and women twice as often as men. Ten to 15% of people over 65 and 25% of those in **nursing homes** show symptoms, and NIMH estimates that better than half of elderly Americans who suffer from major depression do not receive appropriate treatment.

Seasonal affective disorder (SAD)

The unique characteristic of SAD is *when* the depression occurs. Incidences usually occur at a specific time each year. SAD can be either unipolar, showing depressive symptoms only, or bipolar, having cycles of depression and elevated mood. SAD typically begins in the autumn, when the days grow shorter, and continues through the winter, ending in the spring. A less common form begins in the spring and ends in early fall. The NIMH estimates that ten million Americans have SAD.

Bipolar disorder

Close to two million Americans are diagnosed as having bipolar disorder, or manic depression, a mental illness that is characterized by cycles of giddy elation and despondency. Approximately one-fifth of all depressive disorders are termed bipolar. People suffering from bipolar illnesses often first exhibit hypomania, a mild state of

mania, in which they are often able to accomplish a great deal, go without sleep, and exhibit extreme self-confidence. As the disease progresses, they may cycle into full-blown mania, and engage in much more dangerous behavior, such as wild spending sprees, promiscuous sexual activity, substance abuse, and other self-destructive behaviors. This euphoric phase is followed by the depths of classic depression.

Dysthymia

Dysthymia, or chronic mild depression, has been described as sadness that will not end. There has been debate among mental health professionals for several years as to whether dysthymia is a truly separate entity from major depression, and the answer remains unclear. NIMH studies have shown that three-quarters of those diagnosed with dysthymia also had other disorders, including major depression, panic or **anxiety** disorders, and substance abuse. The National Comorbidity Survey suggested that approximately 6% of Americans will develop this disorder in their lifetimes.

Depression due to a general medical condition

Many people are not aware that physical disease can cause depression. One of the significant differences in this type of depression is that patients continue to feel good about themselves, and complain that the depression is interfering with their normal life activities.

Postpartum depression

It is not unusual for a new mother to have what is termed baby blues shortly after giving birth. This involves feeling sadder than usual, crying easily, and typically occurs in the first seven to 10 days after birth. However, about 1% of all new mothers develop a true mental illness, postpartum depression, between a month and a year after giving birth. The symptoms are similar to major depression, but some women may develop more serious complications, including hallucinations and delusions.

Substance-induced depression

Many different medications, both legal and illegal, can cause depression. **Alcoholism** has long been linked closely with depression, but it is now known that one in four alcoholics suffered from depression before they ever drank, and will remain depressed whether they drink again or not, unless the depression is treated.

Causes and symptoms

As study of the **brain** and nervous system has advanced, it has become known that depression is a complicated biological process that interrupts the normal balance of neurotransmitters, or messenger chemicals such as norepinephrine or serotonin.

Major depression

Heredity appears to be strongly linked to major depression. As a rule, the rate of depression between family members of a person suffering from major depression is one to three times higher than in families where there is none. An identical twin is 66% more likely to become depressed if the other develops the illness. However therapists can often see predictable patterns of behavior that lead to depression. Life traumas such as grief also seem to lead to major depression.

Seasonal affective disorder

SAD is common in northern climates. It is nearly nine times more prevalent in New Hampshire as in Florida, indicating that the altered brain chemistry that produces the depression is related to the decrease in light in northern climates during the winter. However, the cause of SAD is still under investigation.

Bipolar disorder

Bipolar disorders are believed to be caused by abnormal functioning of the brain. Heredity is considered a major factor.

Dysthymia

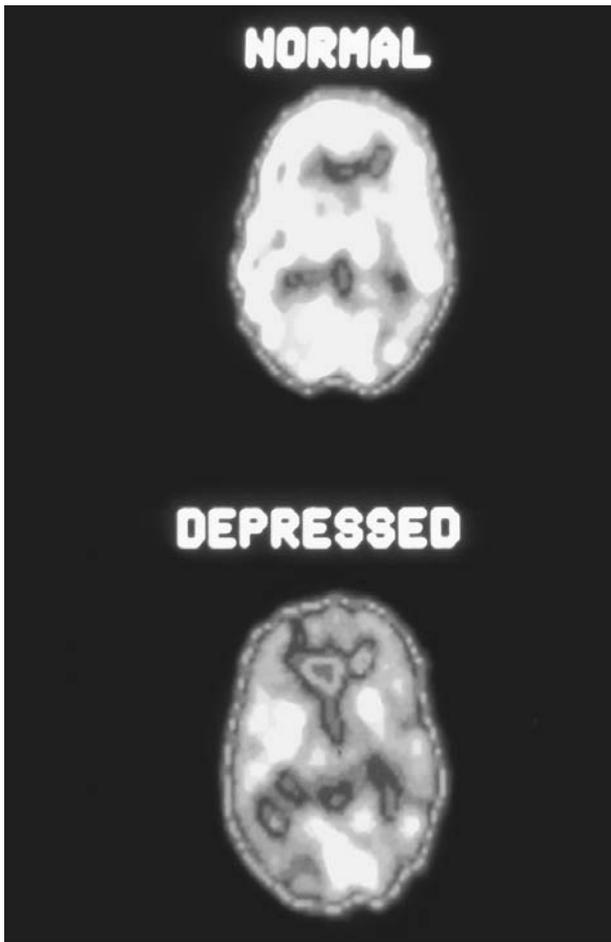

Like other depressions, dysthymia has been related both to hereditary chemical imbalances within the brain and to traumatic events in life, often going back to childhood. Some research has linked dysthymia to attention deficit hyperactivity disorder (ADHD) and conduct and **personality disorders**.

Depression due to a general medical condition

Among the physical illnesses capable of causing depression are **cancer**, **heart** disease, hormonal problems (such as thyroid disorders), Alzheimer's and **Parkinson's Disease**, brain tumors, head injuries, infectious illnesses, and malnutrition/vitamin deficiency.

Postpartum depression

This type of depression appears related to changes in hormonal chemistry that affects a woman's brain chemistry.

Positron emission tomography (PET) scans comparing a normal brain with that of someone with a depressive disorder. (Photo Researchers, Inc. Reproduced by permission.)

Substance-induced depression

Among the substances that are capable of causing depression are:

- alcohol
- minor tranquilizers such as valium
- heroin and other narcotics
- antihistamines
- anticancer drugs
- steroids and corticosteroids
- anti-seizure medications such as dilantin or depakot
- anti-inflammatory drugs
- cocaine, when its initial elevation in mood has passed
- estrogen
- L-dopa, a drug used to treat Parkinson's disease

Diagnosis

Many people go to their primary care practitioner with complaints of insomnia, lack of appetite, or other physical complaints only to discover that what they actually have is depression. A thorough **physical examination** is needed, including a family history of depression, the person's use of alcohol or other drugs, and medications being taken. Psychological testing and a mental status examination may be conducted. Several clinical inventories or scales may be used to assess a patient's mental status and determine the presence of depressive symptoms. Among these tests are: the Hamilton Depression Scale (HAM-D), Child Depression Inventory (CDI), Geriatric Depression Scale (GDS), Beck Depression Inventory (BDI), and the Zung Self-Rating Scale for Depression. These tests may be administered in an outpatient or hospital setting by a general practitioner, nurse, social worker, psychiatrist, or psychologist. The guidelines for diagnosing depression are found in the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*.

Treatment

Major depression, dysthymia, and seasonal affective disorder are all treated effectively with psychosocial therapy of various kinds and antidepressant medications.

Antidepressants

Antidepressant medications, without any other type of treatment, are estimated to relieve the symptoms of 60–70% of clinically depressed people. Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac) and sertraline (Zoloft) reduce depression by increasing levels of serotonin, a neurotransmitter. Some clinicians prefer SSRIs for treatment of dysthymic disorder. Anxiety, **diarrhea**, drowsiness, headache, sweating, nausea, poor sexual functioning, and insomnia are all possible side effects of SSRIs.

Tricyclic antidepressants (TCAs) are older and less expensive medications than SSRIs, but they have more severe side effects, including persistent dry mouth, sedation, dizziness, and irregular heartbeat. Because of these, caution is taken when prescribing TCAs to elderly patients. TCAs include amitriptyline (Elavil), imipramine (Tofranil), and nortriptyline (Aventyl, Pamelor). A 10-day supply of TCAs is potentially lethal, so these drugs are questionable treatment options for patients at risk for suicide.

Monoamine oxidase inhibitors (MAOIs) such as tranylcypromine (Parnate) and phenelzine sulfate (Nardil) block the action of monoamine oxidase, a **cen-**

tral nervous system enzyme. Patients taking MAOIs must restrict foods high in tyramine (found in red wine, aged cheeses, and meats) from their diet to avoid potentially serious **hypertension**.

Heterocyclics include bupropion (Wellbutrin) and trazodone (Desyrel). Bupropion should not be prescribed for patients with **seizure disorder**. Side effects of the drug may include agitation, anxiety, confusion, tremor, dry mouth, fast or irregular heartbeat, headache, low **blood pressure**, and insomnia. Because trazodone has a sedative effect, it is useful in treating depressed patients with insomnia.

Psychosocial therapy

Psychotherapy explores an individual's life to bring to light possible contributing causes of the present depression. During treatment, the therapist facilitates an awareness of thought patterns and how they developed. There are several different subtypes of psychotherapy, but all have the common goal of helping the patient develop healthy problem solving and coping skills.

Electroconvulsant therapy

ECT, or electroconvulsive therapy, is normally employed after other treatment options have been explored. But it may be used sooner if severe depression, suicide risk, or psychosis is present, or if the person is unable or unwilling to take medication. About half of those who do not improve from other therapies recover after having ECT.

The treatment consists of a series of electrical pulses that move into the brain through electrodes on the patient's head. ECT is given under **general anesthesia** and patients are administered a muscle relaxant to prevent convulsions. Although the exact mechanisms behind the success of ECT therapy are not known, it is believed that the electrical current modifies the electrochemical processes of the brain, consequently relieving depression. Headaches, muscle soreness, nausea, and confusion are possible side effects immediately following ECT. **Memory** loss, typically transient, is reported by ECT patients.

Phototherapy

Phototherapy, or exposure to fluorescent light bulbs installed in a metal box with a plastic screen ten to twenty times brighter than indoor lighting, has proven effective in treating SAD. Phototherapy is often combined with other treatments such as medication or psychosocial therapy. The person sits in front of this light box for anywhere from one-half hour to two hours.

Alternative treatment

St. John's wort (*Hypericum perforatum*) is used throughout the world to treat depression. In Germany, St. John's Wort is the most widely used antidepressant. This herbal antidepressant has few reported side effects, but some users have experienced high **blood** pressure, headaches, stiff neck, nausea, and vomiting. NIMH is currently involved in a three-year study of its efficacy. However, in February 2000, a **public health** advisory was issued by the Food and Drug Administration (FDA) stating that St. John's wort may interact with other medications commonly prescribed for heart disease, depression, seizures, and certain cancers, as well as anti-rejection drugs used for transplant patients. Healthcare providers were advised to alert their patients to the risk of this interaction.

Holistic treatment can also be very therapeutic in treating depression. Good **nutrition**, proper sleep, **exercise**, and full engagement in life are very important to a healthy mental state.

Prognosis

Untreated or improperly diagnosed depression is the number one cause of suicide in the United States. Yet treatment can result in dramatic improvement for between 75–80% of patients, and should be clearly evident within three to four months. Five to 10% of patients still report depression two years after initially being treated, but there are varying reasons for this, including medication noncompliance and alcohol abuse. The risk of recurrence climbs significantly with each episode.

Prevention

Education is crucial for patients with depressive disorders. They must learn to recognize symptoms and to take an active part in their treatment. Extended maintenance treatment with antidepressants may be required in some patients to prevent relapse. Physical exercise and staying connected to self-help support groups have both been shown to be effective in preventing depression. Early intervention with children with depression is effective in arresting development of more severe problems.

Health care team roles

Psychiatrist

Psychiatrists are licensed medical doctors who have undergone a three-year psychiatric residency. They diagnose depression, determine appropriate treatment, and provide psychotherapy and support for patients.

KEY TERMS

Clinical depression—Depression that is serious enough to require psychiatric intervention and treatment.

Hypersomnia—The need to sleep excessively; a symptom of dysthymic and major depressive disorder.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells. Changes in the levels of certain neurotransmitters, such as serotonin, norepinephrine, and dopamine, are thought to be related to depressive disorders.

Psychomotor agitation—Disturbed physical and mental processes (fidgeting, wringing of hands, racing thoughts); a symptom of major depressive disorder.

Psychomotor retardation—Slowed physical and mental processes (slowed thinking, walking, and talking); a symptom of major depressive disorder.

Education on the nature of depression, and the various treatment options available, are important adjuncts to the therapy they provide.

Primary care practitioner (PCP)

Though depression is a mental illness, depression may be diagnosed by primary care practitioners because depressed patients often exhibit distinct physical symptoms. Psychiatrists frequently become involved only after a consultation is requested. The importance of a psychiatric referral for further evaluation cannot be overstated. It can literally save a severely depressed person's life.

Registered nurse (RN), psychiatric nurse, or licensed practical nurse (LPN)

Both RNs and LPNs must complete a prescribed nursing course and pass a state examination. RNs typically have a degree in nursing, and psychiatric nurses have additional training specific to their field. Both RNs and LPNs are the health care team members who are most involved with depressed patients in outpatient clinics and in psychiatric units, where patients at risk for suicide must be monitored. Observational skills, empathy, and the ability to listen are necessary assets for nurses. Education about depression typically comes from both physicians and nurses.

Social workers

Social workers are usually either certified (CSW) or licensed clinical social workers (LCSW). A two-year graduate degree, specialized training that includes supervised clinical work with the mentally ill, and state licensure are typical requirements. Social workers often conduct supportive groups or programs that help people vent feelings or work on ways to better be able to cope.

Mental health assistants

These are staff members on inpatient psychiatric units who have been provided with special training in order to assist with the care of people with mental illness. They normally aid patients with day-to-day needs, accompany them to appointments or for walks if necessary, help deal with crises, and assist professional staff in providing care.

Joan M. Schonbeck

Development assessment

Definition

Developmental assessment involves the measure of a child's attainment of physical or cognitive skills that allow continued maturation, learning, and function in society.

Purpose

Developmental assessment is used to observe functional ability in children and to identify any deviations from the norm. It is used to recognize whether or not a disability may exist and if so, where the specific problem areas lie. Developmental tests provide information regarding the milestones a child has attained, and can help in determining the course of intervention to attain further milestones. Results of developmental tests may also be used to indicate the level of progress achieved after intervention, and are often used by both clinicians and researchers.

Description

In addition to the use of a test with established reliability and validity, a developmental assessment should include data collection in the form of an interview, history, and clinical observation. The interview should take place with the parents/caregivers and, if age-appropriate, the child, in an informal and friendly setting. The concerns and goals of the parents and child are important to note, and information regarding the child's developmental and medical history may be obtained at this time. In addition to the parent report, it is important to look at **medical records** if they are available. Information regarding the mother's **pregnancy**, labor, and delivery, and the child's medical/surgical history, health status, medications, precautions, and other items of relevance is helpful in providing a background for the assessment.

Clinical observation of the child is useful in determining factors that may contribute to developmental difficulties. In addition, it is helpful to watch a child moving under his or her own volition, instead of under a therapist's directions. Observation may include, but is not limited to: the manner in which the infant or child is held by the parent (e.g. posture, support required); preferred means of mobility (e.g. wheelchair, ambulation [walking], crawling, scooting, rolling); antigravity posture and movements; equilibrium and righting reactions; balance, including base of support; compensations; and assistance required for stability or mobility.

There are a number of assessment tools available that measure gross motor development. Some, but not all, of these tools will be summarized here.

Screening tests

Screening tests are the most basic form of developmental assessment tool, and are used to determine whether or not a concern exists. The Alberta Infant Motor Scale (AIMS) is used during the first year of life to identify motor delay and to evaluate maturation over time. Fifty-eight items related to posture, movement, and weight bearing in prone, supine, sitting, and standing positions take 10 to 20 minutes to observe. Researchers have found predictive validity, interrater (the consistency of the rating between different people performing the test), and test-retest reliability of the AIMS to be good. In addition, there is high concurrent validity with the Peabody Developmental Motor Scales' gross motor portion.

The Miller First Step Screening Test for Evaluating Preschoolers assesses cognitive and physical function in children 35 to 74 months of age. It uses 18 games that are age-appropriate and takes approximately 20 minutes. The Denver II is a comprehensive screening test encompassing 125 items in the personal-social, fine motor-adaptive, language, and gross motor domains. The test is norm-referenced from birth to six years; however, it has been criticized for poor specificity.

Motor assessments

The Test of Infant Motor Performance (TIMP) consists of observation of 28 items and elicitation of 31 items in infants up to four months of age. It is found to be highly sensitive to small changes in development and valid in measuring behaviors of functional relevance. Test-retest reliability has been found to be high; more research needs to be done on predictive validity. Administration takes 25 to 45 minutes.

The Movement Assessment of Infants (MAI) is a criterion-referenced test for infants in the first year of life. Sixty-five items related to muscle strength/tone, primitive **reflexes**, automatic reactions, and volitional movement, including quality of movement, are assessed. Researchers report that interrater and test-retest reliability is good; however, the MAI has been found to over-identify infants with motor delay (i.e. produce a high rate of false positives).

The Peabody Developmental Motor Scales (PDMS) is a norm- and criterion-referenced test that examines gross and fine motor function in children from birth to 83 months (the second edition includes up to 71 months). The gross motor scale includes reflexes, balance, nonlocomotor, locomotor, and receipt and propulsion of objects. The

fine motor scale includes grasp, hand functions, eye-hand coordination, and manual dexterity. High reliability and validity have been reported; however, criticisms of the test prompted the creation of a second edition, the PDMS-2. This edition is updated with new normative data representative of the current U.S. population. Reliability and validity were studied for gender, race, and other subgroups of the normative sample. In addition, more specific scoring criteria and illustrations were added.

The Bruininks-Oseretsky Test of Motor Proficiency (BOTMP) is a norm-referenced test that examines gross and fine motor function in children aged four-and-a-half to fourteen-and-a-half years. The gross motor subtests assess speed and agility, balance, bilateral coordination, and strength. The fine motor subtests assess upper-limb coordination, speed and dexterity, response speed, and visuomotor control. Administration takes 45 to 60 minutes, and reliability (interrater and test-retest) is high. Critics of the test have pointed out, however, that some of the items, e.g. “tapping feet alternately while making circles with fingers,” do not measure skills relevant to everyday function. In addition, it is important to note that failure of items may result as much from cognitive and perceptual difficulties as from motor difficulties.

The Gross Motor Function Measure (GMFM) is designed to evaluate change in motor performance over time in children with **cerebral palsy**. The test contains 88 items in five groups: lying and rolling; sitting; crawling and kneeling; standing; and walking, running, and jumping. Interrater and test-retest reliability have been demonstrated as high.

Comprehensive assessments

The Bayley II consists of a norm-referenced test of motor performance (manipulation, coordination of large muscle groups, dynamic movement, postural imitation, stereognosis [the ability to recognize solid objects by touch]), and mental ability (object permanence, **memory**, problem solving, complex language) in children from birth to 42 months. It also contains a criterion-referenced behavior scale that looks at affect, interests, activity, and fearfulness. Test-retest and interrater reliability have been found to be higher for older ages than for younger ages with this test. This test takes approximately 45 to 60 minutes to administer.

The Early Intervention Developmental Profile (EIDP) consists of six scales in the following areas: perceptual/fine motor; cognition, language, social/emotional; self-care; and gross motor development. It is designed to be administered wholly by any member of a multidisciplinary team to children from birth to 36 months.

Content validity, in addition to interrater and test-retest reliability, have been found to be good.

Assessments of functional capabilities are not necessarily developmental milestone-based; however, their use is important in determining whether or not specific disabilities exist. These disabilities may be related to mobility, transfer, self-care or social function. Examples of functional assessments include the Pediatric Evaluation of Disability Inventory (PEDI) and the Functional Independence Measure for Children (WeeFIM).

Results

In a norm-referenced test, the child's score is compared to the average of a group of children. This average is obtained by collecting scores from a large population. In a criterion-referenced test, the scores are interpreted based on absolute criteria such as the number of items performed correctly. Raw scores on tests often can be converted to age equivalent scores, standard scores, motor quotients and percentile rankings.

Once scores are obtained, they must be analyzed along with the information gathered during the interview, history, and observation. Although the normative populations used for the tests are representative of the U.S. population, cultural differences in motor development need to be considered as well. All of this information may be used to guide intervention and/or identify areas of progress or concern. Once specific areas of dysfunction are noted, goals and objectives may be formulated to treat these areas.

Health care team roles

Physical and occupational therapists usually perform developmental motor assessments; however, the more comprehensive scales are often designed for administration by any or all members of the health care team. This team may include any or all of the following: physician, nurse, physical therapist, occupational therapist, speech and language pathologist, special educator, psychologist, and social worker. It is important that whoever administers the test takes care to learn the test and procedure for administration.

KEY TERMS

Concurrent validity—Relationship between performance on a given test and another well-established test which is purported to measure the same skills.

Content validity—The likelihood that the test measures what it says it is to measure.

Interrater reliability—Relationship of an individual's score on first administration of a test to the score on second administration.

Predictive validity—The likelihood that a child's performance on the test predicts an actual behavior.

Specificity—Ability of a test to identify those who do not have a disorder.

Test-retest reliability—Index of agreement between two different testers for the same test.

Diabetes mellitus

Definition

Diabetes mellitus is a condition that occurs when either the **pancreas** does not produce enough insulin or the body's cells stop responding to the insulin that is produced. In either case, glucose in the **blood** cannot be absorbed or used by the cells of the body.

Description

Diabetes has been recognized as a disease since ancient times. Egyptian papyri described its symptoms in 1550 B.C., and Hindu physicians noted 500 years later that insects were drawn to the sugary urine of people afflicted with diabetes. The disease was first named in 230 B.C. by Apollonius of Memphis, who took it from the Greek *diabainein* (to pass through), a description of the unquenchable thirst and copious urine produced by diabetics. It was not until the latter part of the eighteenth century that the British physician John Rollo appended the Latin term *mellitus* (honey-sweet) to distinguish diabetes from other diseases that caused excessive urine production.

Diabetes mellitus is a chronic disease that causes serious health complications including renal failure, **heart** disease, stroke, blindness, and peripheral neuropathy with vascular insufficiency, putting patients at risk for **gangrene** and subsequent amputation of the extremities. Approximately 16 million Americans have diabetes; of these, it is estimated that around 5.4 million are undiagnosed. Diabetes afflicts 120 million people worldwide, with the World Health Organization predicting that the number will reach 300 million by 2025.

Physiology

Every cell in the human body requires fuel to function. The body's primary energy source is glucose, a simple sugar resulting from the digestion of foods containing **carbohydrates**. Glucose from the digested food circulates in the blood as a ready energy source for any cells that need it. Insulin is a protein hormone secreted into the blood by cells in the pancreas called islets of Langerhans. Insulin bonds to a receptor site on the outside of a cell, and acts like a key to open a doorway into the cell through which glucose can enter. The **liver** may convert excess glucose to concentrated energy sources like glycogen or fatty acids, which are stored for later use. If there is insufficient insulin production, or when the doorway no longer recognizes the insulin key, glucose stays in the blood rather than entering the cells.

As the level of glucose in the blood rises, a condition called hyperglycemia results. The body will try to dilute this high blood glucose level by drawing water out of the cells, pumping it into the bloodstream, and excreting it in urine. It is not unusual for those with undiagnosed diabetes to complain of constant thirst, to drink large quantities of fluids, and to urinate frequently as their bodies attempt to get rid of the extra glucose.

At the same time that the body is attempting to rid itself of glucose in the blood, its cells are starving for glucose and sends signals to eat more food, giving patients tremendous appetites. To provide energy for the starving cells, the body also tries to convert **fats** and **proteins** into glucose. Breaking down these substances causes acid compounds called ketones to form in the blood and to be excreted in the urine. As ketones build up in the blood, a condition called ketoacidosis can occur. If left untreated, this condition can be life threatening, eventually leading to **coma** and death.

Types of diabetes mellitus

Type 1 diabetes, sometimes called juvenile diabetes, commonly begins in childhood or adolescence. It occurs more frequently in populations descended from northern European countries than in those from southern Europe, the Middle East, or Asia. This form of diabetes is also called insulin-dependent diabetes because people who develop it need to have insulin injections at least once a day. In this form of diabetes, the body produces little or no insulin. Its onset is sudden, and it usually—but not always—occurs in people under 30.

Brittle diabetics are a subgroup of type 1 in which patients have frequent and rapid blood sugar level swings, alternating between hyper- and hypoglycemia. These patients may need several injections of different types of insulin taken at specific times during the day to maintain a blood glucose level within a fairly normal range.

The more common form of diabetes is type 2, sometimes called age-onset or adult-onset diabetes. It accounts for more than 90% of all diabetes in the United States. This form occurs most often in people who are over 50, as well as those who are overweight and sedentary; it is also more common in people of Native American, Hispanic, and African-American descent. People who have migrated to Western cultures from East India, Japan, and Australian Aboriginal cultures are also more likely to develop type 2 diabetes than those who remain in their native countries.

Type 2, also called noninsulin-dependent diabetes, is considered a milder form of diabetes because of its gradual onset (sometimes developing over the course of several years) and because it can often be controlled with

diet and oral medication. The consequences of uncontrolled and untreated type 2 diabetes, however, are as serious as those caused by type 1. Many people with type 2 diabetes are able to control their blood glucose with diet and oral medications, but for those who cannot, insulin injections may be necessary. In recent years, an alarming trend was being noted in Western culture, particularly in the United States: a tendency for children, teenagers, and young adults, particularly those who are obese, to develop this type of diabetes.

Another type of diabetes is **gestational diabetes**, which can develop during **pregnancy** and generally resolves after the delivery of the baby. This diabetic condition develops during the second or third trimester in approximately 2% of pregnancies. The condition is normally treated by diet, however, insulin injections may be required for periodic exacerbation control. Women who develop diabetes during pregnancy are at higher risk for developing type 2 diabetes within five to 10 years.

Diabetes may also develop as a result of or in concert with pancreatic disease, **alcoholism**, malnutrition, or other severe illnesses that tax the body's **immune system**.

Causes and symptoms

The causes of diabetes mellitus are unclear, however, there appear to be both hereditary and environmental factors involved. Research has shown that some people who develop diabetes have common genetic markers. In type 1 diabetes, the immune system is probably triggered by a virus or other microorganism that destroys the cells in the pancreas that produce insulin.

Type 2 diabetes is characterized by the insulin resistance syndrome, in which peripheral adipose and muscle cells fail to respond appropriately to circulating insulin, which the pancreas produces in response to food loads. Research has now shown that the insulin resistance syndrome is closely associated with dyslipidemia, an imbalance in the ratio of total cholesterol to the cholesterol fractions of either low-density lipoproteins (bad cholesterol) or to high-density lipoproteins (good cholesterol). Untreated or inadequately treated dyslipidemia leads to atherosclerosis and eventually to the microvascular complications mentioned above. Patients with type 2 diabetes and dyslipidemia are often treated with one of the drugs from the group known as statins, in addition to oral antidiabetic agents.

Age, **obesity**, and family history may all play a role in the development of type 2 diabetes. Symptoms may begin so gradually that a person may not be aware of them. Early signs are fatigue, extreme thirst, and frequent urination. Other symptoms may include sudden weight

loss, slow wound healing, urinary tract infections, or blurred **vision**. It is not unusual for type 2 diabetes to be detected while a patient is seeing a doctor for another health concern that is actually being caused by the as-yet-undiagnosed diabetes.

Individuals who are at high risk of developing type 2 diabetes mellitus include those who:

- Are obese (more than 20% above their ideal body weight).
- Have a primary relative (immediate family member) with diabetes mellitus.
- Belong to a high-risk ethnic population (African American, Native American, Hispanic, or Native Hawaiian).
- Have been diagnosed with gestational diabetes or have delivered a baby weighing more than 9 lbs (4 kg).
- Have been diagnosed with transient diabetes at the time of a moderate to severe systemic **infection** (like protracted pneumonia).
- Have high **blood pressure** (140/90 mmHg or above).
- Have a high-density lipoprotein cholesterol level less than or equal to 35 mg/dL and/or a triglyceride level greater than or equal to 250 mg/dL.
- Have had impaired glucose tolerance or impaired fasting glucose on previous testing.

Several common medications can impair the body's use of insulin, causing a condition known as secondary diabetes. These medications include treatments for high blood pressure (furosemide, clonidine, and thiazide diuretics), drugs with hormonal activity (oral contraceptives, thyroid hormone, progestins, and systemic glucocorticoids), and the anti-inflammation drug indomethacin. Several drugs used to treat mood disorders can also impair glucose absorption. These drugs include haloperidol, lithium carbonate, phenothiazines, tricyclic antidepressants, and adrenergic agonists. Other medications that can cause diabetes symptoms include isoniazid, nicotinic acid, cimetidine, and heparin.

Symptoms

Symptoms of diabetes can develop suddenly (over days or weeks) in previously healthy children or adolescents, or can develop gradually (over several years) in overweight adults past the age of 40. The classic symptoms include fatigue, frequent urination, excessive thirst, excessive hunger, tingling of hands and feet, pruritus, and weight loss. In sudden-onset diabetes, some patients may have a "fruity" odor to their breath.

Wrinkled, dehydrated skin of a person in a diabetic coma. Untreated diabetes mellitus results in elevated blood glucose levels, causing a variety of symptoms that can culminate in a diabetic coma. (Photo Researchers, Inc. Reproduced by permission.)

Ketoacidosis, a condition that results from starvation or uncontrolled diabetes, is common in patients with type 1 diabetes. Its symptoms include abdominal **pain**, vomiting, tachypnea, and extreme fatigue or lethargy. Patients with ketoacidosis will also have a characteristically sweet, fruity breath odor. Left untreated, this condition may lead to coma and death.

With type 2 diabetes, the condition may not become evident until the patient presents for medical treatment for some other condition. A patient may have heart disease, chronic infections of the gums and urinary tract, blurred vision, numbness in the feet and legs, and slowly healing **wounds**. Women may experience genital itching.

Diagnosis

Urine tests

Diabetes is suspected based on symptoms, but many of its symptoms may also suggest other diseases. Urine tests can begin the winnowing process that leads to a definitive diagnosis. Urine tests can detect ketones and protein in the urine; they can also show urine "spill," the renal threshold at which the **kidneys** will spill excess blood sugar into the urine. They can help assess how adequately the kidneys are functioning, and are used to monitor the disease once the patient is compliant with the recommended diet, oral medications, or insulin.

Blood tests

Although urine tests can confirm an initial suspicion of diabetes, specific blood tests are often required to make the differential diagnosis. One such diagnostic tool

is the fasting glucose test. Blood is drawn via a venipuncture after a period of at least eight hours of fasting, usually in the morning prior to breakfast. The red blood cells are separated from the sample and the amount of glucose is measured in the remaining plasma. A plasma level of 7.8 mmol/L (200 mg/L) or greater can indicate diabetes. The fasting glucose test is usually repeated on another day to confirm the results. A postprandial glucose test involves taking blood one to two hours after the patient has eaten a meal.

A glucose tolerance involves blood and urine sampling over a three- or five-hour period after a patient drinks a specially prepared syrup of glucose and other sugars. During the test the patient drinks no other fluids. When patients are healthy, the blood glucose level rises immediately after the drink and then decreases gradually as insulin is used by the body to metabolize the glucose. In patients with diabetes, the serum glucose rises and stays elevated after drinking the sweetened liquid. A plasma glucose level of 11.1mmol/L (200 mg/dL) or higher two hours after drinking the syrup and at one other point during the two-hour test period confirms the diagnosis of diabetes. During this time, the urine is tested for glucose spill.

A diagnosis of diabetes is confirmed if there are symptoms of diabetes and a blood glucose level of at least 11.1 mmol/L, a fasting plasma glucose level of at least 7 mmol/L, or a two-hour plasma glucose level of at least 11.1 mmol/L during an oral glucose tolerance test.

Monitoring glucose levels

The blood test that gives the best indication of average blood glucose levels over time is the hemoglobin A1C (HbA1C) test. It measures the percentage of hemoglobin A that has become glycosylated (coated with glucose) during the past three months. (Red blood cells have a life span of about 100 days; after that they are recycled by the bone marrow.) A normal reading for healthy individuals is about of 4–6% glycosylated HbA1C. Diabetics whose disease is well controlled will read 7% or lower. A reading of 8% or higher indicates the need for a change in treatment or better dietary compliance; these patients are also at increased risk for such complications as eye disease, kidney disease, and nerve damage. The HbA1C test should be performed at least twice a year to be sure that blood glucose levels stay within safe and healthy levels.

Home blood glucose monitoring kits are available so patients with diabetes can monitor their daily glucose readings. For decades, a small needle or lancet was used to prick the finger and a drop of blood was collected and analyzed by a monitoring device. Modern blood moni-

toring devices, however, are strapped on like a wrist watch; no finger sticks are required. This is especially helpful for patients who need to test their blood glucose levels several times during the day.

Treatment

There is no cure for diabetes; it can, however, be controlled so that patients can live a relatively normal life. Treatment focuses on two goals: keeping blood glucose readings within a normal range (140 mg/dL, the standard accepted by the American Diabetes Association) and preventing the development of long-term complications. Careful monitoring of diet, **exercise**, and blood glucose levels are important, affecting the need for insulin replacement as well as the dose of oral antidiabetic agents. Lack of consistent control leads to complications of the disease.

Dietary changes

Diet and moderate exercise are the first treatments implemented in diabetes. For many type 2 diabetics, weight loss may be an especially important part of treatment. A well balanced, nutritious diet provides approximately 50% to 60% of calories from carbohydrates, around 10% to 20% from protein, and less than 30% of calories from fat. The number of calories required by an individual depends on their age, weight, and activity level. Calorie intake also needs to be distributed over the course of the entire day so that surges of glucose entering the blood are kept to a minimum. The timing of snacks must also correspond to the timing and type of insulin being used.

Counting the calories in different foods can be complicated, so patients are usually advised to consult a nutritionist, who will set up an individualized, easily managed diet for each patient. Both the American Diabetes Association and the American Dietetic Association recommend diets based on the use of food-exchange lists. Each food-exchange unit contains a known amount of calories in the form of protein, fat, or carbohydrate. A patient's diet plan will allow a certain number of exchanges from each food category (meat or protein, fruits, breads and starches, vegetables, and fats) to be eaten at mealtimes and as snacks. Patients can choose which foods they eat as long as they stick with the number of exchanges prescribed and adhere to their schedule if they take a combination of insulin types. The food exchange system, along with an exercise program, can help patients lose excess weight and improve their overall health. This may be especially important for type 2 diabetics.

Oral medications

A variety of oral medications are available to help lower blood glucose in type 2 diabetics. They act in a variety of ways to control postprandial (after meal) glucose levels; the particular medication or combination of drugs chosen will be based largely on the individual patient profile. Some oral medications stimulate the pancreatic beta cells to produce additional insulin. Others change the way receptors on peripheral adipose (fat) and muscle cells receive the insulin and act on it, and still others block the intestinal absorption of food byproducts that would increase blood glucose levels.

All drugs have side effects that may make them inappropriate for particular patients. For example, some medications may stimulate weight gain or cause **stomach** irritation, so they may not be the best treatment for individuals who are already overweight or who have stomach ulcers. While these medications are an important aspect of treatment for type 2 diabetes, they are not a substitute for an appropriate diet and exercise. Oral medications are not effective for type 1 diabetes, in which the patient produces little or no insulin.

Insulin

Patients with type 1 diabetes need daily injections of insulin to help their bodies utilize glucose. The amount and type of insulin required depends on the individual patient's height, weight, age, food intake (quantity and timing), and activity level. Some patients with type 2 diabetes may need to use insulin injections if their diabetes cannot be controlled with diet, exercise, and oral medication. Injections are given subcutaneously, using a small needle and syringe. Injection sites can be anywhere on the body where there is adequate subcutaneous tissue, including the upper arm, abdomen, hips, or upper thigh.

Purified human insulin is most commonly used, however, insulin from beef and pork sources is also available. Insulin may be given as an injection of a single dose of one type of insulin once a day. Different types of insulin (short-acting rapid-onset, slow-onset long-acting) can be mixed and given in one dose or split into two or more doses during the day. Patients that require multiple injections over the course of a day may be able to use an insulin pump that administers small doses of insulin on demand. The small battery-operated pump is worn outside the body and is connected to a tube that is inserted into the abdomen. Pumps can be programmed to inject small doses of insulin at various times during the day, or the patient may be able to adjust the insulin doses to coincide with glucometer readings, meals, and exercise.

There are also multiple-dose insulin injection devices available that are commonly referred to as insulin pens. They are designed to hold a cartridge containing several days' worth of insulin dosages.

Regular human insulin is fast-acting and begins to work within 15–30 minutes; its peak glucose-lowering effect occurs about two hours later and its effects last approximately 4–6 hours. Neutral protamine Hagedorn (NPH) and Lente insulin are intermediate-acting insulins that start to work within 4–8 hours, and last 18–26 hours. Ultralente is a long-acting form of insulin that starts to work within four to eight hours and lasts 28 to 36 hours. Many diabetics combine a long- or intermediate acting insulin with a short-acting one to provide the proper insulin peak at mealtimes. Premixed insulins are available in standard doses. Newer forms of insulin are under investigation.

Although the goal of most diabetes treatment is to lower blood glucose levels, hypoglycemia, or low blood glucose, can be caused by too much insulin, too little food, alcohol consumption, or increased exercise. A patient with symptoms of hypoglycemia may be hungry, irritable, confused, and tired. The patient may be diaphoretic (sweating profusely), pale, and shaky. Left untreated, the patient can lose consciousness or have a seizure soon after these symptoms appear. This condition, called an insulin reaction or insulin shock, should be treated by giving the conscious patient something with readily available sugar to eat or drink like orange juice, hard candy, or sugar cubes. If the patient has declined into unconsciousness, do not try to feed them. This is a critical condition and always requires emergency intravenous therapy.

Surgery

Transplantation of healthy pancreatic tissue into a diabetic patient can be successful. However, it is not clear if the potential benefits outweigh the risks of the surgery and drug therapy required.

Alternative therapies

Since uncontrolled diabetes can be life-threatening if not properly managed, patients should be instructed to not attempt treatments without medical supervision. Patients interested in alternative and herbal remedies should be instructed about the possible benefits, but cautioned to consult with a health care professional before they try them. Some alternative therapies may interact negatively with some of the oral antidiabetic agents or other drugs, such as antihypertensives or anticoagulants.

KEY TERMS

Diabetic peripheral neuropathy—Condition in which the sensitivity of nerves to pain, temperature, and pressure is dulled, particularly in the legs and feet.

Diabetic retinopathy—A condition in which the tiny blood vessels to the retina are damaged, leading to blurred vision, sudden blindness, or black spots, lines, or flashing light in the field of vision.

Hemoglobin A—Normal hemoglobin found in the blood of an adult.

Hemoglobin A1C—One of three fractions of hemoglobin A; the other two are HbA1a and HbA1b. Because HbA1c can become glycosylated, it is an important measure of blood glucose over the past three months.

Hyperglycemia—Abnormally high levels of blood glucose.

Hypoglycemia—Abnormally low levels of blood glucose.

Ketoacidosis—Condition that results in untreated diabetes from the body's attempt to burn fat for fuel when carbohydrates cannot be utilized. Ketones, the byproduct of fat metabolism, enter the bloodstream and make the blood more acidic than the body's tissues.

Pruritus—Itching.

Tachypnea—Rapid breathing.

For patients who are willing to consult with their physician, alternative options may include:

- Fenugreek has been shown in some studies to reduce blood insulin and glucose levels while also lowering cholesterol.
- Bilberry may lower blood glucose levels, as well as help to maintain healthy **blood vessels**.
- Garlic may lower blood sugar and cholesterol levels.
- Cayenne pepper may help relieve the pain of diabetic neuropathy.

Any therapy that lowers **stress** levels may also be useful in treating diabetes by helping to reduce insulin requirements. Among the alternative treatments that aim to lower stress are hypnotherapy, biofeedback, and **meditation**.

Prognosis

Uncontrolled diabetes is a leading cause of blindness, end-stage renal disease, and peripheral vascular insufficiency, which leads to limb amputations. It also doubles the risks of heart disease and increases the risk of stroke. Eye problems including **cataracts**, **glaucoma**, and diabetic retinopathy are also more common in diabetics.

Diabetic peripheral neuropathy is a condition where nerve endings, particularly in the legs and feet, become less sensitive. Diabetic foot ulcers are a particular problem since the patient does not feel the pain of a blister, callous, or other minor injury. Poor blood circulation in the legs and feet contribute to delayed wound healing. The inability to sense pain along with the complications of delayed wound healing can cause minor injuries, blisters, or calluses to become infected and difficult to treat. In cases of severe infection, the infected tissue begins to break down and rot away. The severe infection may further exacerbate diabetes and increase blood glucose levels, perpetuating the problem. In the most serious infection cases, toes, feet, or legs may need to be amputated.

Diabetes can also affect the kidneys, a condition called diabetic nephropathy. This usually means that soft kidney tissue hardens and thickens, a process called sclerosis; this is especially true for the glomerulus (kidney membrane), which filters protein and other waste products from the blood. The ADA estimates that 35–45% of type 1 patients and 20–30% of type 2 patients have damaged kidneys. Because the symptoms of nephropathy may not appear until 80% of kidney function is gone, periodic tests of kidney function are especially important for patients with diabetes. Once renal function drops to 10–15%, **kidney dialysis** or a kidney transplant become necessary.

The risk of heart disease for patients with diabetes is two to four times higher than that of the general population. Death from heart disease is also two to four times higher in diabetics, as is the risk of stroke. These statistics hold for people with both type 1 and type 2 diabetes. The risk of cardiovascular disease increases with age, obesity, smoking, poor blood glucose control, and family history of heart disease.

Health care team roles

All members of the health care team may come into contact with diabetic patients. The nurse plays a particularly important role in teaching patients the skills necessary to manage this complex disease, and educating them about the effects of their medications.

Prevention

Research continues on ways to prevent diabetes and to detect those at risk for developing the disease. While the onset of type 1 diabetes is unpredictable, the risks for developing type 2 diabetes can be reduced by maintaining a healthy weight and exercising regularly. The physical and emotional stresses of surgery, illness (especially systemic infection), pregnancy, and alcoholism can all increase the risks for diabetes, so maintaining a healthy lifestyle is critical to preventing the onset of type 2 diabetes and further complications. Research is in progress to determine the usefulness of placing high-risk patients on metformin (Glucophage; an oral antidiabetic drug used to treat type 2 diabetes) prophylactically in an effort to delay or prevent the onset of type 2 diabetes.

Diagnostic medical sonography

Definition

Diagnostic medical sonography, or ultrasound, is a technique using high frequency sound to create images of specific areas of the body to diagnose various pathologies. The diagnostic medical sonographer performs examinations, records anatomic condition and provides diagnostic information.

Description

Under the supervision of a physician, the diagnostic medical sonographer provides patient services using medical ultrasound to gather data necessary to diagnose various conditions and diseases. The sonographer uses advanced computerized technology to produce images. The images are viewed on a video screen or converted by computer to produce photographs or printouts of ultrasonic patterns. The imaged patterns help the physician determine the diagnosis.

The sonographer's responsibilities include image production through patient positioning and operation of clinical instrumentation, patient care, quality control, technical assistance with interventional procedures, image manipulation and processing, and the preliminary interpretation of the ultrasound examination for the sonologist.

Supporting the physician, the sonographer obtains, reviews, and integrates pertinent patient history and supporting clinical data to facilitate optimum diagnostic results. This involves performing appropriate procedures and recording anatomical, pathological, and/or physiological data for interpretation by a physician, and recording and processing sonographic data and other pertinent observations made during the procedure for presentation to the interpreting physician.

Before the procedure, sonographers explain the ultrasonic procedure to patients and help patients assume the correct physical positions for required exposure to ultrasonic waves. At all times, the sonographer is required to exercise good judgment in the performance of sonographic services.

A pregnant woman undergoes an ultrasound. (Photograph by Larry Mulvehill. Science Source/Photo Researchers. Reproduced by permission.)

Work settings

Some sonographers can work in a variety of medical settings including hospitals, clinics, private offices, and other facilities performing examinations in their areas of specialization. More experienced sonographers may work on a contractual basis or for mobile services.

Education and training

A sonographer must have a thorough knowledge of cross-sectional anatomy and pathology, as well as the skills to manipulate a wide variety of sophisticated instruments. Individuals entering diagnostic medical sonography are required to have a strong academic background in the basic sciences and a strong comprehension of computer technology.

Diagnostic medical sonography programs vary in length from one to four years depending on the program design and the degree or certificate awarded. Program entry requirements range from a high school diploma to specific qualifications in a clinically related Allied Health profession such as nursing, radiotechnology, nuclear medicine, etc. Typical program curriculums can

include ultrasound physics and instrumentation, patient care procedures, professionalism and ethics, physiology and pathophysiology, and sonographic anatomy and scanning techniques.

Many programs involve an internship as part of the course of study. Interns work in medical facilities to apply classroom theory and gain practical skills. Following graduation, candidates take a national qualifying exam administered by the American Registry of Diagnostic Medical Sonographers (ARDMS). Continuing education is required of all sonographers to maintain registration. Candidates become Registered Diagnostic Medical Sonographer (RDMS) when they pass the ARDMS exam.

Advanced education and training

Diagnostic medical sonographers may wish to specialize through formal and/or continuing education after graduation and certification. Recent advancements in the technology have led to increased specialization. Specialties include spectral and color doppler, **vascular**

sonography, endocavity imaging, and intraoperative ultrasound.

Future outlook

Diagnostic medical sonography is a rapidly expanding field. The non-invasive, non-ionizing nature of the technology makes it an attractive modality. Continuing advancements in the technology provide a broader application of sonography. Therefore, an increasing need exists for well-trained and dedicated sonographers.

Important recent advances include the transvaginal scan that involves specially designed probes placed in the vagina that produce better images and more information in patients in the early stages of **pregnancy**. Transvaginal scans are becoming valuable in the early diagnosis of ectopic pregnancies and in detecting fetal abnormalities in the first trimester of pregnancy. Another recent advancement, doppler ultrasound, is useful in detecting fetal **heart** rates and fetal **blood** flow. Color doppler is useful in the diagnosis and assessment of congenital heart abnormalities. Also, three-dimensional ultrasound, which can create better scans by providing volumetric measurement, is moving from the research and development stages and into more widespread application.

Graduates of diagnostic medical sonography programs can find many employment opportunities in hospitals, medical centers, and mobile services. There are many opportunities for advancement, both within an institution and within the field. Advancement can depend on continuing education, specialization, and experience. Starting salaries for recent graduates range from \$28,000 to \$32,000.

Career opportunities also exist outside the healthcare field. Graduates can find employment in industry as education specialists, researchers and administrators and with equipment manufacturers as sales representatives.

KEY TERMS

Color Doppler—An ultrasound technique used to locate areas of motion, such as blood flow in vessels.

Doppler—Technique for calculating the relative velocity between two points by measuring the shift in frequency of a sound wave transmitted from one point to another.

Transducer—Often called probes, transducers come in different shapes and sizes for use in different ultrasonic scanning situations.

Ultrasonic—A sound beyond the range of human hearing.

Ultrasound—The diagnostic or therapeutic use of ultrasound and esp. a noninvasive technique involving the formation of a two-dimensional image used for the examination and measurement of internal body structures and the detection of bodily abnormalities.

Dialysis, kidney

Definition

Dialysis treatment replaces the function of the **kidneys**, which normally serve as the body’s natural filtration system. Through the use of a **blood** filter and a chemical solution known as dialysate, dialysis removes waste products and excess fluids from the bloodstream, while maintaining the proper chemical balance of the blood. There are two types of dialysis treatment: hemodialysis and **peritoneal dialysis**.

Purpose

Dialysis also can be used to remove overdosed drugs or poisons from the bloodstream more quickly than normally functioning kidneys. Its most prevalent application, however, is for patients with temporary or permanent kidney failure. For patients with end-stage renal disease (ESRD), dialysis is the only renal replacement

A man undergoes hemodialysis on a dialysis machine. (Giovax Communication/Phototake NYC. Reproduced with permission.)

therapy available other than kidney transplantation. In the United States, nearly 250,000 patients receive regular dialysis treatments to manage ESRD.

Precautions

Blood pressure changes during hemodialysis may pose a risk for patients with **heart** disease. Peritoneal dialysis may be the preferred treatment option for these patients. Peritoneal dialysis is not recommended for patients with abdominal adhesions or other abdominal defects, such as a hernia, which might compromise the efficiency of the treatment. It is also not recommended for patients who suffer frequent bouts of diverticulitis (inflammation of diverticuli, small pouches in the colon).

Description

There are two types of dialysis treatment: hemodialysis and peritoneal dialysis.

Hemodialysis

Hemodialysis is the most frequently prescribed type of dialysis in the United States. The treatment involves

circulating the patient's blood outside of the body through an extracorporeal circuit (ECC), or dialysis circuit. Two needles are inserted into the patient's vein, or access site, and are attached to the ECC, which consists of plastic blood tubing, a filter known as a dialyzer (artificial kidney), and a dialysis machine that monitors and maintains blood flow and administers dialysate. Dialysate is a chemical bath that is used to draw waste products out of the blood.

Since the 1980s, the majority of hemodialysis treatments in the United States have been performed with hollow fiber dialyzers. A hollow fiber dialyzer is composed of thousands of tube-like hollow fiber strands encased in a clear plastic cylinder several inches in diameter. There are two compartments within the dialyzer (the blood compartment and the dialysate compartment). The membrane that separates these two compartments is semipermeable; it allows the passage of certain sized molecules across it, but prevents the passage of other, larger molecules. As blood is pushed through the blood compartment in one direction, suction or vacuum pressure pulls the dialysate through the dialysate compartment in a counter-current, or opposite direction. These opposing pressures

work to drain excess fluids out of the bloodstream and into the dialysate, a process called ultrafiltration.

A second process, called diffusion, moves waste products in the blood across the membrane into the dialysate compartment, where they are carried out of the body. At the same time, electrolytes and other chemicals in the dialysate solution cross the membrane into the blood compartment. The purified, chemically balanced blood is then returned to the body.

Most hemodialysis patients require treatment three times a week, for an average of three to four hours per dialysis “run.” Specific treatment schedules depend on the type of dialyzer used and the patient’s current physical condition. While the treatment prescription and regimen is usually overseen by a nephrologist (a doctor that specializes in the kidney), dialysis treatments are typically administered by a nurse or dialysis technician in outpatient clinics known as dialysis centers or in hospital-based dialysis units. In-home hemodialysis treatment is also an option for some patients, although access to this type of treatment may be limited by financial and lifestyle factors. An investment in equipment is required and another person in the household should be available for support and assistance with treatments.

Peritoneal dialysis

In peritoneal dialysis, the patient’s peritoneum (lining of the abdomen) acts as a blood filter. A catheter is surgically inserted into the patient’s abdomen. During treatment, the catheter is used to fill the abdominal cavity with dialysate. Waste products and excess fluids move from the patient’s bloodstream into the dialysate solution. After a waiting period of six to 24 hours, depending on the treatment method used, the waste-filled dialysate is drained from the abdomen and replaced with clean dialysate.

There are three types of peritoneal dialysis:

- Continuous ambulatory peritoneal dialysis (CAPD). This treatment is self-administered and requires no machine. The patient inserts fresh dialysate solution into the abdominal cavity, waits four to six hours, and removes the used solution. The solution is immediately replaced with fresh dialysate. A bag attached to the catheter is worn under clothing.
- Continuous cyclic peritoneal dialysis (CCPD). An overnight treatment that uses a machine to drain and refill the abdominal cavity, CCPD takes 10–12 hours per session.
- Intermittent peritoneal dialysis (IPD). This hospital-based treatment is performed several times a week. A

machine administers and drains the dialysate solution, and sessions can take up to 24 hours.

Peritoneal dialysis is often the treatment option of choice for infants and children, whose small size can make vascular access difficult to maintain. Peritoneal dialysis also may be performed outside of a clinical setting, which is more conducive to regular school attendance.

Preparation

A dialysis technologist, nurse, or nursing assistant weighs patients immediately before and after each hemodialysis treatment to assess their **fluid balance**. The dialysis technologist, nurse, or nursing assistant also measures and records blood pressure and temperature and assesses patients for any physical changes since their last dialysis run. Regular blood tests, performed by laboratory technologists, monitor chemical and waste levels in the blood. Prior to treatment, patients are typically administered a dose of heparin (an anticoagulant that prevents blood clotting) to ensure the free flow of blood through the dialyzer and an uninterrupted dialysis run.

Aftercare

Both hemodialysis and peritoneal dialysis patients must be vigilant about keeping their access sites and catheters clean and infection-free during and between dialysis runs.

Dialysis is just one facet of a comprehensive treatment approach for ESRD. Although dialysis treatment is very effective in removing toxins and fluids from the body, there are several functions of the kidney it cannot mimic, such as regulating high blood pressure and red blood cell production. Patients with ESRD need to watch their diet and fluid intake carefully and adhere to prescribed medications to effectively manage their disease.

Complications

Many of the risks and side effects associated with dialysis are a combined result of both the treatment and the poor physical condition of the ESRD patient. Dialysis patients should be instructed to report side effects to their healthcare provider.

Anemia

Hematocrit (Hct) levels, the percentage of whole blood comprised of red blood cells, are typically low in ESRD patients. This deficiency is caused by a lack of the hormone erythropoietin, which is normally produced by the kidneys. The problem is exacerbated in hemodialysis patients, who may incur blood loss during hemodialysis

KEY TERMS

Access site—The vein tapped for vascular access in hemodialysis treatments. For patients with temporary treatment needs, access to the bloodstream is gained by inserting a catheter into the subclavian vein. Patients in long-term dialysis require stronger, more durable access sites, called fistulas or grafts, that are surgically-created.

Dialysate—A chemical bath used in dialysis to draw fluids and toxins out of the bloodstream and supply electrolytes and other chemicals to the bloodstream.

Dialysis prescription—The general parameters of dialysis treatment that vary according to each patient's individual needs. Treatment length, type of dialyzer and dialysate used, and rate of ultrafiltration are all part of the dialysis prescription.

Dialyzer—An artificial kidney usually composed of hollow fiber that is used in hemodialysis to eliminate waste products from the blood and remove excess fluids from the bloodstream.

Erythropoietin—A hormone produced by the kidneys that stimulates the production of red blood cells by bone marrow.

ESRD—End-stage renal disease; chronic or permanent kidney failure.

Extracorporeal circuit (ECC)—The path the hemodialysis patient's blood takes outside of the body. It typically consists of plastic tubing, a hemodialysis machine, and a dialyzer.

Hematocrit (Hct) level—A measure of red blood cells.

Peritoneum—The abdominal cavity; the peritoneum acts as a blood filter in peritoneal dialysis.

treatments. Epoetin alfa, a hormone therapy also known as EPO (sold under the trade name Epogen), and intravenous or oral **iron** supplements are used to manage anemia in dialysis patients.

Cramps, nausea, vomiting, and headaches

Some hemodialysis patients experience cramps and flu-like symptoms during treatment. These may be caused by a number of factors, including the type of dialysate used, composition of the dialyzer membrane, water quality in the dialysis unit, and the ultrafiltration

rate of the treatment. Adjustment of the dialysis prescription often helps alleviate symptoms.

Hypotension

Because of the **stress** placed on the **cardiovascular system** with regular hemodialysis treatments, patients are at risk for hypotension, a sudden drop in blood pressure. This can often be controlled by medication and adjustment of the patients' dialysis prescription.

Infection

Both hemodialysis and peritoneal dialysis patients are at risk for **infection**. Hemodialysis patients should keep their access sites clean and watch for signs of redness and warmth that could indicate infection. Peritoneal dialysis patients must follow the same precautions with their catheters in order to prevent peritonitis. Peritonitis, an infection of the peritoneum, causes flu-like symptoms and can disrupt dialysis treatments if not detected promptly.

Infectious diseases

Because there is a great deal of blood exposure involved in dialysis treatment, a slight risk of contracting hepatitis B and hepatitis C exists. The hepatitis B **vaccination** is recommended for most hemodialysis patients. As of 1997, there has only been one documented case of HIV being transmitted in a United States dialysis unit to a staff member, and no documented cases of HIV ever being transmitted between dialysis patients in the United States. The strict standards of **infection control** practiced in modern hemodialysis units makes the chance of contracting one of these diseases very small.

Results

Fluid retention may be relieved after dialysis treatment. The patient's overall sense of physical well being may also be improved. Because dialysis is an ongoing treatment process for many patients, a baseline for normalcy can be difficult to gauge.

Health care team roles

Patients receiving dialysis treatments are cared for by a team that includes nephrologists, dialysis technicians, nurses, radiology technicians, and laboratory technicians. Registered dietitians, nutritionists, and nurses instruct patients about dietary changes to manage their disease.

Barbara Wexler

Dialysis technology

Definition

Dialysis technology is a highly specialized field of nephrology (care of the **kidneys**). In clinical practice settings dialysis technologists provide dialysis treatment under the supervision of a physician or **registered nurse**. The dialysis technologist is responsible for all medical devices and equipment involved in renal replacement therapies, such as reprocessing and water treatment equipment. Along with patient care and equipment operation, maintenance, and repair, dialysis technologists act to ensure regulatory compliance.

Description

Dialysis is treatment for patients with temporary or permanent kidney failure. For patients with end-stage renal disease (ESRD) dialysis is the only renal replacement therapy available other than kidney transplantation. In the United States, nearly 250,000 patients receive regular dialysis treatments to manage ESRD.

Hemodialysis, performed by dialysis technologists, is the most frequently prescribed type of dialysis in the United States. The treatment involves circulating the patient's **blood** outside of the body through an extracorporeal circuit (ECC), or dialysis circuit. Two needles are inserted into the patient's vein, or access site, and are attached to the ECC, which consists of plastic blood tubing, a filter known as a dialyzer (artificial kidney), and a dialysis machine that monitors and maintains blood flow and administers dialysate. Dialysate is a chemical bath that is used to draw waste products out of the blood.

Dialysis technology involves health care workers with a variety of job titles—dialysis technologist, hemodialysis technician, renal dialysis technician, clinical nephrology technologist. All of these allied health professionals are trained to provide direct patient care to people who must undergo hemodialysis because their kidneys no longer adequately rid their bodies of waste products. Dialysis technologists assess patients' **vital signs** prior to dialysis, perform dialysis, monitor patients during and after treatment, and document clinical findings. They administer drugs, including local anesthetics, and are trained to provide emergency medical intervention such as administering oxygen or performing **cardiopulmonary resuscitation (CPR)**.

Dialysis technologists also are responsible for ensuring the proper functioning of dialysis machines; in some settings they perform routine equipment maintenance and repairs. Dialysis technologists are often involved in **patient education**, instructing patients and families about in-home dialysis treatment and reinforcing the importance of adherence to prescribed treatment.

Work settings

Dialysis technologists may work in hospitals, outpatient clinics, or freestanding dialysis centers. Work environments must be scrupulously clean and well maintained to prevent **infection** of patients and health care workers. In the work setting, there must be strict adherence to safety standards since dialysis technologists routinely handle dangerous chemicals during the course of performing their responsibilities.

Education and training

Dialysis technologist trainees generally require at least a high school diploma; in some states, prior patient care experience and/or college course work in health sciences may be required. The areas of study addressed during course work may include:

- hazard communications and safety; specific risks of peracetic acid solution

- prevention of occupational injuries
- power failure/manual dialysis
- managing chemical agents and chemical emergencies
- water safety, testing, treatment
- monitoring dialysis patients; dialysis process
- pathophysiology of kidney and **urinary system**; hypo/hyperkalemia
- machine preparation and operation
- medication, documentation, and quality assurance

Since 1996, the National Nephrology Technology Certification Organization (NNCO) has offered certification examinations for nephrology clinical technicians and nephrology biomedical technicians. To take the NNCO certification examination, candidates must have a high school diploma or its equivalent, and at least one year or 2,000 hours of experience in nephrology technology or they must have completed a year-long educational program in nephrology technology. The certification exam in biomedical nephrology technology measures candidates' knowledge in the following areas:

- principles of dialysis
- scientific concepts
- electronic applications
- water treatment
- equipment functions
- environmental/regulatory issues

Candidates who pass the national certification examination in clinical nephrology technology may use the designation CCNT after their names. Those who pass the certification examination in biomedical nephrology technology use the designation CBNT after their names. To retain certification, candidates must retake the examination every four years or meet alternative certification requirements. State licensure requirements vary, however, most states require from 15–35 hours of continuing medical education annually.

Advanced education and training

Dialysis technologists can advance from trainee positions to chief technologist posts at major medical centers. Some dialysis technologists participate in clinical research and teaching. Others work closely with biomedical engineers to improve hydraulic and electrical systems used in dialysis equipment. Some medical facilities encourage dialysis technologists to continue their education and advance to become licensed vocational nurses, registered nurses, or other specialized health care therapists or practitioners.

KEY TERMS

Dialysate—A chemical bath used in dialysis to draw fluids and toxins out of the bloodstream and supply electrolytes and other chemicals to the bloodstream.

Dialysis prescription—The general parameters of dialysis treatment that vary according to each patient's individual needs. Treatment length, type of dialyzer and dialysate used, and rate of ultrafiltration are all part of the dialysis prescription.

Dialyzer—An artificial kidney usually composed of hollow fiber that is used in hemodialysis to eliminate waste products from the blood and remove excess fluids from the bloodstream.

Erythropoietin—A hormone produced by the kidneys that stimulates the production of red blood cells by bone marrow.

ESRD—End-stage renal disease; chronic or permanent kidney failure.

Extracorporeal circuit (ECC)—The path the hemodialysis patient's blood takes outside of the body. It typically consists of plastic tubing, a hemodialysis machine, and a dialyzer.

Future outlook

Throughout the United States, the employment prospects for dialysis technologists are excellent. The number of patients on dialysis continues to increase, and the average duration (the length of time patients remain on dialysis) is also increasing. Advances in medical technology, the increasing prevalence of end stage renal disease (ESRD), and the aging population all point to an increasing need for renal care practitioners, especially dialysis workers. For example, according to the California Labor Market Information Division, in the state of California, projected growth in opportunities between 1990–2005 is 42%.

Barbara Wexler

Diarrhea

Definition

Diarrhea is an increased frequency of stools or bowel movements (more than two or three per day) or liquidity of feces.

Description

In a normal adult, about 10 quarts (liters) of fluid waste leaves the **stomach** each day. All but a liter and a half is absorbed in the **small intestine**. The unabsorbed contents enter the large bowel or colon. Most of the fluid in the feces is reabsorbed by the **large intestine**. The fluid loss is about 100 milliliters each day. From a strictly medical perspective, diarrhea is defined as stool weight of more than 250 grams in 24 hours. In practice, the calculation of stool weights is restricted to persons with chronic diarrhea.

There are three broad classes that encompass most cases of diarrhea.

- Non-inflammatory diarrhea. This is described as a watery, non-bloody bowel movement that is associated with diffuse abdominal cramping, nausea, vomiting or bloating. The most common cause of non-inflammatory

diarrhea is a bacterium that produces a toxin. Common examples of non-inflammatory **bacteria** include *Escherichia coli*, *Staphylococcus aureus*, *Bacillus cereus* and *Clostridium perfringens*. Some **viruses** and amoeba such as *Giardia lamblia* also cause non-inflammatory diarrhea. This diarrhea is typically mild but may be voluminous, involving large amounts of fluid (10 to 200 mL/kg/day). Such fluid loss results in **dehydration** and loss of electrolytes. There is usually no **blood** loss.

- Inflammatory diarrhea. This is usually characterized by the presence of **fever** and blood in the stool and is associated with left lower quadrant cramps, urgency and tenesmus (anal spasms). Common causes of inflammatory diarrhea include **infection** with *Campylobacter* or *Yersinia* species or infection with some species of *Escherichia coli*. Diarrhea due to these pathogens tends to be less voluminous, less than 1 liter per day.
- Enteric fever. This is characterized by abdominal tenderness, confusion, prolonged high fever, prostration and occasionally a rash. Common causes of enteric fever-related diarrhea include *Salmonella typhi* or *Salmonella paratyphi*. Multi-organ disease is frequently encountered.

Inflammatory diarrhea must be distinguished from ulcerative colitis.

Non-professionals may use the term diarrhea in reference to increased incidence of bowel movements, a sense of fecal urgency, increased stool liquidity or **fecal incontinence**.

Causes and symptoms

Many cases of non-inflammatory diarrhea are caused by the organisms listed in the description section. The symptoms of diarrhea include nausea, weakness and dehydration. After more than three of four episodes of diarrhea, lethargy develops. Occasionally, diffuse abdominal cramping is experienced.

Inflammatory diarrhea is characterized by fever, nausea, sweating (diaphoresis) and lower abdominal tenderness and cramping. Tenesmus is common but not always present. Weakness and dehydration are often present. Lethargy develops after three or four episodes of diarrhea.

Diarrhea that is associated with enteric illness will be accompanied by prolonged high fever, confusion, prostration, respiratory distress and abdominal tenderness. Organisms that cause diarrhea have been described.

In babies and young children, dehydration is a significant problem that must be rapidly corrected to avoid

severe consequences. Lethargy may be the most prominent symptom in these children.

In cases of chronic diarrhea, anemia may be present due to blood loss. Fatigue and lethargy are the most common observable symptoms. Laboratory tests can be used to confirm anemia due to blood loss. The same persons should be tested for ova and parasites in the stool.

Diagnosis

The causative agent of diarrhea may be recovered from a stool sample. Once recovered, it is grown in a laboratory, using standard culture techniques and procedures. Among persons with dysentery, the rate of positive identification of agents using bacterial culture is 60 to 75%. Persons with a recent history of possible exposure to amoeba, whether through travel or from sexual preference, should have a wet mount examination of stool for amoeba.

Laboratories should be alerted to the possibility of exposure to *E. coli* if exposure to improperly prepared food is suspected.

Stool should be examined for ova and parasites in persons with diarrhea that persists for more than 10 days. Three such examinations for ova and parasites should be performed.

Rectal swabs should be considered for persons suspected of having *Neisseria gonorrhoeae*, *Chlamydia* or herpes simplex virus.

Sigmoidoscopy should be considered for persons with severe rectal **pain**, tenesmus or rectal discharge. Sigmoidoscopy is often useful for differentiating infective diarrhea from ischemic or ulcerative colitis.

Treatment

There are four main elements of treatment: rehydration, diet, antidiarrheal agents, and antibiotic therapy.

Rehydration

Drinking fluids such as tea, sport drinks, fruit juices and some mildly carbonated beverages, augmented with water, will rapidly replace fluid lost through diarrhea. Fluids should be consumed as rapidly as affected persons will tolerate them. Experts recommend fluid intake levels of 50-200 mL/kg/day. Severely dehydrated individuals may require hospitalization and intravenous fluid therapy with lactated Ringer's solution. Persons who do not require hospitalization can make a similar solution that can be taken orally at home. Combine the following:

- 0.5 teaspoon salt

- 1.0 teaspoon baking soda
- 8 teaspoons water
- 8 ounces orange juice
- water to equal 1 quart

Diet

If persons with diarrhea consume adequate **carbohydrates** and fluids, most will avoid dehydration. Fluids that contain electrolytes are especially useful. Broth-based soups with crackers, sport drinks and some soft drinks contain salt, potassium, sugar and bicarbonate. These substances are lost with diarrhea. The bowel should not be stressed during recovery from diarrhea. This can be accomplished by avoiding foods that are high in fiber, fatty foods, milk and dairy foods, alcohol and **caffeine**. Eating relatively small meals on a frequent basis is helpful. Tea and fruit juices provide nourishment without stressing the **digestive system**.

Antidiarrheal agents

Persons with mild to moderate diarrhea usually benefit from antidiarrheal preparations. If diarrhea does not subside or worsens with the use of such agents, they should be discontinued and competent medical assistance sought. Preparations containing opioids (such as loperamide) should not be used by persons with bloody diarrhea or high fevers. In others, they will decrease stool liquidity, quantity and tenesmus. The following preparations are generally useful:

- bismuth subsalicylate (Pepto-Bismol)
- loperamide (Imodium AD)

Antibiotic therapy

For the majority of persons with diarrhea, the condition is self-limiting. As such, antibiotic therapy is not indicated. For persons with moderate to severe diarrhea, antibiotic therapy may be helpful. Symptoms of bloody stools, fever and tenesmus are indications for the use of an antibiotic. The following are often used while awaiting the results of a **stool culture**. Because they are used without accurately identifying a causative agent for the diarrhea, their use is characterized as empirical.

- a fluoroquinolone such as ciprofloxacin
- erythromycin
- trimethoprim/sulfamethoxazole

Antibiotics are indicated for persons with so-called traveler's diarrhea or for diarrhea that is caused by cholera, shigellosis or salmonellosis.

Prognosis

Most cases of diarrhea are self limiting. Once the causative agent or toxin is discharged with the fecal flow, recovery can begin. Over 90% of persons with acute diarrhea will recover fully with adequate rehydration or the use of antidiarrheal agents. Laboratory determination of the cause in such instances is infrequently required. The cost is not justified. Laboratories identify approximately 3% of causative agents from stool cultures.

Laboratories will frequently examine stool samples for the presence of blood to differentiate inflammatory and non-inflammatory causes of diarrhea. After a diagnosis of inflammatory diarrhea has been made, stool cultures are needed to determine appropriate antimicrobial therapy.

Hospitalization for diarrhea is uncommon but warranted for severe diarrhea. Babies and older persons are at increased risk for adverse outcomes, including death, from diarrhea.

Each day, more than 1,700 babies around the world die from diarrheal diseases. Most of these are due to a lack of potable drinking water. With adequate hydration using non-contaminated water, most of these deaths could be prevented. Without clean drinking water, their prognosis is often poor.

Health care team roles

Diarrhea is usually diagnosed by someone other than a professional member of a health care team. Treatment is often provided by the same person. When professional advice is sought, a family physician, internist, pediatrician, physician's assistant or nurse practitioner is most likely to be consulted. A laboratory technician may process stool samples and identify a causative agent. In unusual circumstances, a pathologist may be called upon to identify a causative pathogen. A specialist in infectious diseases may provide assistance. Epidemiologists and sanitarians have an interest in diarrhea outbreaks or clusters of cases. Health officers may be called upon to take preventive measures if food sources, public restaurants or day care centers are shown to be the causes of a diarrhea outbreak.

Prevention

Handwashing and personal hygiene are critical methods for preventing diarrhea. Adequate handwashing alone will prevent a majority of diarrhea cases.

Adequate sanitation and attention to cleanliness are the best ways to prevent outbreaks of diarrhea disease. Persons handling food must always wash their hands

KEY TERMS

Diaphoresis—An alternative for sweating.

Incontinence—The inability to voluntarily control elimination of bodily wastes.

Inflammation—A physiological response to stress on the body that is characterized by redness, tenderness, increased temperature, swelling and decrease or loss of function.

Ova—Eggs.

Sigmoidoscopy—Procedure to visualize the interior of the colon. A flexible tube is inserted in the anus. An operator looks into the colon that is illuminated by a light at the end of the tube.

Stool—An alternative name for feces.

Tenesmus—A feeling that a bowel movement is imminent.

before touching any food. Food, especially poultry and shellfish, must be stored at appropriate temperatures and thoroughly washed before being prepared for consumption.

Food must be properly prepared and held or stored at proper temperatures. Prior to cooking, foods should be kept at temperatures below 40°F (4.4°C). During cooking, the internal temperature of foods should exceed 160°F (71°C) to ensure the destruction of pathogens. While being served, food should be held at temperatures between 40 and 140°F (4.4 and 60°C). The total time that food should be allowed to remain within these temperatures is four hours. After four hours total time, including original serving and subsequent reheating, the food should be discarded. Foods that contain eggs such as mayonnaise and salads should be kept cold and protected from heat and sunlight.

Day care facilities must be constantly cleaned and disinfected. Employees who change diapers must wash their hands before returning to work.

Persons should drink only potable water. Water that is used for washing dishes or personal uses such as tooth brushing should also be boiled before use if the source of the water is not assured to be potable and safe.

Diet and health

Definition

Diet has a tremendous effect on health. Diet plays a role in promoting health and reducing chronic disease for many conditions such as preventing **obesity**, **diabetes mellitus**, coronary **heart** disease, and **cancer**, as well as low birth weight in babies.

Description

The concept of diet quality in relation to health has changed over time. **Nutrition** scientists focused on preventing nutrient deficiencies early in this century, but now the shift has changed, exploring diets and chronic disease prevention and treatment. Adequate nutrition is essential to reduce morbidity and mortality from acute and chronic disease. Well-nourished people are more resistant to disease and are better able to tolerate other therapy and to recover from acute illnesses, surgery, and trauma. Nutrition also plays a key part in a patient's recovery from a disease or treatment.

Consumption of a wide variety of foods, with appropriate amounts of protein, carbohydrate, fat, **vitamins** and **minerals** is the basis of a healthy diet. However, today's major health care problems are increasingly the result of acute and chronic conditions related to dietary intake. In fact, eight of the 10 leading causes of death, including coronary heart disease, stroke, diabetes mellitus, and some cancers, can be attributed to diet and alcohol. Some chronic diseases continue to increase due to factors such as the rise in obesity in Western populations, Americans in particular.

There is no disputing that a healthy diet can help to prevent illness and promotes a feeling of well-being. A research study reported in the *Journal of the American Medical Association* suggested that by following the current dietary guidelines, women are able to live longer. Women whose diets included large amounts of fruits, vegetables, whole grains, low-fat dairy, and lean meats had a lower risk of death. Women who were considered to have the best diets (those eating the highest intake level of recommended foods from the current dietary guidelines) had a 30% lower risk of death from any cause compared with those eating the lowest level of recommended foods.

Viewpoints

The position of the American **Dietetics** Association on the role of nutrition and diet in health promotion and disease prevention programs includes steps for primary, secondary, and tertiary prevention. These steps include the following guidelines:

- **Primary prevention (health promotion):** Health promotion is a population-based approach that encourages behaviors for better health. For example, nutrition classes at a local adult education center could be considered a primary prevention measure.
- **Secondary prevention (risk appraisal and risk reduction):** For people at risk of illness who are beginning to encounter health-related problems, secondary prevention encompasses risk appraisal and screening to detect preclinical disease, and early intervention to promote health and well-being. For example, cholesterol screening for people with a family history of cardiovascular disease could be considered a secondary prevention measure.
- **Tertiary prevention (treatment and rehabilitation):** For people experiencing illness or injury, tertiary prevention includes treatment and rehabilitation to promote maximum health and prevent further disability and secondary conditions resulting from the initial health problem. Examples of tertiary prevention include **medical**

nutrition therapy or diabetes education for people diagnosed with type 2 diabetes mellitus.

Experts in nutrition recommend a variety of foods and the maintenance of an ideal weight. Large amounts of fat, saturated fat, and cholesterol should be avoided. Individuals should consume adequate starch and fiber and avoid excess sugar and sodium.

Dietary guidelines

The Dietary Guidelines for Americans, published by the U.S. Department of Agriculture and Health and Human Services, can provide a broad overall view of good nutrition. These dietary guidelines include these basic recommendations:

- Eat a variety of foods; let the food pyramid guide your food choices.
- Control your weight.
- Be physically active each day.
- Eat a diet low in saturated fat and cholesterol, and moderate in total fat.
- Eat a variety of vegetables, fruits, and grains.
- Eat sugar in moderation.
- Use salt in moderation.
- If you drink alcohol, do so in moderation; no more than two drinks per day of wine, beer, or spirits.
- Keep food safe to eat; follow the government safety precautions as outlined on the food package.

The Food Guide Pyramid was created by the U.S. Department of Agriculture to help Americans choose foods from each food grouping. It focuses on fat intake, which is too high in most Americans. The food pyramid, developed by nutritionists, provides a visual guide to healthy eating. At its base are those foods that should be eaten numerous times each day, while at its apex are those foods that should be used sparingly. The pyramid suggests a range of servings in each group so that the number of servings can be adjusted to suit each individual's caloric requirements. The daily recommendations (from bottom to top) of the food pyramid include:

- bread, cereal, rice, and pasta: 6–11 servings
- vegetables: 3–5 servings
- fruits: 2–4 servings
- milk, yogurt, and cheese: 2–3 servings
- meat, poultry, fish, dried beans, eggs, and nuts: 2–3 servings
- **fats**, oils, and sweets: use sparingly

Other programs use the *National Cholesterol Education Program Step 1 Diet* guidelines, which may be followed to assist in controlling weight. The guidelines provided by the National Cholesterol Education Program can be followed for maintaining optimal **blood** lipid levels [total cholesterol, low-density lipoproteins (LDL), high-density lipoproteins (HDL), and triglycerides]. Health promotion and disease prevention are central components of national recommendations to improve the health of Americans in an initiative called *Healthy People 2000*. This program is a series of national health promotion and disease prevention objectives that examine the association between nutrition and chronic disease. A program called Healthy People 2010 is planned.

National and international trends

Major diet and health targets in the United States include:

- **Obesity.** Obesity has become a major problem for Americans due to inactive lifestyles and poor diets. Estimates suggest that over 50% of Americans are overweight. Dietary modification can reduce obesity, in turn decreasing conditions and diseases such as coronary heart disease, atherosclerosis, **hypertension**, cancer, diabetes, and high blood cholesterol.
- **Diabetes.** Since 1990, type 2 diabetes has jumped by 33% nationwide in the United States. Being overweight and contracting diabetes are closely linked.
- **Fat and cholesterol intakes.** These are still too high. Since the 1960s, the average blood cholesterol level has decreased, mostly due to a shift from red meat to poultry, from whole to lower-fat milk, and from butter and lard to margarine and vegetable oils. Cholesterol has dropped to about an average of 205 mg/dl from the peak of the coronary epidemic in the 1960s of 220 to 230 mg/dl. Intake of saturated fat was about 16% in the 1960s; it has now been reduced to approximately 12%. Fat intake is still too high. It is estimated that the average American consumes about 40% of their calories from fat. Fat source (i.e. saturated, monounsaturated, or polyunsaturated) is an important issue to consider when reducing overall fat in the diet, as some fats reduce cholesterol while others raise cholesterol.
- **Stroke incidence.** Stroke incidence and related deaths have dropped in the last 30 to 40 years, likely due to better **blood pressure** control, less smoking and drinking, and possibly an increase in fruits and vegetable consumption.
- **Lack of exercise.** Energy expenditure has declined due to more sedentary lifestyles. Those who sit at a com-

puter all day expend fewer calories than in physical-labor jobs.

- *“Fad” and herbal diets.* Throughout the 1990s and into this century, the market for dietary supplements and herbal remedies has exploded. The nutritional implications of many of these compounds has not been established with scientific research, and therefore the health implications are unknown in many cases.
- *Health supplements.* There are a great many claims about particular vitamins, minerals, and/or antioxidants having beneficial health effects on the market today. Proper nutrition with an adequate diet is the best way to achieve vitamins, but a supplement may be required when intake is inadequate. It is important to check with a dietitian or doctor before taking nutritional supplements or alternative therapies if other medications are taken for chronic illness, because they may cause a drug interaction.

Dietary recommendations in Europe and Australasia are comparable with those in the United States. The European guidelines suggest, as do those in the United States, that total fat should provide 30% or less total energy, which implies that complex **carbohydrates**, fruits, cereals, and vegetables should be increased to replace the foods rich in total and saturated fat which have been eliminated. The European Atherosclerosis Society states that for those with total cholesterol levels of 200-250 mg/dl (5.2-6.5 mmol/L), dietary modification to reduce the risk of coronary heart disease (CHD) is required. While CHD incidence is declining in western Europe, Australia, and the United States, it is rapidly rising in central and eastern Europe and in some Asian countries. These regions are undergoing unprecedented economic growth and rapidly changing lifestyles in many aspects including dietary intake. These changes have led to an increase in CHD incidence and death. Singapore, the most economically developed country in Asia, also has the highest prevalence of CHD deaths, at rates similar to those of the United States and Australia. This region may serve as a warning that Asia may expect an escalation in CHD. Although cholesterol levels vary widely over Asia, CHD mortality is evidenced where cholesterol levels have increased from previously low levels and in regions where the highest cholesterol levels predominate. Australasian (National Heart Foundation of New Zealand Scientific Committee and the National Heart Foundation of Australia) and European (British Hyperlipidaemia Association, British Hypertension Society) guidelines for the prevention of CHD in clinical practice emphasize the need to determine the absolute CHD risk for any individual in order to decide the most appropriate therapy. This, of course, includes

dietary management to control fat intake and cholesterol. Clearer statements and guidelines on the prevention and control of diabetes and hypertension as well as diet, obesity, **exercise**, and smoking may be appropriate.

Professional implications

Qualified dietetics professionals assist in encouraging good nutrition and/or dietary change as a method of promoting health and preventing chronic disease. Nursing and allied health professionals can reinforce good dietary choices and provide nutrition guidance for patients in hospitals, long-term care facilities, or in community settings.

In general, only registered dietitians (R.D.) have sufficient training and knowledge to accurately assess the nutritional adequacy of a patient's diet, especially if chronic disease is present. A doctor may also have a nutrition background or specialization and may thus be able to conduct a **dietary assessment** or to provide general nutrition advice and/or **diet therapy**.

When an individual or patient is using dietary means to help recover or control a disease or condition, it is often called medical nutritional therapy. To maintain health in a patient with a nutrition-related illness, all health care team members and especially the patient must commit to achieving optimum health through medical nutritional therapy. Prioritized goals are critical when developing the nutrition treatment plan. Continuous assessment is made by the patient and health care team members to evaluate the importance of these and other goals. Physicians must understand the dietary approaches an individual is using and reinforce this diet therapy when interacting with the individual. The position of the American Dietetic Association is that medical nutritional therapy is effective in treating disease and preventing disease complications.

Diet therapy

Definition

Diet therapies are specially designed and prescribed for medical and/or general nutritional reasons.

Purpose

Diet therapy promotes a balanced selection of foods vital for good health. By combining foods appropriate for each individual and drinking the proper amount of water, one can help maintain the best possible health. Eating the proper diet is critical for the health of individuals, groups with special medical and dietary needs, and entire populations afflicted with malnutrition.

Precautions

A particular modified diet is prescribed specifically for each individual. Those individuals who have medical conditions or who are sensitive to certain foods need to be very compliant and cautious about what they eat.

Individuals should not follow a "fad" diet without first consulting a registered dietitian or physician. Popular (but sometimes dangerous) low-carbohydrate diets, for example, may deprive the body of the glucose it needs for **central nervous system** and **brain** functions.

Description

Nutrition is the science concerned with the human body's use of nutrients and food substances. Proper nutrition decisions are important for the optimal health of each individual. This is especially true for those individuals with specific dietary needs and acute or chronic diseases. The nutrients necessary to maintain normal growth and health include **proteins, carbohydrates, fats, vitamins, and minerals**. Included in these nutrients are eight amino acids the body cannot produce but that must be derived from proteins, four fat-soluble and ten water-soluble vitamins, ten minerals, and three electrolytes.

Nutrient classes

PROTEIN. Protein is important for building body tissue and synthesizing enzymes. Enzymes are specialized organic substances that act to regulate the speed of chemical reactions in human **metabolism**. Twenty amino acids of the 100 or more occurring in nature make up proteins. Animals and plants are quick and available sources of what are termed “essential” amino acids; they are called essential because the body cannot build them internally. Normal growth and health are dependent upon these essential amino acids. Dietitians recommend that a healthy diet includes 10–20% of daily calories from protein (poultry, fish, dairy, and vegetable sources).

CARBOHYDRATES. Carbohydrates provide most of the energy in the majority of human diets. Foods rich in carbohydrates are usually the most abundant and cheapest. The carbohydrates containing the most nutrients are the complex carbohydrates, such as unrefined grains, tubers, vegetables, and fruits. Simple carbohydrates or sugars should be eaten in moderation, since they are high in calories but low in nutrients.

Carbohydrates are needed in the form of glucose by the brain and central nervous system (CNS). A minimum of 1.6 oz (50 g) of glucose is required daily for proper functioning of the CNS. If the body is denied carbohydrates, it will use ketone bodies for energy, but this is not a good energy source for the body, and may have unfavorable health effects.

FATS. Fats supply energy and essential fatty acids and promote absorption of the fat-soluble vitamins A, D, E, and K. The accumulation of body fat has become a serious health concern; over 50% of Americans are considered overweight. Fats are compact fuels efficiently stored in the body for later use when carbohydrates are in short supply. Fats produce more than twice as much energy as carbohydrates, approximately 9 Kcals/gram versus about 4 Kcals/gram for carbohydrate and protein. Dietary fats are broken down into fatty acids that pass into the **blood**. These fatty acids are either saturated or unsaturated (mono-unsaturated, polyunsaturated, or trans-unsaturated). Saturated fats, derived mostly from animal sources, have been found to raise the level of total cholesterol in the bloodstream, and certain unsaturated fats tend to lower the level of total cholesterol in the blood stream. For example, mono-unsaturated fats like oleic acid in olive oil reduce low-density lipoprotein cholesterol (bad cholesterol) and increase high-density lipoprotein cholesterol (good cholesterol), thus reducing the risk of **heart** disease. Saturated and trans-unsaturated fatty acids both raise serum cholesterol; in contrast, neither mono-unsaturated nor polyunsaturated fats have this effect.

INORGANIC MINERAL NUTRIENTS. Inorganic mineral nutrients are required to build tissues. They are also important for muscle contractions, nerve reactions, and blood clotting. All of these mineral nutrients must be supplied in the diet. Minerals are categorized as major elements or trace elements. Major elements consist of **calcium**, **phosphorus**, magnesium, **iron**, iodine, and potassium. Trace elements include **copper**, cobalt, manganese, fluorine, and **zinc**.

VITAMINS. Vitamins increase the breakdown and absorption of proteins, carbohydrates, and fats. Certain vitamins help form blood cells, hormones, nervous system chemicals, and genetic materials. Vitamins are classified into two groups: fat-soluble vitamins, such as A, D, E, and K; and water-soluble vitamins, such as **vitamin C** and the B-vitamin complex. Fat-soluble vitamins are usually found in foods that contain fat. Because excess amounts are stored in the body’s fat and in the **liver** and **kidneys**, fat-soluble vitamins do not have to be consumed every day. The water-soluble vitamins, C and B complex, cannot be stored and must be consumed daily to replenish the body’s supply.

Food types

Foods can be widely grouped into breads and cereals; legumes, tubers or starchy roots; vegetables and fruits; meat, fish, and eggs; milk and milk products; fats and oils; and sugars. Breads and cereals are high in starches (carbohydrates), but whole cereals also often supply significant amounts of protein. However, these cereals should be eaten in conjunction with other protein foods to supply all the essential amino acids. Meat, fish, and eggs supply all the essential amino acids that the body needs to build its own proteins.

Milk and milk products also provide a plentiful amount of protein, phosphorus, calcium, and vitamins. Legumes are rich in starch but also furnish more protein than cereals or tubers. Tubers provide a variety of minerals and vitamins. Vegetables and fruits are a direct source of many minerals and vitamins. Fats and oils are high in calories but usually contain few nutrients. Sugars, which are heavily consumed in more affluent countries, contain few nutrients and can cause tooth decay.

Dietary guidelines

The Food and Nutrition Board of the National Research Council of the National Academy of Sciences has determined dietary standards called Recommended Dietary Allowances (RDA). These standards explain the daily amounts of energy, protein, minerals, and fat-soluble and water-soluble vitamins needed by healthy males and females, from infancy to old age. The RDA has been

under revision and is replaced by the Dietary Reference Intakes (DRI) as of 2001. The DRI will be applicable to Canadians and Americans. Like the RDA, the DRI recommends an average daily intake for a nutrient, but the DRI is more comprehensive than the RDA. It incorporates updated scientific research into providing expert guidance for issues such as risk reduction for chronic disease and upper limits of intake for nutrients with adverse health effects.

Experts in nutrition recommend a variety of foods and the maintenance of an ideal weight. Large amounts of fat, saturated fat, and cholesterol should be avoided. Individuals should consume adequate starch and fiber and avoid excess sugar and sodium.

The U.S. Department of Agriculture and the U.S. Department of Health and Human Services have developed official dietary guidelines that include these seven basic recommendations:

- Eat a variety of foods.
- Control your weight.
- Eat a low-fat, low-cholesterol diet.
- Eat plenty of vegetables, fruits, and grains.
- Eat sugar in moderation.
- Use salt in moderation.
- If you drink alcohol, do so in moderation; no more than 2 drinks per day of wine, beer, or spirits.

The food pyramid, developed by nutritionists, provides a visual guide to healthy eating. At its base are those foods that should be eaten numerous times each day, while at its apex are those foods that should be used sparingly. The pyramid suggests a range of servings in each group so that the number of servings can be adjusted to suit each individual's caloric requirements. The daily recommendations (from bottom to top) of the food pyramid include:

- bread, cereal, rice, and pasta: 6–11 servings
- vegetables: 3–5 servings
- fruits: 2–4 servings
- milk, yogurt, and cheese: 2–3 servings
- meat, poultry, fish, dried beans, eggs, and nuts: 2–3 servings
- fats, oils, and sweets: use sparingly

Energy requirements

Carbohydrates, proteins, and fats provide energy in the form of calories to fuel the body for metabolic processes, growth, and activity. When an individual consumes as many calories each day as the body uses, they

are in a state of energy balance and will neither gain nor lose weight. When more calories are eaten than the body uses, the excess calories are stored as fat and weight increases. On the other hand, when fewer calories are consumed than the body needs, stored fat is burned and weight decreases. Using the metric system nomenclature, a kilojoule (kJ) is used instead of a kilocalorie (kcal), where 1 kcal=4.184 kJ and 1 megajoule (MJ)=1000 kJ.

The amount of energy required depends on such factors as an individual's weight, gender, age, and activity level, so an estimation should be made based on these parameters. Some dietary guidelines do suggest an average energy intake for people in different age groups, but many of the guidelines do not base the estimations on measures such as activity level. The Food and Agriculture Organization/World Health Organization uses a more accurate method for estimating energy requirements for populations and individuals. They define energy requirement as "... the amount of energy needed to maintain health, growth, and an appropriate level of physical activity." The "appropriate level of physical activity" is not a standardized level, but is dependent on social, cultural, and lifestyle factors. Physical activity categories for light, moderate activity or heavy work are used to provide a better energy estimation. For example, a 143 lb (65 kg) woman between the ages of 30-60 years who participates in light activity would require about 2190 kcal/day (9.2 MJ/day). At a moderate activity level, this same woman would require approximately 2300 kcal/day (9.6 MJ/day) and 2550 kcal/day (10.7 MJ/day) for heavy activity.

Calorie-modified diet

Calorie-modified diets are prescribed to correct weight problems with a healthy diet. Low-calorie diets are designed for weight reduction and are prescribed for people who are overweight or obese. High-calorie diets are recommended for people with greatly increased energy needs such as athletes in training or individuals fighting diseases such as **cancer**, **AIDS**, or **cystic fibrosis**. High-calorie diets are also prescribed to treat anorexia nervosa.

Calorie-modified diets are planned by dietitians and should be prescribed following a complete **physical examination** and **dietary assessment** or dietary history. A low-calorie diet provides enough energy to meet the person's metabolic needs and activity level. It includes a balanced variety of foods, but limits carbohydrates and alcohol. A low-calorie diet should not aim to promote a weight loss of more than approximately 1–2 lb (500 grams to one kilogram) per week. In general, for a slightly overweight person, it is not wise to lose more than 1 lb (about 500 grams) per week. A high-calorie diet usually

provides an extra 500–1,000 calories, leading to a weight gain of about 1 lb (500 grams) per week for most people. It has a high protein content, normal fat content, and emphasizes foods that pack many calories into a small volume. Snacking between meals is encouraged as a way to increase the calories consumed.

When caloric limits allow, have no more than two drinks of wine, beer or liquor per day.

Fiber-modified diet

Fruits and vegetables are excellent sources of fiber. Fiber has important nutritional benefits such as facilitating the movement of food through the digestive tract, helping to prevent constipation. Research suggests low dietary fiber may be responsible for increasing the incidence of diverticulosis and may also be associated with cancer of the colon.

High-fiber diets, including whole grains (especially bran), raw vegetables, unpeeled fresh fruits, nuts, and seeds, are recommended to:

- increase fecal bulk
- increase intestinal movement
- prevent or treat constipation, diverticulosis, **Crohn's disease**, or irritable bowel syndrome
- help lower cholesterol
- assist with weight loss in people who are overweight and improve sugar tolerance in diabetics

Low-fiber diets exclude raw fruits and vegetables, whole grains, nuts, and seeds, while emphasizing soft, mild foods. They are recommended to:

- decrease fecal bulk
- slow intestinal movement
- decrease **stomach** acid secretion
- treat a variety of disorders including indigestion, **diarrhea**, bowel inflammation, and heart attack

Protein-modified diet

High-protein diets are designed to provide about 0.05 oz (1.5 g) of protein for each kilogram of a person's body weight. Complex proteins, such as milk and meats, should make up one-half to two-thirds of the daily protein requirement. High-protein diets are recommended for people who:

- have an increased need for protein due to protein-calorie malnutrition, severe **stress**, or conditions such as AIDS, cancer, or **burns** with high metabolic rates that lead to the loss of large amounts of protein

- have malabsorption syndromes, celiac disease, or other disorders characterized by poor food absorption

A low-protein diet excludes dairy products and meats, and requires that about three-fourths of the daily allowance of protein come from high-value protein sources. Supplements may be prescribed to prevent amino acid deficiencies. Low-protein diets are used in treatment of cirrhosis and kidney disease.

Low-cholesterol diet

Dietary modification is the first weapon in the fight against the high cholesterol levels that contribute to heart disease and atherosclerosis. Low-cholesterol diets are prescribed to reduce the risk of heart disease and to treat atherosclerosis, diabetes, high cholesterol (which may be hereditary and might also require cholesterol-reducing drugs), and high **blood pressure**. A low-cholesterol diet is not a cure for the conditions it is prescribed to treat, so most people must stay on the diet for the rest of their lives.

The American Heart Association eating plan recommends that total cholesterol intake should be less than 0.01 oz (300 mg) per day and total fat intake should be 30% or less of total calories. Saturated fatty acid intake should be less than 10% of calories or for anyone with elevated blood cholesterol levels or heart disease, saturated fat and cholesterol intake is limited even further to 7% of total calories per day.

The AHA eating plan also suggests:

- Polyunsaturated fatty acid intake should be 8–10% of calories.
- Mono-unsaturated fatty acids should make up the rest of the total fat intake, up to 15% of total calories.

These guidelines apply to all healthy individuals over two years of age.

Low-fat diet

Most American diets contain too much fat. Fat often makes up about 40% of total calories consumed each day. Registered dietitians recommend limiting fat to 30% or less of daily calories, since consumption of too much fat has been linked to **obesity**, heart disease, and several types of cancer. A low-fat diet usually limits daily fat intake to 1.76 oz (50 g), while an extremely low-fat diet limits fat consumed each day to 0.88–1.05 oz (25–30 g). The grams of fat in your diet will depend on the calories you need. Low-fat diets are recommended to:

- help prevent heart disease
- help prevent colon, prostate, and breast cancers

- help treat a variety of conditions including **gout**, AIDS, **gallbladder** disease, liver disease, celiac disease, inflammatory bowel disease, and heartburn
- lose or control weight

Some fat is required in the diet to prevent essential fatty acid deficiencies, but most people consume more than enough fat to meet these needs.

Cutting back on fat will likely help you eat fewer calories. Make sure to read the nutrition facts label on foods. The Dietary Guidelines recommend limiting fat intake to 30% of calories or less, which corresponds to 1.87 oz (53 g) of fat in a 1,600 kcal diet, 2.57 oz (73 g) of fat in a 2,200 kcal diet, and 3.28 oz (93 g) of fat in a 2,800 kcal diet.

Gluten-free diet

Gluten and gliadin are proteins found in certain grains and grain-containing products. These proteins are toxic to cells within the intestinal tract of an individual who is “intolerant” and cause difficulty in food absorption. Celiac disease is caused by intolerance to these proteins. This intolerance causes patients with celiac disease to suffer weight loss, diarrhea, malnutrition, and bloating. By eliminating foods containing gluten from the diet, further damage to the intestines can be prevented, symptoms are relieved, and malabsorption of nutrients is corrected. A gluten-free diet eliminates all foods containing wheat, rye, barley, and malt, and must be followed for life.

Low-purine diet

This diet restricts food, such as sardines, liver, and eggs, that cause the body to produce uric acid. It is usually prescribed as part of a treatment program for gout (a disease usually caused by having too much uric acid in the body) and **kidney stones**, which also includes **exercise** and medication. In addition to excluding organ meats (sweetbreads, liver, kidney) and certain types of fish (anchovies, sardines, mackerel) and limiting the amount of other purine-containing foods such as shrimp, meats, and dairy products, this diet emphasizes drinking about 2 qt (1.89 l) of water and fruit juice daily, to promote the excretion of uric acid, and eating fruits and vegetables that increase urine alkalinity and the solubility of uric acid.

Low-salt diet

On the average, Americans consume about 0.17 oz (5 g) of salt or sodium daily. Dietary guidelines suggest that 0.08 oz (2.4 g) of sodium should be the upper limit, even if there are no signs of heart disease. Most people

with heart disease should limit their sodium intake to less than 0.07 oz (2 g) a day, and some low-salt diets restrict sodium to as little as 0.008 oz (250 mg) per day. The amount of salt in the diet is important for people who have high blood pressure or congestive **heart failure**.

Some experts believe excessive intake of salt is a major reason for high blood pressure, especially in Western countries. Excess sodium encourages the body to retain fluid, thereby increasing fluid pumped by the heart and circulating in the bloodstream. Diets high in salt also can be harmful to people with congestive heart failure because the excess fluid backs up into the **lungs**, causing congestion.

Potassium chloride is a common ingredient in salt substitutes. But too much potassium can be harmful for people with kidney problems. One way to enhance the flavor of food while eliminating salt is to add lemon juice, herbs, spices, or flavored vinegar.

Low phenylalanine diet

A low phenylalanine diet is normal treatment for phenylketonuria (PKU). PKU is a rare genetic disorder in the degradation of dietary phenylalanine that if left untreated, can result in severe progressive mental retardation. The diet is extremely restrictive, and rigorous dietary compliance is necessary to reduce or prevent mental retardation. Close supervision by a registered dietitian or physician is necessary.

A normal diet cannot be tolerated by people with PKU. Dietary treatment necessitates avoiding foods containing high levels of protein. A diet contains only the amount of phenylalanine which is essential for the body. Basic principles of the PKU diet state that:

- Meat, fish, cheese, eggs, milk and nuts are not allowed because they are rich in protein and thus phenylalanine.
- Other foods which contain moderate amounts of protein (i.e. potato and cereals) are given in small measured quantities. These foods are spread out between the day's meals to keep the phenylalanine levels steady.
- Most fruits, some vegetables, and salads can be taken in normal quantities but excessive use should be avoided.
- Sugar, jam, syrups, and fats such as butter, lard, and cooking oil can be used fairly freely.
- There are many low protein manufactured foods available on prescription. These can all be taken freely to provide variety in the diet. Foods include pasta, low protein bread, biscuits, flour, and spaghetti, etc.
- Infants can be fed phenylalanine-free formulas.

There is a high incidence of tooth decay among individuals affected by PKU because of the increased amounts of CHOs consumed.

Diabetic diet

For the most part, dietary management is the key to keeping diabetes in check. There is controversy regarding dietary recommendations for diabetes control and at present, there is no single diet that meets the needs of all diabetics. The general rules for healthy eating as discussed previously apply to diabetics as well.

Several dietary methods are available for controlling blood sugar levels. The Food Guide Pyramid is recommended by the U.S. government for everyone including diabetics. Some experts believe these dietary guidelines may be sufficient for diabetics, although there are more detailed dietary methods available for controlling blood sugar. These methods may be complex, however, which deters many diabetics from using them. The American Diabetic Association and American Dietetic Association developed the Diabetic Exchange Lists, the most common system used for controlling blood sugar. Other nutrition experts recommend adopting a Mediterranean diet because they point out the food pyramid has some drawbacks; for example, there is little focus on meal planning. Carbohydrate counting plans may assist but may also be complicated and require a committed learner; the concepts of the Diabetic Exchange Lists may be difficult to understand for some people.

Type 1 and type 2 diabetics on insulin or oral medication must focus on controlling blood glucose levels by coordinating food intake with insulin administration or medication, or other variables such as exercise.

Nutrition habits that assist in glucose control:

- Stick to a meal plan.
- Appropriately treat hypoglycemia (low blood sugar).
- Quickly respond to hyperglycemia (high blood sugar).
- Maintain consistent snacking habits.

The recommendation given by the American Diabetes Association is to eat more starches. This is the opposite of what has been advised in past years. Current research studies now show it is healthiest for everyone to eat more grains, beans, and starchy vegetables to control fat and cholesterol. Total carbohydrate intake has greater impact on blood glucose control than the source of carbohydrate. However, consumption of complex carbohydrates (i.e. whole grain bread, beans, etc.) are better than eating foods that are sucrose (simple sugar) based.

Both weight loss and blood sugar control are particularly important for overweight type 2 diabetics who are not taking medication. Health effects are most beneficial after initial weight loss. A 10% decrease in body weight can control the progression of type 2 diabetes. Other important issues are controlling lipid (cholesterol and triglyceride) levels, and blood pressure. Controlling fat intake is important because diabetics are about twice as likely to get cardiovascular disease compared to other people.

Research shows that diabetics have the same protein requirements as other people, but with onset of nephropathy, protein should be limited to 0.8 grams/kg per day for adults, with 80% coming from high biological value protein.

Traditional diets may offer some health advantages

Certain populations have dietary habits that are much healthier than the typical Western diet, which is often too high in fat and cholesterol. Research has shown that the traditional Mediterranean diet, Japanese diet, or “hunter-gatherer” diets have health advantages. The dietary habits characteristic of Mediterranean countries with the consumption of olive oil (mono-unsaturated fatty acid) as the main fat source appear to provide optimal health benefits with a low incidence of coronary heart disease. The Mediterranean diet consists of large amounts fruit, vegetables, pulses, nuts, cereal products, and fish, while generally only small amounts of meat and dairy foods are consumed.

Preparation

Effective estimation of an individual’s diet is required in order to provide **dietary counseling** and guidance. If a dietary assessment is not conducted in preparation, using proper methodologies, it will be difficult for the dietitian to draw any conclusions regarding the need for diet therapy.

Despite the diet type, all foods should be prepared appropriately. This includes adequate cooking time and proper storage. Some diets must be phased-in gradually.

Aftercare

Regular physician follow-up is always important when the individual has been placed on a special diet because of a health condition.

One cannot live on “a diet” permanently, because strict guidelines are difficult and painstaking to follow. Therefore, dietary modifications have to be lifestyle

KEY TERMS

Calorie—Commonly referred to as a calorie, but is actually a kilocalorie (kcal). A kilocalorie is the energy required to raise the temperature of one kilogram of water one degree Celsius. It is how the energy content of food is measured.

Dietary assessment—An estimation of food and nutrients eaten over a particular time point. Some of the most common dietary assessment methods are food records, dietary recalls, food frequency questionnaires, and diet histories.

Dietitian—A dietitian is a health professional who has a bachelor's degree, specializing in foods and nutrition, and in addition undergoes a period of practical training in a hospital or community setting. Many dietitians further their knowledge by pursuing master's or doctoral degrees. The title "dietitian" is protected by law so that only qualified practitioners who have met education qualifications can use that title.

Electrolytes—Any of the various ions, such as sodium, potassium, or chloride, required by cells to regulate the electric charge and flow of water molecules across the cell membrane.

Kilojoule—In Europe and other countries, food energy values are frequently given in kilojoules (kJ), the metric unit of energy. Using the metric system nomenclature, a calorie is converted into a kilojoule (kJ), where 1 kcal=4.184 kJ and 1 megajoule (MJ)=1000 kJ. To convert kilojoules to kcals, divide by 4.184.

Legumes—A pod, such as a pea or bean, that splits into two valves with the seeds attached to one edge of the valves.

Nutritionist—Some dietitians call themselves "nutritionists" but in general, the term "nutritionist" is not protected by law, therefore anyone can call themselves a nutritionist.

Trans-unsaturated fatty acids (also called trans-fatty acids or trans-fat)—To make foods that will stay fresh on the shelf or to get a solid fat product, such as margarine, food manufacturers hydrogenate (i.e. add hydrogen) to polyunsaturated oils. This changes the double bond on the carbon atom from a cis configuration to a trans configuration, making the fatty acid saturated, and more of a health concern. For example, stick margarines are known to contain more trans fatty acids than liquid oils.

changes in food selection and more healthy attitudes about nutrition and wellness.

Risks

There is always the possible risk of non-compliance of any diet. However, when the individual is placed on the appropriate diet and the primary physician is aware of any known **allergies**, there are very few risks involved, if any.

Results

When special diets are followed as prescribed, better health is the expected outcome, with a decreased risk of acquiring many diseases. However, it is up to an individual to implement the necessary dietary modifications. If a patient does not follow the recommended dietary guidance, then they will not receive a benefit. Typically, modest effects are seen in weight loss or reduction in serum **lipids** (i.e. cholesterol) often due to failure to fully comply with the dietary recommendations provided by a dietitian or doctor.

The outcome of any diet therapy will be better when combined with exercise unless the patient is unable to exercise for medical reasons.

If the appropriate diet is prescribed by medical professionals, abnormal results are very rare.

Health care team roles

A certified nutrition professional such as a registered dietitian (R.D.) should be seen for a dietary assessment and professional dietary counseling prior to commencing diet therapy. Beware of individuals prescribing diets without an education in **dietetics** and nutrition. In general, only registered dietitians have sufficient training and knowledge to accurately assess the nutritional adequacy of a patient's diet, especially if chronic disease is present. Some dietitians call themselves nutritionists, but the term "nutritionist" is not regulated by law; therefore anyone can call themselves a nutritionist. A doctor may also have a nutrition background or specialization and may thus be able to conduct a dietary assessment or to provide general nutrition advice and/or diet therapy.

Dietary assessment

Definition

A dietary assessment is an estimation of food and nutrients eaten over a particular time point. There are a number of dietary assessment tools used by dietitians, nutritionists, and doctors that aid in **dietary counseling**. These include:

- food records or diaries (including weighed intakes)
- dietary recalls

- food frequency questionnaires (FFQs)
- dietary histories
- observed intakes
- chemical analyses of duplicate collections of foods consumed
- biological assessments (e.g. doubly-labelled water, plasma carotene, etc.)

Purpose

A dietary assessment is often conducted to determine the macronutrient (energy or caloric, protein, and fat) content and the micronutrient (vitamin and mineral) content of the diet to assist in providing dietary counseling. The validation of dietary assessment instruments is important to evaluate the diet in terms of a chronic disease risk factor. It is often used as a tool to help the patient lose weight, or to prevent or treat conditions or diseases that are influenced by food intake and nutritional status (i.e. cardiovascular disease, **cancer**, **obesity**, diabetes, hyperlipidemia).

A guide to the amount an average person needs each day to remain healthy has been determined for each vitamin and mineral as well as macronutrients. In the United States, this guide is called the recommended daily allowance (RDA). Consumption of too little or too much of certain **vitamins** and **minerals** may lead to a nutrient deficiency or a nutrient toxicity respectively. The RDA suggests a level of vitamin and minerals that is adequate for approximately 98% of healthy people in the population. The dietitian may use the dietary assessment to compare it to population requirements for nutrients (such as the RDA) to ensure the diet has proper intakes of energy, protein, fat, vitamins, and minerals. The RDA is under revision and will become the Dietary Reference Intakes, and will be applicable to Canadians and Americans.

Precautions

Dietary assessments are estimations based on an intake of a particular time point and cannot generalize that the diet is adequate or inadequate since intake varies day to day. For example, fruit and vegetables may be lacking on a day that was surveyed for the dietary assessment while overall the diet may be adequate in fruit and vegetable intake. Thus, care must be taken regarding generalizations about deficiencies or adequacy of nutrient intake. Intake of energy, **carbohydrates**, and protein varies less from day to day and may be estimated more closely than vitamin and mineral intakes.

Description

Some of the most common tools that assist in providing dietary advice include food records, 24 hour dietary recalls, food frequency questionnaires, diet histories, and several other methods including biochemical indices. These tools are explained in greater detail below. Furthermore, a scientific assessment of nutritional status may be made by using a combination of the information collected from clinical evaluations, biochemical tests, and dietary information. The clinical evaluation includes measurements of various anthropometric parameters such as height, weight, and percent body fat (determined by skinfolds or hydrostatic weighing). In addition, a clinical evaluation may also include observations for signs of nutrient deficiencies in the mouth, skin, eyes, and nails. The information collected from a clinical evaluation can be compared with that obtained from the dietary assessment and biochemical tests to provide a comprehensive picture of the patient's current nutritional status and relative risk factors for diet-related illnesses.

Food records

This method instructs subjects to record at the time of consumption all foods and beverages consumed for a specified duration, typically one to seven days, in order to quantify intake. Three or seven day food records are the most common. Food records can be estimated or weighed, the latter providing a more precise measure of intake. Portion sizes can be obtained through the use of household measures, cups, spoons, and scales. All days of the week should be proportionally included to avoid day of the week effects on nutrient and compositional intake. The weighed food record is the preferred method for assessing individual requirements because of its ability to determine intake quantitatively. Disadvantages of the method are that it is laborious and it may be a considerable burden to correctly measure and record intake.

24-hour recall

The 24-hour recall is a method for quantifying dietary intake for a group average and is not suited for individual dietary characterization although it is often used for this purpose. A person's previous 24-hour food intake is probed by an interviewer to provide detailed descriptions of portion sizes, condiments used, cooking method, and brand names. Quantities are often estimated in household measures or using food models for assistance to more accurately quantify intake. Recalls can be repeated on several occasions in the same person in order to increase accuracy and precision. Advantages of the 24-hour recall is that it is inexpensive, quick, and places little burden on the patient. Single 24-hour recalls do not

provide sufficient information on nutrient intakes and cannot account for day to day variation in intake, however, repeated 24 hour recalls can be used to more precisely estimate intake.

Food frequency questionnaire

A food frequency questionnaire (FFQ) is generally designed to provide qualitative data regarding food consumption patterns rather than nutrient composition and intake. The aim is to assess the frequency at which certain foods are consumed, for example, daily, weekly, monthly or yearly. Advantages of the FFQ are that it is quick, inexpensive, and can be administered by patients themselves. Disadvantages are that it cannot provide adequate quantitative data to use for individuals, although semi-quantitative FFQs provide some measure of quantity. As well, it does not address culture-specific foods since it primarily contains lists of somewhat standard North-American type foods. Accuracy and validation in specific cultures necessitates the use of another dietary assessment tool.

Diet history

The diet history attempts to measure usual intake in the past over a longer time period than other methods of dietary assessment. It consists of three parts, although it is often modified, including a 24 hour recall, a food frequency questionnaire, and a 3 day food record. Portion sizes are estimated by a variety of methods including household measures, food models, household utensils, photographs, or actual food. An advantage of the diet history is that it provides qualitative and quantitative data of food intake. It also considers seasonal and day to day variations. Disadvantages are that the method is labor-intensive.

Other methods

The use of a portable electronic set of tape recording scales (PETRA), photographs, voice-taped, and videotaped recordings have been used as dietary assessment tools.

Biochemical tests may also be used to further identify a patient's nutritional status. Serum albumin, hemoglobin or **hematocrit** are used to measure plasma protein. Lymphocytes and various skin tests are used to measure **immune system** integrity, and various urine tests such as a calculation of urinary nitrogen are used as an indication of protein **metabolism**. Other indices include urinary potassium, serum concentrations of carotenoids, and stable isotopes that measure water turnover which is an indicator of energy expenditure. These indices are often more reliable and representative of true intake than methods which rely on the subject's ability to record or recall intake.

Other sources that can be used for dietary reference and guidance for food choices are “The Dietary Guidelines for Americans” which is published by the U.S. Department of Agriculture and Health and Human Services. The “Food Guide Pyramid” was created by the U.S. Department of Agriculture to help Americans choose foods from each food grouping. It focuses on fat intake, which is too high in most Americans.

There are also a number of internet websites where food records or recalls can be self-administered by patients for dietary assessment. Some of these websites are listed in the resources sections below.

Preparation

Systematic problems exist in the quantification of food intake using dietary assessment tools that depend on self-reported measures (i.e. when the patient subjectively reports their own food intake). This is due to the fact that these methods rely on the patient’s ability to recall or record food intake accurately. Therefore, selection of the appropriate method for dietary assessment is important to meet the goals of dietary counseling.

Complications

Measurement of dietary intake typically relies on self-reported data. Most dietary collection tools using self-reported intake have not included a test for accuracy or bias to validate the data collected. These validations are difficult to conduct because in an individual who is eating at home, there are few methods to use as a reference to validate the dietary intake data.

There are subgroups of the population that are more likely to provide inaccurate intake data, creating error. In general, obese people are more apt to underestimate their food consumption because they may go on “a diet” or deliberately omit foods during the food-recording period. Individuals may alter their food intake temporarily as they are cognizant that their food intake is being monitored, possibly to conform to socially acceptable foods and food habits. For example, during a 24 hour recall, an obese person may not want to admit to a dietitian that they overate the previous day, therefore, they may underreport their food intake.

Another source of error comes from weighing and measuring foods. Errors involved in the estimation of food portions can reach 90% but are typically 20-50% when scales are not used to weigh foods.

KEY TERMS

Dietary assessment—An estimation of food and nutrients eaten over a particular time point. Some of the most common dietary assessment methods are food records, dietary recalls, food frequency questionnaire, and diet histories.

Dietitian—A dietitian is a health professional who has a bachelor’s degree, specializing in foods and nutrition, and undergoes a period of practical training in a hospital or community setting. Many dietitians further their knowledge by pursuing master’s or doctoral degrees. The title “dietitian” is protected by law so that only qualified practitioners who have met education qualifications can use that title.

Macronutrient—A nutrient such as protein, carbohydrate, or fat.

Micronutrient—An organic compound such as vitamins or minerals essential in small amounts and necessary to growth and health of humans and animals.

Nutritionist—Some dietitians call themselves “nutritionists,” but in general, the term “nutritionist” is not protected by law, therefore anyone can call themselves a nutritionist.

Results

A dietary assessment may indicate where a nutritional problem or inadequacy may lie, but it is up to an individual to implement the necessary dietary modifications. If a patient does not follow the recommended dietary guidance following dietary assessment, then they will not receive any benefit from dietary assessment. Typically, modest effects are seen in weight loss or reduction in serum **lipids** often due to failure to fully comply with the dietary recommendations provided.

Health care team roles

In general, only registered dietitians (R.D.s) have sufficient training and knowledge to accurately assess the clinical evaluation and nutritional adequacy of a patient’s diet. Although there are many websites and software programs that provide guidance for self-use for conducting a basic dietary assessment, these should be used with caution. The term “nutritionist” is not regulated by law; therefore anyone can call themselves a nutritionist. A doctor may also have a **nutrition** background or special-

ization and may thus be able to conduct a dietary assessment or to provide general nutrition advice. However, one research study demonstrated that even though most doctors admitted they had ready access to a publicly funded dietician, 50% of doctors refer less than a quarter of their patients to dietitians. Major barriers for doctors to improving dietary counseling for patients include short visit times, limited nutrition coursework in medical schools, and poor patient compliance with physicians' dietary prescriptions.

Crystal Heather Kaczowski, MSc.

related illnesses such as cardiovascular disease, **cancer**, **obesity**, diabetes, and hyperlipidemia.

Purpose

Today's major health care problems are increasingly the result of acute and chronic conditions related to poor **nutrition** and/or overconsumption. A large proportion of coronary disease and cancer can be attributed to unhealthy eating habits and obesity. Chronic diseases continue to increase due to such factors as the rise in obesity in the American population.

Individualized nutritional counseling can provide the patient important insight into food-related illnesses and education regarding how various nutrients (protein, carbohydrate, fat, alcohol) affect illnesses or obesity. Alternatively, dietary counseling can provide prevention of nutrition-related conditions such as the need for weight management. Dietary counseling can be tailored to meet the treatment needs of patients at diagnosis of specific illnesses, can help reduce complications and/or side effects, and can improve general well-being. Prevention at all levels: primary (preventing disease), secondary (early diagnosis), and tertiary (preventing or slowing deterioration) requires active patient participation and guidance and support from the dietician or physician. Education, motivation, and counseling are needed for effective patient participation. In addition to **patient education**, dietary counseling often includes meal planning.

A guide to the amount an average person needs each day to remain healthy has been determined for each vitamin and mineral as well as macronutrients. In the United States, this guide is called the *recommended daily allowance (RDA)*. The RDA is under revision and will become the Dietary Reference Intakes, and will be applicable to Canadians and Americans. Dietary counselors may use the RDA as a guide when providing counseling. Consumption of too little or too much of certain **vitamins** and **minerals** may lead to a nutrient deficiency or a nutrient toxicity respectively. A dietitian can advise the patient about any vitamin or mineral inadequacy concerns during the dietary counseling session.

Precautions

When providing dietary counseling, registered dietitians and nutritionists should recognize the benefit of individualizing nutritional care and that a "one-size-fits-all" approach to modifying eating habits cannot be effective.

Dietary counseling

Definition

Dietary counseling provides individualizing nutritional care for encouraging modification of eating habits. It may also assist in prevention or treatment of nutrition-

Description

Effective dietary counseling includes a comprehensive evaluation that considers presence of disease, lipid profile, **blood pressure**, and weight history and goals. In addition, factors such as lifestyle, time available for food preparation, work schedule, and personal food preferences must be considered. Food choices are driven not only by the physiological necessity for nutrients, but also by the social aspects of food consumption, i.e. gathering with friends at a restaurant. This complex relationship concerning food choices often makes dietary counseling a challenge for managing specific nutrition-related disease or conditions. For example, a patient with cardiovascular disease may need to select low-fat foods when attending a social dinner or party.

There are many issues related to nutrition goal outcomes that need to be considered when planning appropriate dietary counseling. When considering the appropriate counseling approach for an individual with a specific illness, particular attention needs to be given to usual food choices, food likes and dislikes, learning style, cultural issues, and socioeconomic status.

Other factors that may be assessed during dietary counseling include:

- medical history, including assessment of any nutrition-related illnesses, and biochemical and anthropometric measures
- **dietary assessment** (dietary analyses)
- psychosocial evaluation, including food-related attitudes and behaviors
- sociological evaluation, including cultural practices, housing, cooking facilities, financial resources, and support of family and friends
- nutrition knowledge
- readiness to learn or change; as well as learning style analyses
- current **exercise** and activity level

Preparation

A dietary assessment is often conducted to determine the macronutrient (energy or caloric, protein, and fat) content and the micronutrient (vitamin and mineral) content of the diet to assist in providing dietary counseling. The validation of dietary assessment instruments is important to evaluate the diet in terms of chronic disease risk factors such as a high fat diet or a diet low in antioxidants and/or fruits and vegetables.

Some of the most common dietary assessment tools that assist in providing dietary counseling include food

records, dietary recalls, food frequency questionnaires, diet histories, and several other methods including biochemical indices. A scientific assessment of nutritional status may be made by using a combination of the information collected from clinical evaluations, biochemical tests, and dietary information. The clinical evaluation includes measurements of various anthropometric parameters such as height, weight, and percent body fat (determined by skinfolds or hydrostatic weighing). In addition, a clinical evaluation may also include observations for signs of nutrient deficiencies in the mouth, skin, eyes, and nails. The information collected from a clinical evaluation can be compared with that obtained from the dietary assessment and biochemical tests to provide a comprehensive picture of the patient's current nutritional status and relative risk factors for diet-related illnesses.

Aftercare

Dietary counseling is only effective if the individual is willing to implement the necessary dietary modifications. If patients do not follow the recommended dietary guidance, they will not receive a benefit from counseling. Typically, modest effects seen in weight loss or reduction in serum **lipids** are often due to failure to comply fully with the dietary recommendations provided.

Complications

Systematic problems exist in the quantification of food intake using dietary assessment tools and self-reported measures (i.e. when the patients subjectively report their own food intake). This is due to the fact that these methods rely on the patient's ability to recall or record food intake accurately. Therefore, selection of the appropriate method for dietary assessment is important to meet the goals of dietary counseling.

Results

Goals of dietary counseling for preventative nutrition or treatment of nutrition-related illness:

- Providing adequate calories for attaining reasonable weights for adults, ensuring normal growth and development rates for children and adolescents, and meeting increased metabolic needs during **pregnancy** and **lactation** or recovery from catabolic illness. Reasonable weight for adults is defined by considering weight history and is a weight that both the individual and health professional determine is attainable and can be maintained long term.
- Achieving optimal lipid levels. The guidelines provided by the *National Cholesterol Education Program* can be followed for maintaining optimal **blood** lipid levels

KEY TERMS

Dietary assessment—An estimation of food and nutrients eaten over a particular time point. Some of the most common dietary assessment methods are food records, dietary recalls, food frequency questionnaires, and diet histories.

Dietary counseling—Individual nutritional advice provided to a patient by a registered dietitian, nutritionist, or doctor for encouraging modification of eating habits.

Dietitian—A dietitian is a health professional who has a bachelor's degree, specializing in foods and nutrition, and undergoes a period of practical training in a hospital or community setting. Many dietitians further their knowledge by pursuing master's or doctoral degrees. The title "dietitian" is protected by law so that only qualified practitioners who have met education qualifications can use that title.

Macronutrient—A nutrient such as protein, carbohydrate, or fat.

Micronutrient—An organic compound such as vitamins or minerals essential in small amounts and necessary to growth and health of humans and animals.

Nutritionist—A general term for someone who works with the principles of nutrition. Some dietitians call themselves "nutritionists," but the term "nutritionist" is not protected by law, and therefore anyone can call themselves a nutritionist.

[total cholesterol, low-density lipoproteins (LDL), high-density lipoproteins (HDL), and triglycerides]. Nutrition intervention plays an important role in reaching recommended lipid levels through maintenance of a low-fat diet.

- Ensuring the diet contains appropriate or reasonable amounts of protein, **carbohydrates**, fat, vitamins, and minerals.
- Preventing, delaying, or treating nutrition-related risk factors and complications.
- Improving overall health through optimal nutrition.

What methods are most helpful for dietary modifications?

Clearly, dietary advice tailored to suit individual needs and tastes is more appropriate than general dietary

advice. The issue is how to elicit a beneficial change in dietary habits and how to encourage a patient to stick to the dietary recommendations provided. Typically, dietary modifications have demonstrated limited success especially regarding weight control. Several methods have been used to induce behavioral change in individuals such as the *Transtheoretical (Stages of Change) Model*. It is one of most popular models of health behavior change that classifies individuals into stages according to their degree of readiness to consider change, and identifies the factors that can induce transitions from one stage to the next. The model suggests change in health behavior involves progression through six stages including precontemplation, contemplation, preparation, action, maintenance, and termination. It utilizes different types of skills training and advice at different stages and has shown promising success in diet modification interventions.

It may be easier to introduce new behaviors than to eliminate established behaviors. Therefore, if weight loss is a concern, recommending the patient start exercising regularly may be more effective than changing current dietary patterns.

Positive feedback or implementation of a reward system may be advantageous in helping some patients follow dietary advice.

In general, changing behaviors such as making healthier food choices and increasing exercise will be much more successful and pleasurable in the long-term than dieting. Furthermore, an individual cannot live on a diet permanently; therefore, when food intake increases, weight gain will follow unless energy expenditure is increased through exercise or by other means. Dieting may encourage a "yo-yo" weight loss/gain where often even more weight is gained back than was lost and often in less favorable proportions of a fat to muscle ratio. When weight is lost, muscle and fat are both lost. Sometimes the weight that is regained after weight loss has a higher content of "fat" (adipose tissue) than the weight previously lost (which may have contained a significant percent of skeletal muscle). This is only one of the reasons why exercise is so important in maintaining body weight. In fact, because muscle is metabolically active tissue, the body actually needs more energy or calories to feed the muscles even when at rest (for example, sitting still or sleeping). Dietary counseling may help reinforce dietary modifications and assist in achieving permanent weight control.

Other sources that can be used for dietary reference and self-counseling for individuals are *The Dietary Guidelines for Americans* which is published by the U.S. Department of Agriculture and Health and Human Services. *The Food Guide Pyramid* was created by the

U.S. Department of Agriculture to help Americans choose foods from each food grouping. It focuses on fat intake, which is too high in most Americans. In addition, the *National Cholesterol Education Program* provides a Step 1 diet that may be followed to assist in controlling weight.

Health care team roles

In general, only registered dietitians (R.D.s) have sufficient training and knowledge to accurately assess the nutritional adequacy of a patient's diet. The term "nutritionist" is not regulated by law; therefore anyone can call themselves a nutritionist. A doctor may also have a nutrition background or specialization and may thus be able to provide general nutrition counseling. However, one research study demonstrated that even though most doctors admitted they had ready access to a publicly funded dietician, 50% of doctors refer less than a quarter of their patients to dietitians. Major barriers to improving dietary counseling for patients include short visit times, limited nutrition coursework in medical schools, and poor compliance with physicians' dietary prescriptions.

For effective therapy to occur, all health care team members and especially the patient with the nutrition-related illness must commit to the goals of counseling. The prioritized goals are critical when developing the nutrition treatment plan. Continuous assessment is made by the patient and health care team members to evaluate the importance of these and other goals. Physicians must understand the nutrition approaches an individual is using and reinforce this therapy when interacting with the individual.

Dietetics

Definition

Dietetics professionals are responsible for educating individual clients in developing healthy lifestyles, as well as for providing quality nutritional services to the public. Standards of professional practice have been developed by the American Dietetic Association to ensure that dietetics professionals are the most reliable sources of information regarding food and **nutrition**.

Description

Registered dietitians (RD) and dietetic technicians (DTR) receive their credentials from the Commission on Dietetic Registration, which ensures that these professionals have fulfilled all academic requirements and completed a registration examination. Dietetics professionals work in a variety of settings involving foodservice management, clinical nutrition, and community nutrition. They work to provide nutrition education classes on topics such as breastfeeding, food safety, and diet fads. They may counsel hospital patients on health-related conditions and facilitating weight loss. They are also qualified to educate the public on proper nutrition for people of all ages including infants and the elderly.

Work settings

Registered dietitians and dietetic technicians are qualified to work in a variety of settings including hospitals, **nursing homes**, schools, and health clinics. In hospitals and nursing homes, dietetics professionals usually perform more clinical duties such as assessing the nutritional status of patients to aid in their treatment and recovery. They must demonstrate an understanding of a variety of nutrition topics, including calculating nutrient and tube feeding needs, and various nutrition-related diseases, such as diabetes, **Crohn's disease**, and cardiovascular disease. In schools, dietitians can provide services to cafeterias in helping them develop healthy meals and snacks, as well as conduct nutrition education classes for

students and teachers. Dietitians also play a very prominent role in health clinics such as WIC (Supplemental Program for Women, Infants, and Children), in which they advocate the healthy development of children by educating women on the importance of breastfeeding and **infant nutrition**. Many dietetics professionals also become certified as dietary managers in which they are responsible for supervising in a foodservice setting.

Education and training

To become a registered dietitian, a bachelor's or master's degree in dietetics may be received from a school that is a Coordinated Program (CP) accredited by the Commission on Accreditation for Dietetics Education (CADE) in which academics and supervised practical experience are combined. A graduate of a Coordinated Program may then take the Registration Examination for Dietitians to become an RD. Individuals may also enroll in a Didactic Program in Dietetics (DPD) that is also approved by CADE. After graduating with a bachelor's degree, the supervised practical experience may be completed either at a CADE-accredited Dietetic Internship or a CADE-approved Preprofessional Practice Program (AP4). This also qualifies the individual to take the Registration Examination for Dietitians.

To become a registered dietetic technician, an associate's degree must be received from a CADE-accredited Dietetic Technician Program or a baccalaureate degree from a CADE-approved DPD. DTRs must also participate in a supervised practical experience at the Dietetic Technician Program, but it is not required that they take a registration examination.

The academics involved in the undergraduate study of dietetics includes generalized courses such as biology, chemistry, statistics, and management. More detailed courses are devoted to topics such as general nutrition, food science, nutritional assessment, advanced nutrition, experimental foods, and **diet therapy**. Undergraduate work also consists of clinical experience in work settings in which students gain a more hands-on experience in the field of dietetics. This allows students to get a new perspective on the field that goes beyond traditional teaching methods. By encouraging active participation, students will gain a better understanding of what is necessary to develop the counseling skills and research capabilities essential to dietetics.

Advanced education and training

Dietitians can further enhance their education and abilities by receiving a master's degree in dietetics or another field related to nutrition. Some CADE-accred-

ed/approved programs also offer graduate coursework that can be completed at the same time as the dietetic internship. Dietetics professionals are also responsible for keeping up to date with the latest information regarding nutrition and utilizing the available technology that can enhance learning.

Future outlook

Dietetics is a constantly changing field in which new information is being uncovered and advances in technology are being made. While technology has become an integral part of nutrition education, it is likely to become even more prominent in years to come. Many dietitians have even designed web sites in order to market their practice. Dietitians have begun utilizing services such as email and the Internet to communicate with clients. This also allows them to communicate with people who travel or are too busy to schedule an appointment. Using the Internet to communicate with clients has its advantages as well as its disadvantages though. While it offers more flexibility for both the client and the professional and allows dietitians to reach a wide geographical range of people, it also limits dietetics professionals in accurately assessing patients because they are not seen in person.

One of the major drawbacks to using the web for nutrition information is that much of the information tends to be inaccurate or exaggerated. This will give dietetics professionals an even bigger role in working to ensure that the public is getting the most accurate and up-to-date information from the web and has resulted in more career opportunities for dietetics professionals. Since most nutrition information comes from search engines like <www.yahoo.com> or <www.medscape.com>, these companies have begun hiring dietetics and nutrition professionals to edit content and develop appropriate health-related messages for consumers. Many dietitians also work as consultants for Web sites who may need expert advice on nutrition-related topics. With the advances in technology and development of new computer programs for nutrition education, the role of dietitians will continue to grow as the need for the most up-to-date information continues to grow.

Digestive system

Definition

The digestive system is a group of organs and tissues responsible for the conversion of food into absorbable chemicals which are then used to provide energy for growth and repair.

Description

The digestive system is also known by a number of other names, including the gut, the digestive tube, the alimentary canal, the gastrointestinal (GI) tract, the intestinal tract, and the intestinal tube. The digestive system consists of the mouth, esophagus, **stomach**, and small and large intestines, along with several glands, such as the salivary glands, **liver**, gall bladder, and **pancreas**.

Function and role in human health

The glands in the digestive system secrete digestive juices containing enzymes that break down the food chemically into smaller, more absorbable molecules. In addition to providing the body with the nutrients and energy it needs to function, the digestive system also separates and disposes of waste products ingested with the food.

Food is moved through the alimentary canal by a wavelike muscular motion known as peristalsis, which consists of the alternate contraction and relaxation of the smooth muscles lining the tract. In this way, food is passed through the gut in much the same manner as toothpaste is squeezed from a tube. Churning is another

type of movement that takes place in the stomach and **small intestine**, which mixes the food so that the digestive enzymes can break down the food molecules.

Food in the human diet consists of **carbohydrates**, **proteins**, **fats**, **vitamins**, and **minerals**. The remainder of the food is fiber and water. The majority of minerals and vitamins pass through to the bloodstream without the need for further digestive changes, but other nutrient molecules must be broken down to simpler substances before they can be absorbed and used.

Ingestion

Food taken into the mouth is first prepared for digestion in a two-step process known as mastication. In the first stage, the teeth tear and break down food into smaller pieces. In the second stage, the tongue rolls these pieces into balls (boluses). Sensory receptors on the tongue (**taste buds**) detect taste sensations of sweet, salt, bitter, and sour, or cause the rejection of bad-testing food. The olfactory nerves contribute to the sensation of taste by picking up the aroma of the food and passing the sensation of **smell** on to the **brain**.

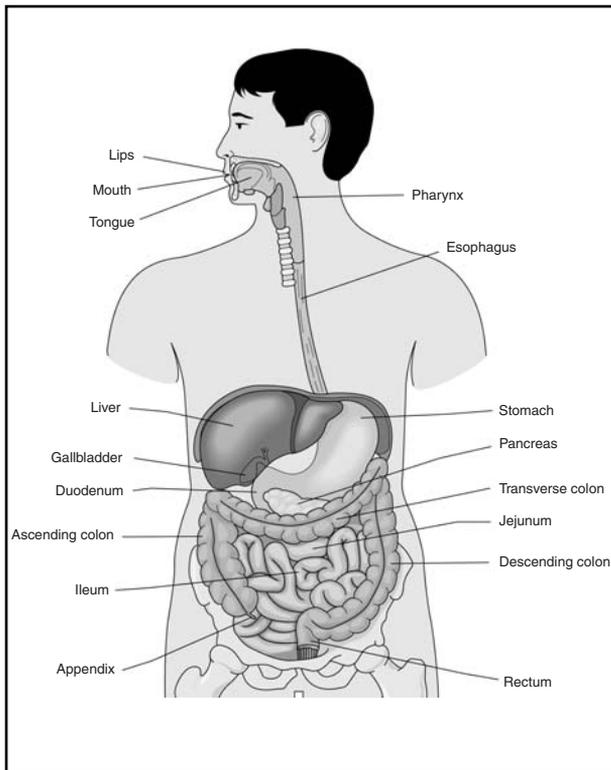

The sight of the food also stimulates the salivary glands. Altogether, the sensations of sight, taste, and smell cause the salivary glands, located in the mouth, to produce saliva, which then pours into the mouth to soften the food. An enzyme in the saliva called amylase begins the break down of carbohydrates (starch) into simple sugars, such as maltose. Ptyalin is one of the main amylase enzymes found in the mouth; ptyalin is also secreted by the pancreas.

The bolus of food, which is now a battered, moistened, and partially digested ball of food, is swallowed, moving to the throat at the back of the mouth (pharynx). In the throat, rings of muscles force the food into the esophagus, the first part of the upper digestive tube. The esophagus extends from the bottom part of the throat to the upper part of the stomach.

The esophagus does not take part in digestion. Its job is to get the bolus into the stomach. There is a powerful muscle (the esophageal sphincter), at the junction of the esophagus and stomach, which acts as a valve to keep food, stomach acids, and bile from flowing back into the esophagus and mouth.

Digestion in the stomach

Chemical digestion begins in the stomach. The stomach, a large, hollow, pouched-shaped muscular organ, is shaped like a lima bean. When empty, the stomach becomes elongated; when filled, it balloons out.

The parts of the human gastrointestinal tract. (Delmar Publishers, Inc. Reproduced by permission.)

Food in the stomach is broken down by the action of the gastric juice containing hydrochloric acid and a protein-digesting enzyme called pepsin. Gastric juice is secreted from the lining of the stomach walls, along with mucus, which helps to protect the stomach lining from the action of the acid. The three layers of powerful stomach muscles churn the food into a fine semiliquid paste called chyme. The chyme (pronounced “kime”) is periodically passed through an opening (the pyloric sphincter), which controls the passage of chyme between the stomach and the beginning of the small intestine.

Gastric juice

There are several mechanisms responsible for the secretion of gastric juice in the stomach. The stomach begins its production of gastric juice while the food is still in the mouth. Nerves from the cheeks and tongue are stimulated and send messages to the brain. The brain in turn sends messages to nerves in the stomach wall, stimulating the secretion of gastric juice before the arrival of the food. The second signal for gastric juice production occurs when the food arrives in the stomach and touches the lining. This mechanism provides for only a moderate addition to the amount of gastric juice that was secreted when the food was in the mouth.

Gastric juice is needed mainly for the digestion of protein by pepsin. If a hamburger and bun reach the stomach, there is no need for extra gastric juice for the bun (carbohydrate), but the hamburger (protein) will require a much greater supply of gastric juice. The gastric juice already present will begin the break down of the large protein molecules of the hamburger into smaller molecules: polypeptides and peptides. These smaller molecules in turn stimulate the cells of the stomach lining to release the hormone gastrin into the bloodstream.

Gastrin then circulates throughout the body, and eventually reaches the stomach, where it stimulates the cells of the stomach lining to produce more gastric juice. The more protein there is in the stomach, the more gastrin will be produced, and the greater the production of gastric juice. The secretion of more gastric juice by the increased amount of protein in the stomach represents the third mechanism of gastric juice secretion.

Digestion and absorption in the small intestine

While digestion continues in the small intestine, it also becomes a major site for the process of absorption, that is, the passage of digested food into the bloodstream, and its transport to the rest of the body.

The small intestine is a long, narrow tube, about 20 ft (6 m) long, running from the stomach to the **large intestine**. The small intestine occupies the area of the abdomen between the diaphragm and hips, and is greatly coiled and twisted. The small intestine is lined with muscles that move the chyme toward the large intestine. The mucosa, which lines the entire small intestine, contains millions of glands that aid in the digestive and absorptive processes of the digestive system.

The small intestine, or small bowel, is sub-divided into three sections, the duodenum, the jejunum, and the ileum. The duodenum is about 1 ft (0.3 m) long and connects with the lower portion of the stomach. When fluid food reaches the duodenum it undergoes further enzymatic digestion and is subjected to pancreatic juice, intestinal juice, and bile.

The pancreas is a large gland located below the stomach that secretes pancreatic juice into the duodenum via the pancreatic duct. There are three enzymes in pancreatic juice which digest carbohydrates, **lipids**, and proteins. Amylase, (the enzyme found in saliva) breaks down starch into simple sugars such as maltose. The enzyme maltase in intestinal juice completes the break down of maltose into glucose.

Lipases in pancreatic juice break down fats into fatty acids and glycerol, while proteinases continue the break-down of proteins into amino acids. The gallbladder,

located next to the liver, secretes bile into the duodenum. While bile does not contain enzymes, it contains bile salts and other substances that help to emulsify (dissolve) fats, which are otherwise insoluble in water. Breaking the fat down into small globules allows the lipase enzymes a greater surface area for their action.

Chyme passing from the duodenum next reaches the jejunum of the small intestine, which is about 3 ft (0.91 m) long. Here, in the jejunum, the digested breakdown products of carbohydrates, fats, proteins, and most of the vitamins, minerals, and **iron** are absorbed. The inner lining of the small intestine is composed of up to five million tiny, finger-like projections called *villi*. The villi increase the rate of absorption of the nutrients into the bloodstream by extending the surface of the small intestine to about five times that of the surface area of the skin.

There are two transport systems that pick up the nutrients from the small intestine. Simple sugars, amino acids, glycerol, and some vitamins and salts are conveyed to the liver in the bloodstream. Fatty acids and vitamins are absorbed and then transported through the **lymphatic system**, the network of vessels that carry lymph and white **blood** cells throughout the body. Lymph eventually drains back into the bloodstream and circulates throughout the body.

The last section of the small intestine is the ileum. It is smaller and thinner-walled than the jejunum, and it is the preferred site for **vitamin B₁₂** absorption and bile acids derived from the bile juice.

Absorption and elimination in the large intestine

The large intestine, or colon, is wider and heavier than the small intestine, but much shorter—only about 4 ft (1.2 m) long. It rises up on one side of the body (the ascending colon), crosses over to the other side (the transverse colon), descends (the descending colon), forms an s-shape (the sigmoid colon), reaches the rectum, and anus, from which the waste products of digestion (feces or stool), are passed out, along with gas. The muscular rectum, about 5 in (13 cm) long, expels the feces through the anus, which has a large muscular sphincter that controls the passage of waste matter.

The large intestine extracts water from the waste products of digestion and returns some of it to the bloodstream, along with some salts. Fecal matter contains undigested food, **bacteria**, and cells from the walls of the digestive tract. Certain types of bacteria of the large intestine help to synthesize the vitamins needed by the body. These vitamins find their way to the bloodstream along with the water absorbed from the colon, while excess fluids are passed out with the feces.

Liver

The liver is the largest organ in the body and plays a number of vital roles, including metabolizing the broken-down products of digestion, and detoxifying substances that are harmful to the body. The liver also provides a quick source of energy when the need arises and it produces new proteins. Along with the regulation of stored fats, the liver also stores vitamins, minerals, and sugars. The liver controls the excretion and production of cholesterol and metabolizes alcohol into a mild toxin. The liver also stores iron, maintains the hormone balance, produces immune factors to fight infections, regulates blood clotting, and produces bile.

Gallbladder

The **gallbladder** lies under the liver and is connected by various ducts to the liver and the duodenum. The gallbladder is a small hollow organ; its main function is to store bile until it is concentrated enough to be used by the small intestine. The gallbladder can store about 2 oz of bile. Bile consists of bile salts, bile acids, and bile pigments. In addition, bile contains cholesterol dissolved in the bile acids.

Appendix

The appendix is a hollow finger-like projection that hangs from the cecum at the junction between the small intestine and the large intestine. The appendix does not function in humans; however, in some animals, such as rabbits, the appendix is rather large and helps in the digestion of cellulose from bark and wood, which rabbits eat. The appendix in humans is therefore a vestigial organ, which may have had uses for earlier types of ancestral human digestive processes before the evolution of *Homo sapiens*.

Pancreas

When food reaches the small intestine, the pancreas secretes pancreatic juices. When there is no food in the small intestine, the pancreas does not secrete its juices.

Insulin is another important hormone secreted by a group of cells within the pancreas called the islets of Langerhans, which are part of the **endocrine system**, rather than the digestive system. Insulin released into the bloodstream targets liver and muscle cells, and allows them to take excess sugar from the blood and store it in the form of glycogen.

KEY TERMS

Amylase—A digestive enzyme found in saliva and the pancreas that breaks down carbohydrates to simple sugars.

Bile—Liquid produced in the liver and stored in the gallbladder that emulsifies fats.

Gastric juice—Digestive juice produced by the stomach wall that contains hydrochloric acid and the enzyme pepsin.

Gastrin—A hormone produced by the stomach lining in response to protein in the stomach that produces increased gastric juice.

Helicobacter pylori—Recently discovered bacteria that live in gastric acids and are believed to be a major cause of most stomach ulcers.

Lower esophageal sphincter—A strong muscle ring between the esophagus and the stomach that keeps gastric juice and even duodenal bile from flowing upwards out of the stomach.

Lymphatic system—The system that produces, transports, and filters lymph throughout the body. It also transports fats, proteins, and some vitamins to the blood system.

Mucosa—The digestive lining of the intestines.

Nutrients—Vitamins, minerals, proteins, lipids, and carbohydrates needed by the body.

Peristalsis—The wavelike motion of the digestive system that moves food through the digestive system.

Villi—Fingerlike projections found in the small intestine that add to the absorptive area for the passage of digested food to the bloodstream and lymphatic system.

Common diseases and disorders

Several disorders of the esophagus are esophagitis, esophageal spasm, and esophageal **cancer**. Esophagitis (heartburn) is an inflammation of the esophagus usually caused by the reflux of gastric acids into the esophagus and is treated with antacid (alkalis). Esophageal spasm is also caused by acid reflux. Esophageal cancer can be caused by smoking and is generally fatal.

Disorders of the stomach include hiatal hernia, ulcers, and gastric cancer. A hiatal hernia occurs when a portion of the stomach extends upwards into the thorax through a large opening in the diaphragm. It is a condi-

tion that commonly occurs in people over the age of 50. Stomach ulcers are sores that form in the lining of the stomach. They may vary in size from a small sore to a deep cavity, surrounded by an inflamed area, sometimes called ulcer craters. Stomach ulcers and ulcers that form in the esophagus and in the lining of the duodenum are called peptic ulcers because they need stomach acid and the enzyme pepsin to form. Duodenal ulcers are the most common type. They tend to be smaller than stomach ulcers and heal more quickly. Ulcers that form in the stomach lining are called gastric ulcers. About 4 million people have ulcers, and 20% of those have gastric ulcers. Those people who are at most risk for ulcers are those who smoke, are middle-age and older men, are chronic users of alcohol, and those who take anti-inflammatory drugs, such as aspirin and ibuprofen. It is believed that about 80% of stomach ulcers may be caused by the bacterial **infection**, while about 20% may be from other causes, such as the use of anti-inflammatory medicines.

The most common liver disorder in the United States and other developed countries is cirrhosis of the liver. The main cause for this disease is **alcoholism**. Cirrhosis is characterized by the replacement of healthy liver cells by fibrous tissue. The replacement process is gradual and takes a period of two to 10 years to complete. There is no cure for the disease. Symptoms may not be noticed in its early development, but in its advanced stages there are a number of symptoms and the condition can lead to **coma**. Close medical attention is required to treat the disease.

Another common liver disorder is hepatitis. It is an inflammation of the liver caused by **viruses**. The most noticeable symptom of this disease is **jaundice**, that is, the skin, eyes, and urine turn yellow. The nine viruses known to cause hepatitis include hepatitis A, B, C, D, and E; the recently discovered F and G viruses; and two herpes viruses (Epstein-Barr and cytomegalovirus).

Gallstones may form in the gallbladder. If the amount of cholesterol in the bile acids increases or the amount of acid decreases, then some of the cholesterol will settle out of the acid to form gallstones that accumulate and block the ducts to the gallbladder. Infection in the gallbladder may lead to gallstones. Gallstones may be in the gallbladder for years without giving any signs of the condition, but when they obstruct the bile duct they cause considerable **pain** and inflammation. Infection and blockage of the bile flow may follow. Surgical removal of the gallbladder may be necessary to treat this condition. Since the liver both produces and stores sufficient amounts of bile, the loss of the gallbladder does not interfere with the digestive process provided fat intake in the diet is regulated. If the gallstones contain mainly cholesterol, drug treatment for the stones may be possible. But if there is too much other material in the gallstones, sur-

gery may still be necessary. Even after being treated successfully by drugs and diet, the condition can return. The drug treatment takes years to dissolve gallstones.

If food gets trapped in the appendix, an irritation of its membranes may occur leading to swelling and inflammation, a condition known as **appendicitis**. If the condition becomes serious, removal of the appendix is necessary to avoid a life-threatening condition if it were to rupture.

When the pancreas does not produce sufficient insulin to store dietary sugar, the blood and urine levels of sugar reach dangerous levels. **Diabetes mellitus** is the resultant disease. Mild cases can be controlled by a properly regulated diet, but severe cases require the regular injection of insulin.

Disease transmission

Definition

Disease transmission is the means by which contagious, pathogenic microorganisms are spread from one person to another.

Description

There are four major pathways by which pathogenic organisms may be spread to an individual: contact transmission, airborne transmission, vehicle transmission, and vector transmission.

Contact transmission

Infectious particles may be spread through direct or indirect contact with an infected individual, animal, or inanimate object. Direct contact refers to instances in which there is direct person-to-person spread of a disease. This occurs in the case of sexually transmitted diseases (STDs), when the genitals of one individual come into direct contact with the genitals of a person suffering from an STD such as herpes simplex virus (HSV). Contact of an uninfected person with infected **wounds** or **blood** may result in direct transmission, such as in the case of human **immunodeficiency virus** (HIV), if he/she is not protected by **universal precautions**.

A very common form of direct contact transmission occurs when infectious particles in the form of airborne droplets are expelled by an infected individual by sneezing or coughing and inhaled by another individual. Expelled droplets may travel for several meters before falling and therefore are easily spread to surrounding individuals. Examples of diseases that are caused by inhalation of infectious droplets are **influenza** (caused by the influenza virus) and **tuberculosis** (caused by the bacterium *Mycobacterium tuberculosis*).

Indirect contact results in the transmission of infectious particles from person to person via an intermediary carrier. Inanimate objects such as eating utensils, medical instruments, or equipment used in food preparation may become contaminated with a pathogenic microorganism and in turn spread the disease to other individuals. Infected needles may be the source of indirect transmission of pathogens between intravenous drug users. The hands of a health care worker may also cause the transmission of infectious particles from patient to patient if adequate handwashing practices are not enforced.

Organ transplantation presents a unique mode by which disease may be transmitted. Microorganisms that have disseminated to the donor organ may be transplanted to the recipient and subsequently cause disease. For example, hepatitis C virus (HCV) may be transmitted by **liver** transplantation if the donor organ is infected. Similarly, transmission of cytomegalovirus (CMV) from infected donor **kidneys** may occur.

KEY TERMS

Cleaning—The physical removal of microorganisms from an object, usually with water with or without a detergent.

Disinfection—Treatment which destroys most microorganisms from an object.

Droplet nuclei—Tiny particles on which microorganisms may be carried in airborne transmission.

Sterilization—The complete removal of all living microorganisms from an object or fluid.

Universal precautions—An infection-control technique designed to prevent the transmission of blood-borne diseases. These guidelines were initially developed by the Centers for Disease Control in 1987.

Airborne transmission

Airborne transmission differs from droplet transmission in that infectious particles are carried on tiny particles called droplet nuclei and may remain suspended or carried in the air for hours or days. These aerosolized particles may be widely dispersed before settling, therefore increasing the chance that they will be inhaled. Organisms that survive well under dry conditions (e.g. *Staphylococcus aureus*) are often spread by the airborne route.

There are many ways in which infectious microorganisms remain airborne. Droplet nuclei may be dispersed by ventilation and respiratory equipment, such as nebulizers, humidifiers, and air conditioners. *S. aureus* may be shed on skin scales from contaminated skin. *Mycobacterium tuberculosis* may be transmitted by droplet or airborne transmission and may survive for years in dust particles. Other organisms may be transmitted by disrupted soil or dried fecal matter.

Vehicle transmission

The spread of infectious agents through a common reservoir such as food or water supply is referred to as vehicle or common supply transmission. Food products may become contaminated after being handled by unwashed hands or processed by unclean equipment. Cattle infected with bovine spongiform encephalopathy (BSE, also known as mad cow disease) may cause **Creutzfeldt-Jakob disease** in humans who consume the cow's nervous system tissue. Water may be contaminated by infected feces, urine, or other body fluids, and diseases can be spread by drinking or bathing in this contaminated

water. For example, the diarrheal disease cholera (caused by the bacterium *Vibrio cholerae*) is often spread by drinking water contaminated by infected fecal matter.

The blood supply is another means of vehicle transmission. Donated blood may be infected with any number of microorganisms (HIV, HCV, etc.) that could be transmitted upon transfusion. Contaminated drugs or intravenous fluid supplies at hospitals may also result in vehicle transmission of disease.

Vector transmission

Vector transmission occurs when an insect, arthropod, or rodent is the source of **infection**. Often the source of infection is an animal reservoir and the vector serves as an intermediate in the chain of infection. In the case of Lyme disease, the vector is a deer tick that transmits the spirochete *Borrelia burgdorferi* from deer to humans. **Malaria** is spread by the bite of female *Anopheles* mosquitoes infected with the protozoan *Plasmodium*. Rodents may also act as a vector—hantavirus infects many species of wild mice without causing disease but it causes disease in humans who inhale virus particles in aerosolized feces or urine.

Role in human health

There are numerous practices that can be adopted in a home, business, or health care setting in order to reduce the risk of disease transmission. These include:

- **Handwashing:** Good hand hygiene is the simplest and most effective method for preventing hospital-acquired (nosocomial) infections. Antiseptic agents that have both detergent and antimicrobial effects are recommended.
- **Food preparation:** Common causes of food contamination are *Salmonella*, *Staphylococcus aureus*, and *Clostridium perfringens*. To reduce the risk of food-borne illness, it is recommended that food be cooked to a temperature of 74°C (165°F) or greater and then stored at 4°C (40°F) or cooler.
- **Waste disposal:** Serious enteric (intestinal) diseases are common in less developed countries where adequate drainage and treatment of sewage is not available. For example, cholera is often spread in areas where there is no clean water supply or sanitary disposal of sewage.
- **Sterilization:** An object is sterile when it is free of living organisms. There are multiple techniques that can be used to sterilize an object or fluid, including heat (moist or dry), irradiation, chemical treatment, or filtration. It is almost always recommended that critical items (those that enter normally sterile areas of the body) be sterilized.

- **Cleaning and disinfecting:** Cleaning is the physical removal of microbes from an object, while disinfection is defined as treatment to destroy microorganisms (although this does not normally lead to sterile conditions). Semicritical or noncritical items (those that do not enter sterile areas of the body) may be cleaned or disinfected based on the degree of risk of infection.
- **Protective barriers:** The Centers for Disease Control and Prevention (CDC) recommend that universal precautions be used by all health care workers in contact with the body fluids of patients. These precautions include the following: wearing gloves when in contact with the blood, body fluids, mucous membranes, or non-intact skin of patients; wearing masks and/or protective eyewear during procedures that are likely to generate droplets of blood; and placing all disposable sharp items (needles, scalpel blades, etc.) in puncture-resistant containers for disposal.

Dislocations and subluxations

Definition

Dislocation is the displacement of bones that form a joint. A joint is where two or more bones meet. In a dislocation, the surfaces of the bones that normally articulate with each other (i.e., join together to allow movement) no longer line up correctly, and none of the joint surfaces are touching. Subluxation is a partial dislocation, so some contact remains between the joint surfaces.

Description

Ligaments and joint capsules are tough bands of connective tissue that hold the bones together. Muscles and tendons also help strengthen joints. Any event that subjects a joint to unusual force may cause a dislocation by stretching and tearing these supporting structures. This trauma allows one or more of the bones to go out of alignment, so that the articular (joint) surfaces of the bones no longer have their correct relationship with each other. A dislocation may affect any size joint in the body. The most common dislocations of the major joints involve the shoulder, patella (i.e., kneecap), and elbow. The process of restoring the bones to their correct alignment is known as reduction.

Several important problems that may arise from a dislocation require urgent attention. First, the injury is almost always very painful until the dislocation is reduced. Second, the deformity produced by the dislocation may stretch, kink, or tear adjacent major **blood vessels** or nerves. This effect on the neurovascular structures may severely threaten the circulation or nerve function in the more distal part of the limb, and may cause irreversible damage if not corrected in time. Complete dislocation of the knee (i.e., not just the kneecap) is especially dangerous in this regard. A different problem, which particularly affects the hip, is that part of the bone may receive its normal **blood** supply through the joint itself; when the joint dislocates, that part of the bone may lose its blood supply and become ischemic. Finally, hemorrhage and swelling progressively develop in the joint and the surrounding structures, so relocating the bones may become more difficult as time elapses. For all these reasons, prompt reduction of a dislocation is important.

Physicians describe a dislocation by referring to the movement of the more distal of the bones involved. Thus, an anterior dislocation of the shoulder is one in which the humerus shifts anteriorly with respect to the shoulder socket. Additionally, a dislocation may be open or closed.

This x ray shows the dislocation between two bones in a finger. (Photo Researchers, Inc. Reproduced by permission.)

This refers to the skin overlying the joint, meaning that an open injury is one in which the joint surfaces are exposed to the environment outside the body. An open injury creates a serious risk of bacterial **infection** of the joint. In a closed dislocation the skin remains intact.

Causes and symptoms

Common causes of dislocations and subluxations include **falls**, motor vehicle accidents, sports, and horse-play. These activities may apply isolated or combined forces such as stretching, twisting, and compression to the affected joint. The force involved may be as minor as yawning, which may allow the mandible to slip out of the temporomandibular joint. Conditions that predispose to dislocation include:

- shallow or abnormally formed joints
- joints weakened by disease or previous dislocation

- previous joint replacement surgery
- medical diseases that contribute to falls

Diagnosis

History

A thorough history is important to determine:

- the circumstances that led to the injury
- the time at which the injury occurred
- the type of force applied to the joint
- the likelihood of other associated injuries
- other medical and orthopedic history
- medications and allergies
- use of alcohol and illicit drugs
- time of the last oral intake
- tetanus status, if there are any open wounds

Physical examination

The examination must always start with the ABCs of resuscitation: airway, breathing, and circulation. Doctors and nurses must not allow a painful, deformed joint to distract them from potentially life-threatening injuries to the head, neck, chest, or abdomen. The examination of a dislocated joint typically will show deformity, tenderness, and resistance to movement. There may not be visible swelling. The distal neurovascular examination is very important—a dislocation that causes loss of the pulse in a limb is a far greater emergency than one in which the circulation is intact. Also, later exams will determine whether efforts to reduce the dislocation have affected the neurovascular function. The nurse must frequently inspect the injured limb for color, pulse, and function of motor and sensory nerves.

X-ray studies

Standard x-ray pictures of a joint usually will show a dislocation, and may show the additional presence of a fracture or other injury. Occasionally, special views or even advanced techniques such as computerized tomography (CT) may be necessary to demonstrate the problem.

Shoulder dislocation

A shoulder dislocation is a condition in which the head of the upper arm bone (humerus) is dislocated from the socket (glenoid). It can dislocate forward, backward, or downward. The injury is extremely painful, and may happen when throwing an object forcefully. The affected arm will be put in a sling, and instructions for the care of

the injury will be given to the patient. The area should be iced three or four times every day, and the shoulder should be exercised to speed healing and prevent reinjury in the future.

Shoulder separation

A different condition that may be mistaken for a dislocation is acromioclavicular separation, often called AC separation or shoulder separation. This is technically a sprain, involving the stretching and tearing of ligaments that hold the tips of the acromion (i.e., part of the scapula) and the clavicle near each other. Shoulder separation typically results from a direct blow to the top of the shoulder, often in a young man, as may occur in contact sports or a motorcycle accident. The injury is painful, the patient will not want to move the shoulder, and the shoulder may lose its normal contour. The part of the shoulder just beyond the tip of the clavicle will be very tender. Regular x-ray pictures may not demonstrate a widening of the space between these two bony areas.

Knee dislocation

A patellar or patellofemoral dislocation (dislocation of the knee cap) is another common injury. In this condition, the knee cap moves laterally (to the outside of the leg) due to sideways motion of the lower leg while the upper leg is stationary. The injury will present with swelling and **pain** in the knee area. On palpation, the patella is discovered to be in the wrong position. Weakness of the joint makes it more susceptible to reinjury, and certain exercises may be prescribed to strengthen the area. Patellar injury also makes a person more likely to develop arthritis in the joint.

Nursemaid's elbow

Another injury, common only in children between the ages of one to four, is subluxation of the radial head, or Nursemaid's elbow. This condition may also cause damage to the annular ligament. The case of Nursemaid's elbow demonstrates some of the challenges and pitfalls of diagnosing dislocation or subluxation. The cause is a simple, direct pull on the outstretched hand or wrist of a small child; this may occur when dangling a toddler by the hands in play, or when lifting a child who has fallen. The pulling action causes the head of the radius to move slightly out of position at the elbow. Often the caregiver may not associate such an innocent act with the onset of the problem. The child keeps the arm still against the body and cries if someone moves it. Often, the caregiver and even the medical staff will mistakenly believe that the problem lies in the wrist or the shoulder. The nurse and doctor must question the caregiver in detail about the

events leading to the onset of pain. Then, a careful examination will show that even slight supination of the forearm, which rotates the radius, is the motion that causes pain and resistance. X-ray studies are of little use in this condition, because the head of the radius is not displaced enough to appear abnormal.

Treatment

Initial treatment

Immediate treatment of a dislocation involves splinting the affected area. Splinting diminishes pain, protects the joint and nearby structures from further injury, and assists in transporting the patient. The patient may effectively splint the joint by supporting it with the hand; otherwise, the initial care provider may use pillows, a sling, folded cardboard, or other handy material to fit around the area. Application of ice helps control swelling and pain. The patient must receive nothing by mouth, in case anesthesia is necessary. Care providers should remove any rings or other constricting items distal to the site of injury. The patient will appreciate prompt medication for pain.

Emergency department reduction

Successful reduction of many dislocations and subluxations is possible in the emergency department (ED). Often, the physician will order intravenous (IV) medications such as narcotics (i.e., fentanyl) or morphine sulfate (Morphine) and benzodiazepines (i.e., lorazepam [Ativan] or midazolam [Versed]) to relieve pain, sedate the patient, and relax the surrounding muscles. Then the physician will employ a suitable technique of manipulating the joint in order to bring the bones back into alignment.

Operative reduction

Reduction in the ED is not always successful, sometimes due to the patient's severe pain or **anxiety**. In other cases, swelling and entrapment of structures around the joint prevent the bones from returning to their proper position. In these instances, the patient will require **general anesthesia** in the operating room (OR). Also, in cases of open dislocation, the orthopedist usually will take the patient to the OR in order to thoroughly flush contamination from the joint.

Post-reduction care

The pain and limitation of joint movement will improve substantially after successful reduction. After any manipulation the nurse and physician must recheck and document the neurovascular function in the limb. In almost all cases the physician will request repeat x-ray studies in order to demonstrate that the reduction was

KEY TERMS

Anterior—Toward the front of the body.

Benzodiazepines—The class of drugs related to diazepam (Valium), used to relax muscles and cause sedation.

Clavicle—The collarbone.

Distal—Farther from the center of the body.

Humerus—The arm bone, connecting the shoulder and the elbow.

Ischemic—Suffering from lack of arterial blood supply.

Narcotics—The class of drugs related to morphine, used to relieve pain.

Neurovascular—Pertaining to the function of nerves and blood vessels.

Prosthetic—Referring to an artificial part of the body.

Radius—The bone of the forearm which joins the wrist on the same side as the thumb.

Reduction—The restoring of bones to their correct alignment.

Scapula—The shoulder blade.

Splinting—Preventing movement of a joint.

Supination—The twisting motion of the forearm, wrist, and hand that turns the palm upward.

Temporomandibular—Relating to the meeting point of the skull and the lower jaw.

successful. The physician will usually order pain medicine and a splint or support for the injured area. Most patients will be able to go home after reduction of a dislocation, although a patient who receives heavy sedation or anesthesia may require several hours of recovery before discharge. The nurse will need to instruct the patient and caregivers regarding:

- allowable movement of the injured area
- proper application of a splint or other support
- use of ice (**Heat treatments** are contraindicated in acute and subacute stages.)
- dosing and side effects of medications
- warning signs of impending problems with neurovascular function
- plans for follow-up appointments

Prognosis

Almost all patients who have a dislocation will need follow-up with an orthopedist. The injured ligaments and other joint structures may require many weeks to heal. Exercises and **physical therapy** will help improve function and decrease pain. Recurring dislocation or persistent loss of function may lead to surgical reconstruction, or even replacement of a joint.

Numerous factors influence the ultimate outcome of a dislocation. These include:

- extent of the original injury to the joint
- presence of associated injuries
- time delay to reduction of the dislocation
- the patient's prior overall fitness as well as previous function of the affected joint
- the patient's motivation to **exercise** and strengthen the injured area
- the patient's ability to modify behavior and avoid re-injury

For some patients, especially athletes, decrease in limb function and time lost from normal activities may jeopardize career prospects and future earning potential. The patient, family, or coaches may put pressure on the doctor and support staff for a rapid and complete recovery, although this may not always be possible.

Health care team roles

Emergency medical technicians perform initial rescue, begin to stabilize the patient, splint the injured area, and transport the patient to the hospital. The nurse receives the patient at the ED, performs further assessment, and orders x-ray tests directly or after consulting with the physician, depending on local policies. Later, the nurse carries out orders for medications and other treatments as directed by the physician, monitors the patient throughout the hospital stay, and prepares the patient for discharge. The aide assists the nurse.

A radiology technician performs the x-ray studies ordered by the doctor or nurse. Later, a social worker may help coordinate care after discharge. The physical therapist works to rehabilitate the patient through exercise, massage, and other treatments. A certified athletic trainer (ATC) is sometimes employed in an effort to reduce the possibility of repeated injury in susceptible persons.

Prevention

Prevention of dislocations and subluxations starts with awareness of inherently dangerous activities (e.g., riding motorcycles, climbing ladders, consuming alcohol) and avoidance of behavior that may cause specific injuries (e.g., crossing the legs for prosthetic hip dislocation, pulling toddler by hand for Nursemaid's elbow). Participants should use appropriate protective equipment for work or sports, maintain good overall fitness, and allow sufficient time for healing of a previously injured body part before resuming full activity.

Diverticulitis see **Diverticulosis and diverticulitis**

Diverticulosis and diverticulitis

Definition

Diverticulosis is a condition in which the inner layer of the colon herniates (bulges out) through the outer, muscular layer, creating pouches called diverticula. Diverticulitis refers to inflammation and **infection** in one or more diverticula.

Description

Diverticula tend to occur most frequently in the last segment of the **large intestine**, the sigmoid colon. They occur with decreasing frequency toward the beginning of the colon. The chance of developing diverticula increases with age, so that by the age of 50, about 20–50% of all people will have some diverticula. By the age of 90, virtually everyone will have developed some diverticula. Most diverticula measure about 3 mm (0.19 inches) to just over 3 cm (1.18 inches) in diameter. Larger, or giant diverticula, are extremely rare, but may measure as large as 15 cm (5.9 inches) in diameter.

Causes and symptoms

Diverticula are believed to be caused by overly forceful contractions of the muscular wall of the large intestine, often caused by straining to produce a bowel movement. As areas of this wall spasm, they become progressively weaker, allowing the inner lining to bulge through. The anatomically weakest areas of the intestinal wall occur next to **blood vessels** which course through the wall, so diverticula commonly occur in this location.

Diverticula are most common in the developed countries of the West (North America, Great Britain, northern and western Europe). This is thought to be due to the diet of these countries, which tends to be low in fiber. This produces smaller volumes of stool. In order to move this smaller stool along the colon and out of the rectum, the colon must narrow itself significantly, and does so by contracting forcefully. This causes an increase in pressure, which, over time, weakens the muscular wall of the intestine and allows diverticular pockets to develop.

The origin of giant diverticula development is not completely understood; one theory involves gas repeatedly entering and becoming trapped in an already existing diverticulum, causing it to stretch and expand.

The great majority of people with diverticulosis will remain symptom-free. Many diverticula are incidentally discovered during examinations for other conditions of the intestinal tract.

Some patients with diverticulosis have symptoms such as constipation, cramping, and bloating. It is unclear whether these symptoms are actually caused by the diverticula themselves, or whether some other gastrointestinal condition, such as irritable bowel syndrome, might be responsible. Because many diverticula develop in areas near **blood vessels**, one serious, although infrequent, risk of diverticulosis is intestinal bleeding. Seventy-five percent of such bleeding episodes occur in diverticula located on the right side of the colon. About 50% of the time the bleeding will stop on its own.

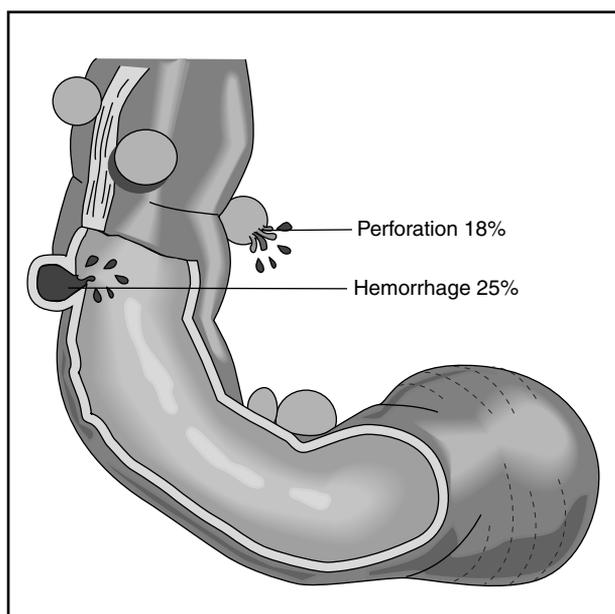

Illustration of diverticula in the sigmoid colon. Diverticulosis is almost always located in the descending or sigmoid colon. (Delmar Publishers, Inc. Reproduced by permission.)

One of the most common and potentially serious complications of diverticulosis is inflammation and infection of a particular diverticulum, a condition called diverticulitis. Diverticulitis is usually found in the sigmoid colon, the final segment of the large intestine that empties into the rectum where most diverticula are found. Older adults have the most serious complications from diverticulitis, although very severe infections also may occur in patients under the age of 50. Men are three times as likely as women to be stricken with diverticulitis.

Diverticulitis is believed to occur when a hardened piece of stool, undigested food, and **bacteria** (called a fecalith) becomes lodged in a diverticulum. This blockage interferes with the blood supply to the area, and infection sets in.

The patient with diverticulitis experiences **pain** (especially in the lower left side of the abdomen) and **fever**. In response to the infection and the irritation of nearby tissues within the abdomen, the abdominal wall muscles may begin to spasm. About 25% of all patients with diverticulitis have some rectal bleeding, although this rarely becomes severe. Abscesses (pockets of infection) may appear within the wall of the intestine, or even on the exterior surface of the intestine. When a diverticulum weakens sufficiently, and is filled to bulging with pus, a perforation in the intestinal wall may develop. When the infected contents of the intestine spill into the abdomen, peritonitis may occur. Other complications of

diverticulitis include the formation of fistulas and colonic strictures.

Diagnosis

The majority of diverticula do not cause any symptoms, and are often found during an examination being performed for some other medical condition. When diverticula are suspected because a patient begins to have sudden rectal bleeding, the location of the bleeding can be identified with **colonoscopy**. In this procedure a colonoscope, a small, flexible tube, is inserted through the rectum and into the colon. The tip of the scope has a fiber-optic camera, which allows the view through this colonoscope to be projected onto a television screen. The operator can introduce the colonoscope through the entire colon to find the source of the bleeding.

Angiography can also trace the source of intestinal bleeding, although it is used less often. It involves inserting a tiny tube through the femoral artery in the groin, and advancing it into one of the major arteries that supplies the colon. Contrast medium that will appear on x-ray films is injected, and the area of bleeding is located by looking for an area where the contrast is leaking into the lumen of the colon.

Diagnosis of diverticulitis is not difficult in patients with previously diagnosed diverticulosis. The presence of left-lower quadrant abdominal pain and fever in such patients should prompt suspicion of diverticulitis. Examination of the abdomen will usually reveal tenderness to touch, with the patient's abdominal muscles contracting strongly to protect the tender area.

During a rectal exam, the clinician may be able to feel an abnormal mass if there has been perforation and **abscess** formation at the site of the perforation. Palpating this mass may prove painful to the patient.

When diverticulitis is the suspected cause of the patient's symptoms, tests traditionally used to diagnose colonic disorders such as **barium enema** and endoscopy are contraindicated during the acute phase of the illness. The concern is that the increased pressure exerted on the colon during these exams may increase the likelihood of perforation of the diverticula. After several weeks, when the diverticulitis has resolved, these examinations may be performed in order to confirm the diagnosis and extent of the disease.

Treatment

Only about 20% of patients with diverticulosis experience symptoms that prompt them to seek medical care. Most people never know that they have diverticula. For those individuals with cramping pain and constipation

due to diverticulosis, the usual treatment involves increasing the fiber in the diet. This may be done with dietary supplements of bran or psyllium seed to increase stool volume, or by increasing the patient's intake of fruits, vegetables, legumes, and whole-grain foods. Bleeding diverticula are usually treated by bed rest, with blood transfusion if needed for hemorrhaging. In cases of very heavy hemorrhaging, medications to encourage clotting may be injected during the course of a diagnostic angiography.

While there are almost no situations when uncomplicated diverticulosis requires surgery, giant diverticula always require removal due to the high risk of infection and perforation. The usual treatment involves removing that portion of the intestine.

Treatment for uncomplicated diverticulitis usually requires hospitalization to rest the bowel. This involves keeping the patient from eating and drinking anything. The patient receives IV (intravenous) fluids and **antibiotics**. Some physicians treat mildly ill patients at home with a liquid-only diet and oral antibiotics.

The complications of diverticulitis need to be treated aggressively, because mortality (death rate) from perforation and peritonitis is quite high. Abscesses may be drained of their infected contents by inserting a needle through the skin of the abdomen and into the abscess. If this is unsuccessful, laparotomy (open abdominal surgery) is required to resect the segment of the colon that contains the abscess. Fistulas require surgical repair by removing a segment of the colon that contains the origin of the fistula, followed by immediate anastomosis (reconnection) of the two free ends of colon. Peritonitis requires open surgery. The entire abdominal cavity is irrigated (washed) with a warmed sterile saltwater solution, and the damaged piece of intestine is removed. Obstructions require immediate surgery to prevent perforation. Massive, uncontrollable bleeding is rare, and may require removal of part or all of the large intestine.

During any of these procedures, the surgeon must decide how much of the intestine must be removed. When the amount of intestine removed is great, it may be necessary to perform a **colostomy**, which involves pulling the end of the remaining intestine through the abdominal wall, to the outside. This bit of intestine is then fashioned so that a bag can be fitted over it. The patient's feces collect in the bag, because the intestine no longer connects with the rectum. The colostomy may be temporary, in which case another operation will be required to reconnect the intestine, after substantial healing has occurred. Otherwise the colostomy is permanent, and the patient must adjust to living permanently with the

colostomy bag. Most patients with colostomies are able to lead full, active lives.

Occasionally, a patient has such severe diverticular disease that the surgeon recommends removal of a portion of the colon as a preventive measure, to avoid the high risk of surgery performed after a complication has set in. It is recommended for patients identified as at very high risk of experiencing dangerous complications of diverticulosis. Such elective surgery may be recommended:

- for older patients who have had several attacks of diverticulitis
- for patients under age 50 who have had even one attack
- when treatment does not get rid of a painful mass
- when the intestine appears to be strictured on colonoscopic or barium enema (This could suggest the presence of cancer.)
- when certain patients begin to regularly experience painful urination or urinary infections (this suggests that there may be a connection between the intestine and the bladder)
- when there is any question of **cancer**
- when the diverticular disease appears to be progressing rapidly

Prognosis

The prognosis for people with diverticula is excellent, with only 20% of such patients ever seeking any medical care for their condition.

While diverticulitis can be a difficult and painful disease, it is usually quite treatable. Prognosis is worse for individuals who have coexisting medical problems, particularly those requiring the use of steroids, which increase the chances of developing a serious infection. Prognosis is also worse in the elderly.

Health care team roles

Diverticulitis and diverticulosis are often diagnosed by primary care practitioners and gastroenterologists during the course of examinations for other problems. In some instances, patients may require surgical intervention. Imaging studies to assist in diagnosis are performed by x-ray technologists; laboratory technologists may be involved in obtaining blood and stool samples for analysis.

Patient education

Nurses, dietitians, and nutritional counselors have important roles in teaching patients about dietary

KEY TERMS

Angiography—An x-ray study of the arteries in a particular part of the body. Angiography is often performed in order to localize internal bleeding.

Bowel obstruction—A blockage in the intestine which prevents the normal flow of waste down the length of the intestine.

Colonic stricture—Strictures that form after a bout of diverticulitis resolves, leaving scar tissue that narrows the colon lumen.

Colostomy—A procedure performed when a large quantity of intestine is removed. The end piece of the intestine leading to the rectum is closed.

Diverticula—Outpouchings in the large intestine caused when the inner, lining layer of the large intestine (colon) bulges out (herniates) through the outer, muscular layer.

Endoscopy—Examination of an area of the gastrointestinal tract by putting a lighted scope, usually bearing a fiber-optic camera, into the rectum, and passing it through the intestine.

Fistula—An abnormal connection formed between two organs which usually have no connection whatsoever (e.g. the colon and bladder).

Peritonitis—A potentially life-threatening infection and inflammation of the lining of the abdominal cavity, the peritoneum.

Sigmoid colon—The final portion of the large intestine which empties into the rectum.

changes to prevent these conditions. Nurses, social workers, and ostomy specialists also may be involved in educating patients pre- and postoperatively about **colostomy care**.

Prevention

While there is no absolutely certain way to prevent the development of diverticula, it is believed that high-fiber diets are beneficial. Foods recommended for their high-fiber content include whole-grain breads and cereals, and all types of fruits and vegetables. Most experts suggest that individuals consume about 20–35 grams of fiber daily. If this is not possible to achieve through diet, there are fiber products that can be mixed into 8 ounces of water or juice, and which provide about 4–6 grams of fiber per dose.

DNA typing

Definition

DNA typing is a laboratory procedure that detects normal variations in a sample of DNA (deoxyribonucleic acid). DNA typing is most often used to establish identity, parentage, family relationship and appropriate matches for transplantation of organs and tissues.

Description

DNA

DNA is a molecule that stores genetic information required for the development of the body and the control of cellular processes. Each strand of DNA is made of individual nucleotides that are joined together. Each nucleotide is made up of a phosphate group, a five-car-

bon sugar (deoxyribose), and an organic base. Adenine, thymine, guanine, and cytosine are the four bases found in DNA. The sequence of bases in DNA determines the genetic code of an individual. Every person excluding identical twins has a different sequence of bases.

The DNA sequence is made up of coding and non-coding regions. A coding region is a section of DNA, called an exon, that contains the instructions for the production of a particular protein. The primary structure of **proteins** is determined by the sequence of bases in the exons of a gene. Exons are located within the genes but are separated by non-coding regions called introns. Genes make up about 5% of human DNA and the other 95% consists of non-coding regions. The function of the non-coding regions is for the most part unknown.

Normal variations can occur in the DNA sequence of the coding and non-coding regions. Sequence polymorphism and length polymorphism are the two main forms of DNA variation. Sequence polymorphism results from differences in the sequence of bases at a particular locus. A locus is a specific location on a DNA molecule. Length polymorphism results from differences in the length of DNA at a particular locus. Differences in the length of the DNA are due to variations in the number of times that a certain sequence of bases is repeated. The number of times that a certain sequence is repeated at a specific locus will often vary between individuals. A locus that has a repeated unit of nine to ninety-eight bases is called a variable number tandem repeat locus (VNTR) or minisatellite. Loci that have a repeating unit of only two to seven bases are called short tandem repeats (STRs) or microsatellites. For example CAGACAGACAGA is an STR of four bases that is repeated three times.

Nuclear and mitochondrial DNA

Two strands of single stranded DNA wind together to form double stranded DNA in the form of a double helix. The DNA strands are held together by hydrogen bonds that form between the bases. Adenine joins with thymine and guanine joins with cytosine. Two sequences are said to be complementary if they have a sequence that allows them to join together to form double stranded DNA.

Most DNA is packaged with proteins to form microscopic structures called chromosomes. Chromosomes are found in the nucleus of each cell of the body and can be visualized under the **microscope**. Each cell of the body, except for the egg and the sperm cells, normally contains 22 pairs of chromosomes and two sex chromosomes (46 chromosomes in total). The egg and sperm cells each contain 23 chromosomes.

DNA is also found in the mitochondria. The mitochondria are energy producing organelles found in most cells. There are many mitochondria found in each cell. Each mitochondria contains one copy of circular DNA. Since there are many mitochondria in each cell, a lot of mitochondrial DNA may be present in only a small sample of cells. Mitochondrial DNA is found in the egg cells but not the sperm cells. Mitochondrial DNA is, therefore, only passed down from a mother to her offspring.

Methods of DNA typing for identity, parentage, and family relationships

RESTRICTION FRAGMENT LENGTH POLYMORPHISM (RFLP) ANALYSIS. RFLP analysis was the first technique used for forensic DNA typing. During RFLP analysis, DNA that has been isolated from a sample is cut into short sections by an enzyme called a restriction endonuclease. An enzyme is selected that will make a cut in the DNA at a specific sequence of bases on either side of a VNTR locus. This results in different sized fragments of DNA. Different people will have fragments of DNA of different lengths due to differences in the number of repeating units at a particular DNA locus. After the DNA is cut into pieces, the fragments are separated according to size by a process known as gel electrophoresis. DNA fragments are negatively charged at an alkaline pH owing to the phosphate groups. The smaller the fragment, the faster it will migrate to the positive electrode (anode). After separating the DNA fragments, the gel is soaked in a solution of sodium hydroxide and sodium chloride which separates the double stranded DNA into single stranded DNA, a process called denaturation. The single stranded DNA is transferred from the gel to a nylon membrane. A piece of DNA called a probe is added to the DNA that is affixed to the membrane. The probe will attach to a section of DNA on the membrane that has a complementary base sequence. The probe chosen corresponds to a specific locus that has a variable number of repeats containing the bases complementary to the probe. Either a fluorescent or radioactive material is bound to the probe so that it can be visualized. Either one or two bands will be visualized for each probe used. If the person has inherited the same length DNA fragment at a locus from both parents then only one band will be seen. If two different sized DNA fragments are inherited then two bands will be visualized. The DNA is analyzed using a panel of probes each specific for a different locus. A DNA type is made up of a pattern of different sized bands at different loci. The frequencies of the VNTRs that are inherited at each locus determines the probability of a DNA match.

POLYMERASE CHAIN REACTION (PCR). PCR based STR analysis is a more modern approach to DNA typing. The first step of the process is to isolate DNA from a

sample of tissue such as **blood** or semen. The isolated DNA, called the template, is mixed with a heat-stable form of DNA polymerase (e.g., Taq polymerase), deoxynucleotide triphosphates, and DNA primers. These reagents are suspended in a buffer and together are called the master mix. The template and master mix are added to a tube and the tube is placed into an incubator called a thermal cycler. The purpose of the thermal cycler is to control the temperature of each of the three phases of DNA amplification.

The first step in PCR is denaturation. This is accomplished by heating the mixture to 94°C, which separates the strands. After denaturation, the temperature of the thermal cycle is automatically lowered to 64°C. The primers are short sequences of DNA that can bind to one of the DNA strands on either side of the target sequence to be amplified. Four primers are required for each section of DNA that is being analyzed. The primers are selected so that they flank an STR region. The binding of the primers to complementary base sequences on the target DNA is called annealing, and requires a lower temperature. After the annealing step, the temperature is increased to 72°C, which is the optimal temperature for DNA polymerase. Once the primers have annealed, the DNA polymerase binds to single stranded DNA between the primers and fills in the sequence with the deoxynucleotide triphosphates. This results in synthesis of a new piece of double stranded DNA consisting of the STR locus and the primer regions. This process is called primer extension. After extension, the new double strands of target DNA are denatured by heating the mixture to 94°C again. After a suitable incubation, the temperature is lowered to 64°C to facilitate annealing of primers, and then is adjusted to 72°C for extension of new complementary strands. Each cycle increases the number of DNA pieces containing the STR locus. Each time this process is repeated the amount of target DNA doubles. After 20 cycles (about two hours) there will be over one million identical copies of the STR locus. DNA typing for identification, parentage and familial studies uses probes that encompass various STR loci. If a person has inherited the same number of repeats from his or her mother and father, then only one band will appear for that locus. If the person has inherited a different number of repeats from his or her mother and father, then two bands will be seen for that locus.

DNA typing to establish identity, parentage, and family relationship

DNA typing used for identification purposes and the establishment of parentage and family relationships looks for variation within the non-coding regions of the

DNA. It relies on the presence of length polymorphisms such as VNTRs and STRs.

DNA typing determines the number of times that a particular sequence is repeated at a particular locus. DNA typing usually analyzes the number of repeats at four or more separate loci. The loci chosen for DNA typing have a high degree of variability and are usually found on different chromosomes.

It is possible that two unrelated individuals will possess the same number of repeats at a particular locus. It is less likely, however, that two unrelated individuals will have the same number of repeats at a number of different loci. In order to determine the possibility that a match in DNA types occurred by chance, the frequency of the determined number of repeats in the individual's ethnic group is calculated. For example, if the frequency of the repeat number in the ethnic group is 1 in 10,000, then there is a 1 in 10,000 chance that the match occurred by chance. By using a number of different loci, one can decrease the chances that the match occurred by chance and increase the chances that the two DNA samples are from the same individual. While it is mathematically impossible to prove that two samples are identical using this procedure, it is possible to prove absolutely that two samples are not identical. This occurs when a different number of repeats is found at a locus.

Mitochondrial DNA typing may be performed if nuclear DNA typing is not successful or when there is insufficient nuclear DNA for typing. It is also sometimes used to help establish maternity. Variations in mitochondrial DNA are typically discovered by sequencing (determining the order of bases).

PARENTAGE AND FAMILY RELATIONSHIP. DNA typing used for establishment of parentage and family relationships uses either RFLP analysis or PCR based STR analysis. DNA typing is the method most often used to establish paternity. It may also be used to establish parentage in cases where neonates have been mistakenly switched in the nursery. DNA typing can be used to resolve immigration cases when family relationships are disputed.

The basis for DNA typing in parentage and family relationship cases is that each child inherits one of each chromosome from their mother and one of each chromosome from their father. The child should, therefore, inherit a set number of repeats at a particular locus from their mother and a set number of repeats at that locus from their father. At some loci they may inherit the same number of repeats from their mother and from their father. During parentage analysis the number of repeats found at different loci is compared between the child and the alleged parent. It is helpful, but not absolutely necessary,

to perform DNA typing on the known parent as a comparison. Sometimes the DNA of siblings and other family members will also be typed for comparison. If the alleged parent is the true biological parent, then at each locus analyzed, the child should have the same repeat number as the parent. Since a match can occur by chance it is necessary to calculate the frequency of the repeat number in the alleged parent's ethnic group. Usually when a match is found the chance of parentage is greater than 99%. For example a 1/1000 chance that the match occurred by chance corresponds to a 99.9% chance that the alleged parent is the true biological parent.

If the alleged parent's repeat numbers do not match with the child's repeat numbers then parentage can usually be ruled out. What can make this analysis tricky is that sometimes a small alteration can occur in the DNA of the child that is not present in the parent. This can cause the child to have a different repeat number than their true parent at a specific locus. It is therefore important that more than one loci be analyzed.

Forensic and non-forensic identification

Modern day DNA typing for identification purposes usually uses PCR and STRs rather than RFLP analysis. DNA typing can be used to help identify a victim of a homicide. The DNA type of the victim can be compared to the DNA types of alleged family members to see if there is a match. DNA typing has also been used to identify soldiers killed in battle. The U.S. Department of Defense has a collection of tissue samples from soldiers so that, if necessary, they can be identified through DNA typing.

DNA typing can also help to determine whether a suspect was at a particular crime scene. DNA can be isolated from tissue such as skin, blood, hair and semen left at the scene. The DNA type of the sample at the crime site can be compared to the DNA type of the suspect. If there is a difference in the DNA type at any locus then the DNA obtained is definitely not from the suspect. If the DNA type is identical at all loci then the probability that this occurred by chance must be determined.

Transplantation matches

DNA typing for transplantation matches looks at normal variation in the coding region of the DNA. DNA typing can be used to identify an appropriate match for a transplant such as a bone marrow transplant. A successful transplant requires a close match of human leukocyte (HLA) antigens between donor and recipient. The HLA antigens are proteins that are located on the surface of most cells. There are six subregions on chromosome number six that each contain at least one HLA locus. The

subregions are divided into two classes. HLA-A, HLA-B, and HLA-C comprise Class I and HLA-DR, HLA-DP, and HLA-DQ comprise class II. Each subregion has at least one gene that has a number of different genetic variants (allels). The HLA gene products mediate the recognition and the destruction of foreign cells such as **bacteria** and **viruses**. They also mediate the destruction (rejection) of transplanted cells that do not express the same HLA alleles as the recipient. Therefore, a transplant from a donor with very different HLA antigens is likely to be rejected by the body's **immune system**. Conversely, if the donor and recipient have a close HLA match then the transplant has a better chance of being successful.

DNA typing looks for characteristic sequence differences in the genes that produce the HLA antigens. For example, there are more than fifty HLA-A variants. Each HLA-A variant is produced by a different gene. The HLA variants inherited by an individual can be determined by extracting DNA from blood cells and using PCR to amplify the HLA loci. Specific primers or probes are used to identify the variants for each of the six subregions.

Viewpoints

Early use of DNA typing for forensic evidence was marred by technical difficulties. By the year 2001, however, DNA typing techniques had improved considerably and had become highly accurate tools for forensic evidence. DNA typing evidence is now widely used in most North American and European courts. The quality of the evidence is still dependent, however on the methodology used, the number of loci examined and the quality of the laboratory where the typing is performed. Contamination of the DNA sample collected from the crime site is also a concern if proper techniques are not followed.

The increasing use of DNA typing has led to the formation of databases that contain DNA typing information. DNA data banks of convicted criminals exist in each of the 50 states and in many other countries. The FBI has also created a national DNA data bank of convicted criminals called CODIS (combined DNA index system). These DNA data banks require convicted felons to donate blood samples for DNA typing prior to parole. The type of felonies for which DNA typing is required varies from state to state. It is anticipated that most laws will be amended to require DNA typing of all convicted felons. It is also possible that laws may be enacted to force all people arrested for a crime to donate a DNA sample to the database.

Many countries obtain DNA samples from ordinary citizens when trying to eliminate suspects of a particular

KEY TERMS

Amniocentesis—Prenatal testing performed at 16-20 weeks of pregnancy which involves inserting a needle through the abdomen of a pregnant mother and obtaining a small sample of fluid from the amniotic sack. Can be used to obtain a sample of the baby's cells for DNA typing.

Antibody—Protein produced by the body in response to the presence of a foreign antigen.

Antigen—A substance that induces an immune response.

Chorionic villus sampling (CVS)—Prenatal testing performed at 10-12 weeks of pregnancy which involves inserting a catheter through the vagina of a pregnant mother or inserting a needle through the abdomen of the mother and obtaining a sample of placenta. Can be used to obtain a sample of cells for DNA typing.

Chromosome—A microscopic structure, made of a complex of proteins and DNA, that is found within each cell of the body.

DNA (deoxyribonucleic acid)—The hereditary material that influences the development and functioning of the body.

Eugenics—A discredited movement which attempts to improve the human race by preventing the creation of offspring in individuals with undesirable traits and promoting the creation of offspring in those with desirable traits.

Forensic—Related to or used in the courts of law.

Gene—A functional segment of DNA that contains the instructions for the production of a particular protein. Each gene is found on a specific location on a chromosome.

HLA typing—The determination of the type of human leukocyte antigens possessed by an individual.

Locus—Specific physical location on a DNA molecule.

Nucleus—A membrane bound spherical structure that contains the chromosomes and is found in most cells.

Polymorphism—Genetic variation.

STR (short tandem repeats)—A locus of DNA that has a repeating unit of two to seven bases.

VNTR (variable number tandem repeats)—A locus of DNA that has a repeating unit of 9 to 98 bases.

crime. For example DNA samples may be collected on hundreds of men in a rural area where a sexual assault has occurred. Although citizens are not required by law to donate their DNA, it is likely that they experience a great deal of social coercion. The United States does not currently allow DNA typing of those who are not convicted of a crime. There are concerns, however, that the databases could be expanded to include all citizens and be used as a method of identification similar to a social security number.

Commercial databanks exist which store DNA samples or DNA typing results of children. If the child is later kidnapped then DNA samples obtained from such items as gum and licked stamps can be used to try and locate and identify the child. Some people would argue that these databanks are unnecessary since a child's DNA type can be deduced from that of other family members should it become necessary. This stored information could also be used later as evidence against the child. If the commercial data bank becomes bankrupt or changes ownership then there may be concerns about the control, availability and ownership of the DNA. In addition, issues of non-paternity can be discovered during this process.

The existence of DNA databanks raise concerns about privacy and discrimination. There is a concern that DNA typing may yield other unintended genetic information about the individual and his or her family. There has been some discussion about donating DNA samples that have been collected for forensic DNA typing to researchers. This research could yield very specific genetic information on the individual. There is a concern that the genetic information obtained could be used for discriminatory purposes. For example, the information could result in the discrimination of citizens by employers and health insurance companies.

Professional implications

DNA typing results often become evidence in a court of law. It is, therefore, important that health care professionals involved in collecting samples for DNA typing follow strict protocols that prevent contamination and insure that samples are obtained from the correct person. It is also important that a chain-of-evidence is established. A chain-of-evidence documents who has handled the evidence and when it was transferred to another person. A chain-of-evidence can help to demonstrate that evidence was not altered prior to its introduction in court. Often, laboratories that perform DNA typing for parentage have kits designed to insure that proper protocols are followed. They may also have designated blood collection centers that will obtain the samples required for DNA typing. Many hospitals have specific protocols,

kits, and chain-of-evidence procedures in place to insure that samples for DNA typing are collected and handled properly. In some cases special training programs are offered to health care professionals who are involved in collecting samples for DNA typing used as forensic evidence.

It is important that health care professionals try to help prepare their patients for paternity test results since the results can sometimes be unexpected and can often be quite devastating. It can be helpful to explore the motivation behind the testing and discuss the implications of possible test results. The limitations of the testing should also be adequately discussed. The quality of the laboratory chosen for paternity testing should also be evaluated.

Some health care professionals may be called upon to offer paternity testing prenatally. The patient needs to be informed about the risks of losing a normal **pregnancy** if prenatal testing methods such as **amniocentesis** and **chorionic villus sampling** are performed. It is also typically more expensive to perform paternity testing prenatally. Many patients when provided with complete information about prenatal paternity testing choose to have the tests performed after the child is born.

Echocardiography

Doppler ultrasonography

Definition

Doppler ultrasonography, also called Doppler ultrasound, is a noninvasive diagnostic procedure that uses an ultrasound scanner to convert sound waves into images of **blood** flow in body tissue and organs. Doppler ultrasonography does not use ionizing radiation and is used for a variety of clinical applications.

Purpose

Doppler ultrasonography is used during an ultrasound examination to assess the direction, velocity, and turbulence of blood flow. It is frequently used in cardiac and vascular scanning to evaluate blood flow and diagnose abnormalities in flow. Cardiac applications include the detection of **heart** valve problems, the determination of arterial vessel narrowing (stenosis) or blockage, the diagnosis of congenital cardiac defects, and the evaluation of damage following **myocardial infarction** (heart attack). Vascular applications include the work-up of stroke patients, the assessment of blood flow in the major abdominal arteries, and the evaluation of vessels in the arms, legs, and neck. Vascular conditions that can be diagnosed using Doppler ultrasonography include deep vein thrombosis (DVT), a blocked carotid artery, blood clots, tumors with vascular involvement, and abdominal aortic aneurysm. Doppler ultrasonography can also be used to determine whether a patient is a candidate for a surgical or other interventional procedure, such as vascular grafting, or it can be used during and after cardiac and

A physician can monitor blood flowing through a patient's carotid artery using the Doppler technique. (*Science Source/Photo Researchers. Reproduced by permission.*)

vascular surgical procedures to assess blood flow and the success of the procedure. In obstetric ultrasound, Doppler ultrasonography is used to check fetal cardiac activity.

Doppler ultrasonography can be performed in a hospital radiology or cardiology department, a hospital vascular laboratory, at the patient's bedside, in the emergency department, in an operating room, or in an outpatient imaging center, depending on the patient's medical condition. Doppler ultrasonography is a noninvasive, safer, and faster alternative to x-ray **angiography**, which involves radiation exposure, the injection of a contrast dye, and catheterization of **blood vessels**, although ultrasound may not yield images that are as detailed as those from x rays during catheterization.

A new device introduced in 2000 combines Doppler ultrasonography with endoscopy. The Doppler ultrasound scanner is interfaced with an endoscopy system, and the Doppler ultrasound images can be simultaneously displayed with the endoscopic images on one monitor, like a picture-in-picture display. Clinical applications include the evaluation of ulcers and hemorrhaging, vascular abnormalities of the intestinal tract, and enlarged vessels in the digestive tract, as well as assessment during endoscopic surgical procedures.

Precautions

The test is widely used because it is noninvasive, uses no x rays, and gives excellent images. It is harmless, painless, and widely available.

Because smoking can cause constriction of blood vessels, patients should not smoke before an ultrasound examination of the blood vessels.

Description

Doppler ultrasonography is performed using an ultrasound scanner with Doppler imaging capabilities; most scanners used for general-purpose abdominal, cardiac, and vascular scanning are equipped with Doppler. Ultrasonography involves the use of sound waves above the level of human **hearing**, and works similarly to sonar or radar. Sound waves are transmitted through the body and echoed back to produce an image of the area of interest. Ultrasound waves used for diagnostic imaging are typically in the range of 2 to 10 megahertz (MHz).

Doppler ultrasonography uses the frequency shift caused by the Doppler effect to produce images of blood flow. The Doppler effect is a principle of physics involving light and sound; relative to an observer, the frequency of any light or sound wave will vary as the source of the wave approaches or moves away. With regard to medical ultrasound, the Doppler principle states that sound waves increase in frequency when they echo from objects (in this case, red blood cells) moving toward the transducer and decrease in frequency when they echo from objects moving away from it. This change in frequency, which is related to the velocity of the moving red blood cells, is then measured and used to determine blood flow velocity. Therefore, Doppler imaging allows the frequency of the speed of blood flow to be calculated relative to a computer marker placed by the sonographer.

There are several different modes of Doppler ultrasound. Most ultrasound scanners include both continuous- and pulsed-wave Doppler. Continuous-wave Doppler is the simplest mode, and is commonly used in cardiac studies for blood flow analysis. This mode receives flow information from all the moving reflectors in the path of the beam and can provide maximum velocity through the target area. Pulsed-wave Doppler allows the operator to select the area of interest for flow analysis using cursors superimposed on the 2-D image. Depth-selective information is obtained by acoustic pulses emitted from the transducer, allowing the precise location of the target area, as well as the flow, to be determined. Most ultrasound scanners also have color Doppler imaging capability, which superimposes color over moving structures on the gray-scale images. For example, red and

yellow in a blood vessel image indicate flow away from the probe, while blue and green indicate flow toward the probe. Color Doppler imaging can be used to identify areas of arterial narrowing. Another Doppler feature is power Doppler, which is more sensitive than color Doppler imaging and can produce images of structures not normally able to be depicted with ultrasound, for example, inflammation or signs of congenital heart disease in a fetus. Power Doppler mode may only be included on advanced ultrasound scanners.

During an ultrasound examination, the patient is positioned on a bed or table so the area to be imaged can be easily accessed. An acoustic coupling gel, a special gel that enhances the transmission of ultrasound waves, is spread on the skin over the area of interest. A handheld ultrasound probe with a transducer (a crystal that transmits and receives the sound waves) is placed on the skin and positioned appropriately to acquire images of the blood vessels. Usually gray-scale images, which use different shades of gray to indicate differences in the strength of echoes (echoes from blood are of lower strength and appear darker than surrounding tissue) are acquired first, and then the Doppler mode is selected to acquire Doppler images that are superimposed over the gray-scale images. The sonographer is able to use the scanner's computer to mark areas and calculate parameters of interest, such as blood flow velocity in vessels with narrowing or blockage. Ultrasound scanners are usually equipped with a videotape recorder or digital image acquisition system to record the Doppler examination, as well as a medical image printer for hard copies of still images.

Preparation

There is no special preparation needed for this test, other than removing clothing and jewelry covering the area to be imaged.

Aftercare

No special aftercare is necessary.

Results

A Doppler ultrasonography test that shows no restricted blood flow or other abnormalities is a normal finding.

Findings indicating restricted blood flow or other cardiovascular abnormalities are abnormal results. Disrupted or obstructed blood flow through the carotid artery or other neck arteries may indicate the person is at risk of having a stroke. Narrowed arterial flow or clots in

KEY TERMS

Angiography—During cardiac catheterization, the procedure of acquiring x rays of the heart and coronary arteries after injection of a radiopaque substance (often referred to as a dye or contrast agent).

Catheter—A flexible or preshaped curved tube, usually made of plastic, used to evacuate or inject fluids into the body. In cardiac catheterization, a long, fine catheter is inserted through a blood vessel into the chambers of the heart.

Doppler imaging—A mode of ultrasound imaging that uses the physics principle of the Doppler effect (sound frequency waves shift relative to the observer, allowing velocity measurement) to produce color or gray-scale images of blood flow velocity and heart motion.

Endoscopy—A minimally invasive procedure that uses a scope with a camera on the end to examine the inside of a body cavity or organ.

Grafting—Implantation of a biological or artificial portion of a blood vessel to repair the vessel and restore flow. Doppler ultrasound is used to evaluate the patency of the grafted area.

Noninvasive—Pertaining to a diagnostic procedure or treatment that does not require the skin to be broken or a body cavity to be entered.

Transducer—A device that converts electrical signals into ultrasound waves and ultrasound waves back into electrical impulses, also called a probe.

Ultrasound—Sound waves at high frequencies beyond the level of human hearing; frequencies of approximately 2 to 10 megahertz are often used for diagnostic imaging.

the legs may also be imaged. Abnormal findings are then used to plan further diagnostic tests and/or treatment.

Health care team roles

Doppler ultrasonography is performed by an ultrasonographer with special training in ultrasound techniques, particularly cardiac and vascular imaging. The sonographer should be a registered vascular technologist or a registered cardiac sonographer. A radiologist, cardiologist, or other physician experienced in ultrasound imaging techniques interprets the ultrasound examination results. During some examinations, the sonographer may

print out images and consult with the radiologist or cardiologist; alternatively the radiologist or cardiologist may perform some of the scanning.

Down syndrome

Definition

Down syndrome is the most common chromosome disorder and genetic cause of mental retardation. It occurs because of the presence of an extra copy of chromosome 21. For this reason, it is also called trisomy 21.

Description

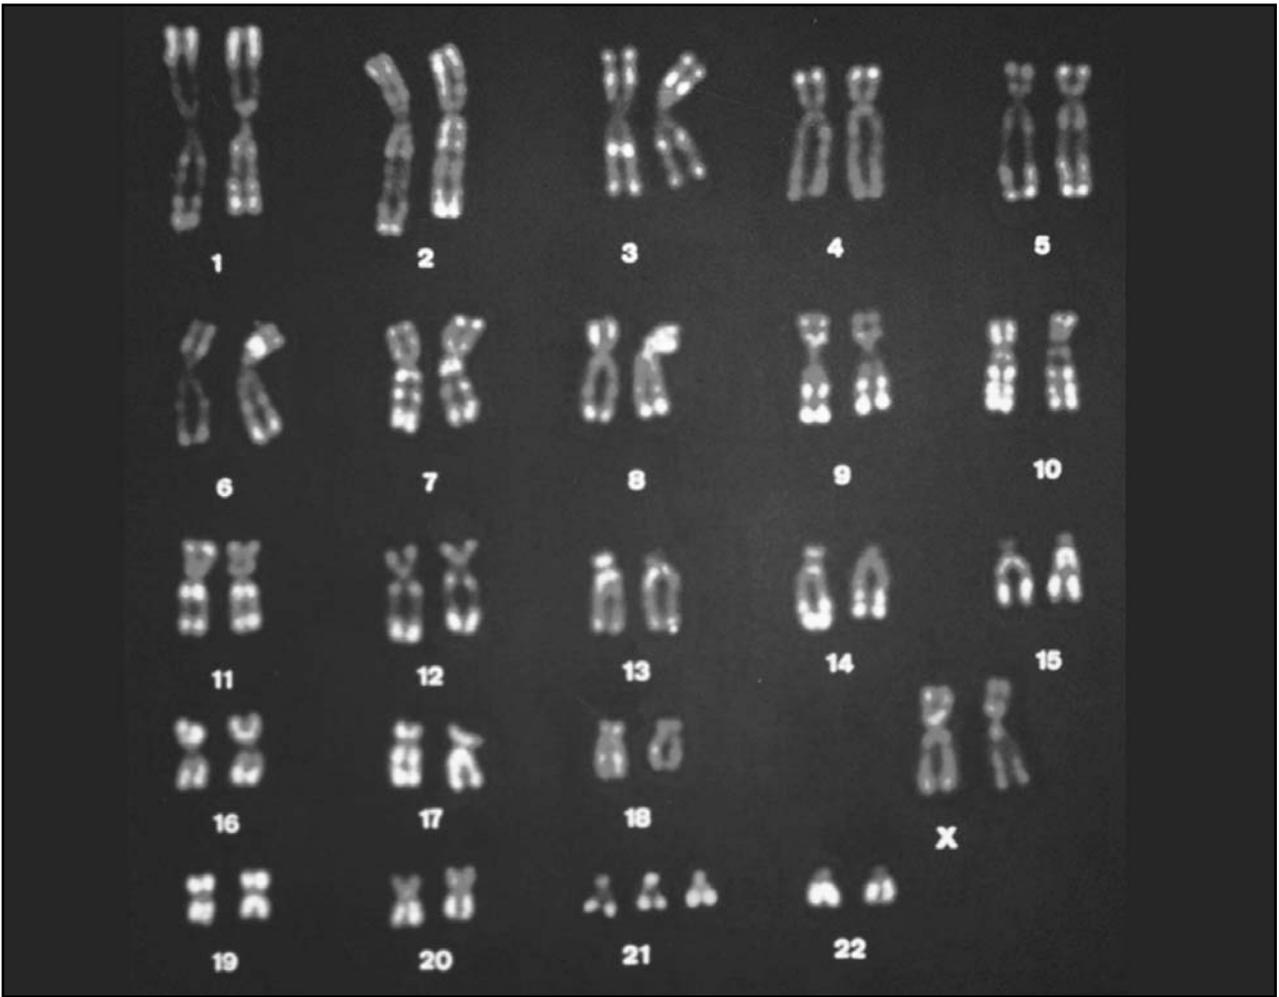

Chromosomes are the units of genetic information that exist within every cell of the body. Twenty-three distinctive pairs, or 46 total chromosomes, are located within the nucleus (central structure) of each cell. When the sperm cells from the father and egg cell from the mother are formed, they both undergo a reduction of their total number of chromosomes from 46 to 23. This process is called meiosis. When a baby is conceived by the combination of one sperm cell with one egg cell, the baby receives 23 chromosomes from each parent, for a total of 46 chromosomes. Occasionally, an error occurs in the reduction process. Instead of passing on 23 chromosomes to the baby, a parent will pass on 24 chromosomes. This event is called non-disjunction and occurs in 95% of Down syndrome cases. The baby, therefore, receives an extra chromosome at conception. In Down syndrome, this is an extra chromosome 21. The total number of chromosomes in individuals affected with Down syndrome is 47 instead of 46.

In approximately 1-2% of Down syndrome cases, the original egg and sperm cells contain the correct number of chromosomes, 23 each. The problem occurs sometime shortly after fertilization; during the phase where cells are dividing rapidly. One cell divides abnormally, creating a line of cells with an extra copy of chromosome 21. This form of genetic disorder is called mosaicism. An individual with this type of Down syndrome has two types of cells: those with 46 chromosomes (the normal number), and those with 47 chromosomes (as occurs in Down syndrome). Individuals affected with this mosaic form of Down syndrome generally have less severe signs and symptoms of the disorder.

Another relatively rare genetic accident that causes Down syndrome is called translocation. During **cell division**, chromosome 21 somehow breaks. The broken off piece of this chromosome then becomes attached to another chromosome. Each cell still has 46 chromosomes, but the extra piece of chromosome 21 results in the signs and symptoms of Down syndrome. Translocations occur in about 3 to 4% of cases of Down syndrome.

Genetic profile

Down syndrome is usually the result of an extra copy of chromosome 21 (trisomy 21). As described earlier, Down syndrome may occur because of: nondisjunction within the sperm, or more commonly, the egg cell; genetic mosaicism, which occurs after conception; or translocation, which also occurs after conception.

This chart shows the abnormality in chromosome 21 present in Down syndrome. (Account Phototake/NYC. Reproduced by permission.)

Once a couple has had one baby with Down syndrome, they are often concerned about the likelihood of future offspring also being born with the disorder. Women who are 34 and younger have a recurrence rate of 1% for having another Down syndrome child. Women who are 35 and older are at increased risk. The specific risk varies and increases as their age increases. When a baby with Down syndrome has the type that results from a translocation, it is possible that one of the two parents is a carrier of a balanced translocation. When one parent is a carrier of a balanced translocation, the chance of future offspring having Down syndrome is greatly increased. Specific risks must be assessed by a genetic counselor.

Demographics

The incidence of Down syndrome is about 1 in 800 live births. It affects an equal number of male and female

babies. The majority of cases of Down syndrome occur due to an extra chromosome 21 within the egg cell supplied by the mother (nondisjunction). As a woman's age (maternal age) increases, the risk of having a Down syndrome baby significantly increases. By the time the woman is age 35, the risk increases to one in 400; by age 40 the risk increases to one in 110; and, by age 45 the risk becomes one in 35. There is no increased risk of either mosaicism or translocation with increased maternal age.

Causes and symptoms

While Down syndrome is a chromosomal disorder, a baby is usually identified at birth through observation of a set of common physical characteristics. It is important to remember that not all children with Down syndrome will exhibit all of the features discussed. There is great variability in both the number and severity of character-

istics. Babies with Down syndrome tend to be overly quiet, less responsive to stimuli, and have weak, floppy muscles. A number of physical signs may also be present. These include: a flat appearing face; brighter sparkles in the iris of the eye (Brushfield spots); a small head; a flat bridge of the nose; a smaller than normal, low-set nose; small mouth. This causes the tongue to stick out and to appear overly large. They have upward slanting eyes; extra folds of skin located at the inside corner of each eye, near the nose (epicanthal folds); rounded cheeks; and small, misshapen ears. They tend to have small, wide hands; an unusual deep crease across the center of the palm (simian crease); a curved little finger; a wide space between the great and the second toes; unusual creases on the soles of the feet; overly-flexible joints (sometimes referred to as being double-jointed); and, a shorter than normal length.

Other types of problems often accompany Down syndrome. Approximately 30 to 50% of all children with Down syndrome are found to have **heart** defects.

Malformations of the gastrointestinal tract are present in about 5 to 7% of children with Down syndrome. The most common malformation is a narrowed, obstructed duodenum (the part of the intestine into which the **stomach** empties). This disorder, called duodenal atresia, interferes with the baby's milk or formula leaving the stomach and entering the intestine for digestion. The baby often vomits forcibly after feeding, and cannot gain weight appropriately until the defect is repaired. Another relatively common problem is a tracheo-esophageal fistula. This is an abnormal connection between the trachea (windpipe) and esophagus that interferes with both eating and breathing.

Other medical conditions occurring in persons with Down syndrome include an increased chance of developing infections, especially ear infections and **pneumonia**; certain kidney disorders; thyroid disease (especially low or hypothyroidism); **hearing loss**; **vision** impairment requiring glasses (corrective lenses); and a 20 times greater chance than the population as a whole of developing leukemia.

Development in a baby and child affected with Down syndrome occurs at a much slower than normal rate. Because of weak, floppy muscles (hypotonia), babies learn to sit up, crawl, and walk much later than their unaffected peers. Talking is also quite delayed. The level of mental retardation is considered to be mild-to-moderate in people with Down syndrome. The degree of mental retardation varies greatly among children with Down syndrome. While it is impossible to predict the severity of Down syndrome at birth, with proper education, children who have Down syndrome are capable of

learning. Most children with Down syndrome can read and write and are placed in special education classes at school. The majority of individuals with Down syndrome become semi-independent, meaning that they can take care of their own needs with some assistance. Many hold non-complex jobs.

As people with Down syndrome age, they face an increased chance of developing the **brain** disease called Alzheimer's (sometimes referred to as **dementia** or senility). People without Down syndrome have a lifetime risk of 12% for developing **Alzheimer's disease**. In contrast, by age 40-50, almost all persons with Down syndrome will also develop Alzheimer's disease.

As people with Down syndrome age, they also have an increased chance of developing a number of other illnesses, including **cataracts**, thyroid problems, diabetes, and seizure disorders.

Diagnosis

Diagnosis is usually suspected at birth, when the characteristic physical signs of Down syndrome are noted. Once this suspicion has been raised, **genetic testing** (chromosome analysis) can be undertaken in order to verify the presence of the disorder. This testing is usually done on a **blood** sample, although chromosome analysis can also be performed on other types of tissue, including the skin. The cells to be studied are prepared in a laboratory. Chemical stain is added to make the characteristics of the cells and the chromosomes stand out. Chemicals are added to prompt the cells to go through normal development, up to the point where the chromosomes are most visible, prior to cell division. At this point, they are examined under a **microscope** and photographed. The photograph is used to sort the different sizes and shapes of chromosomes into pairs. In most cases of Down syndrome, one extra chromosome 21 will be revealed. The final result of such testing, with the photographed chromosomes paired and organized by shape and size, is called the individual's karyotype. A female with Down syndrome will have a 47, XX+21 karyotype; a male with Down syndrome will have a 47 XY+21 karyotype.

Women who are over the age of 35 are offered prenatal tests to determine if their developing baby is affected with Down syndrome. A genetic counselor meets with these families to inform them of the risks and to discuss the tests that are available to make a diagnosis prior to delivery. Because there is a slight risk of **miscarriage** following some prenatal tests, all testing is optional. Couples must decide whether or not they desire to take this risk to learn the status of their unborn baby. Couples must also decide if they wish to know whether or not the

baby the mother carries has Down syndrome. Some couples choose not to have the test because they are certain they would not choose an abortion if they find theirs is a Down syndrome baby.

Ultrasound is now available for prenatal screening. Some abnormalities associated with Down syndrome, including intrauterine growth retardation, may be detected using ultrasound. The use of ultrasound as a screening test for Down syndrome is limited by the difficulty of producing reliable sonographic images of critical fetal structures.

A counselor needs to inform a woman that her risk of having a baby with Down syndrome increases with her increasing age. Two types of testing are available during a **pregnancy** to determine if the baby being carried has Down syndrome.

Screening tests are used to estimate the chance that an individual woman will have a baby with Down syndrome. All pregnant women under the age of 35 are offered a maternal serum alpha-fetoprotein (MSAFP) screen. This test is normally performed at 15-22 weeks of pregnancy. The MSAFP screen measures a protein and two hormones normally found in maternal blood during pregnancy. A specific pattern of these hormones and protein can give a pregnant woman an increased risk for having a baby born with Down syndrome. Carrying a baby with Down syndrome often causes MSAFP to be lower than normal. Test results reveal only an increased risk and cannot diagnose a baby born with Down syndrome. The MSAFP test can detect up to 60% of all babies who will be born with Down syndrome. Women with an increased risk are offered **amniocentesis**.

The only way to definitively (with about 99% accuracy) establish the presence or absence of Down syndrome in a developing baby is to test tissue from the pregnancy itself. This is usually done either by amniocentesis or **chorionic villus sampling** (CVS). In chorionic villus sampling, usually performed at 10-12 weeks of pregnancy, a tiny tube is inserted into the opening of the uterus to retrieve a small sample of the placenta (the organ which attaches the growing baby to the mother via the umbilical cord, and provides oxygen and **nutrition**). In amniocentesis, a small amount of the fluid in which the baby is floating is withdrawn with a long, thin needle. Both amniocentesis and CVS allow the baby's own karyotype to be determined. Both tests carry a small risk of causing miscarriage. The risk from CVS is 1% and the risk from amniocentesis is 0.5%. This small risk must be considered when deciding to perform these tests. If test information is positive for Down syndrome, a couple must then decide how to use this information to begin to prepare for the arrival of a baby with Down syndrome, to

consider adoption for the baby or to terminate the pregnancy. It must be noted that while the results of prenatal tests can diagnose Down syndrome, they are unable to predict the severity of symptoms.

Treatment

No treatment is available to cure Down syndrome. Treatment is directed at addressing the individual concerns of a particular person. For example, heart defects will many times require surgical repair, as will duodenal atresia or a tracheo-esophageal fistula. Many persons with Down syndrome will need to wear glasses to correct vision. Persons with **hearing** impairment benefit from **hearing aids**.

While some decades ago, all Down syndrome children were quickly placed into institutions for lifelong care, research shows very clearly that the best outlook for children with Down syndrome is a normal family life in their own homes. This requires careful support and education of both parents and siblings. It is a life-changing event to learn that a new baby has a permanent condition that will affect essentially all aspects of development. Some community groups exist to help families deal with the emotional effects of this new information, and to help plan for the baby's future. Schools are required to provide services for children with Down syndrome, sometimes in separate special education classrooms, and sometimes in regular classrooms (this is called mainstreaming or inclusion).

As of 2001, the genetic sequence for chromosome 21 was fully determined, which may open the door to new approaches to the treatment of Down syndrome through the development of gene-specific therapies.

Prognosis

The prognosis in Down syndrome is quite variable, depending on the types of complications (heart defects, susceptibility to infections, development of leukemia) of each individual baby. The severity of the retardation can also significantly vary. Without the presence of heart defects, about 90% of children with Down syndrome live into their teens. People with Down syndrome appear to go through the normal physical changes of aging more rapidly, however. The average age of death for an individual with Down syndrome is about 50 to 55 years.

The prognosis for a baby born with Down syndrome continues to improve. Due to modern medical treatments, including **antibiotics** to treat infections, and surgery to correct heart defects, duodenal atresia and tracheo-esophageal fistula, life expectancy has greatly increased. Community and family support allows people with

KEY TERMS

Cell—A fundamental unit of living tissue. The specialized nature of organs and tissues in a human body reflects the specialized structure and function of its constituent cells.

Chromosome—The structures that carry genetic information. Chromosomes are located within every cell and are responsible for directing the development and functioning of all the cells in the body. The normal number is 46 (23 pairs).

Genetic counseling—A communication process by which personal genetic risk information is translated into practical information for families. Genetic counselors are health care professionals with specialized training and experience in the areas of medical genetics and counseling.

Karyotype—The specific chromosomal makeup of a particular cell.

Mental retardation—A condition where an individual has a significantly lower-than-normal IQ, and thus is developmentally delayed.

Mosaic—A term referring to a genetic situation in which all of an individual's cells do not have the same composition of chromosomes. In Down syndrome, this may mean that some of an individual's cells have a normal 46 chromosomes, while other cells have 47 chromosomes.

Nondisjunction—A genetic term referring to an event that takes place during cell division in which a genetic accident causes an egg or sperm cell to have 24 chromosomes, rather than the normal 23.

Translocation—A genetic term referring to a situation during cell division in which a piece of one chromosome breaks off and sticks to another chromosome.

Trisomy—The condition of having three identical chromosomes, instead of the normal two.

Down syndrome to have rich, meaningful relationships. Because of educational programs, some people with Down syndrome are able to hold jobs.

Most men with Down syndrome appear to be sterile (meaning that they are unable to have offspring). There has been at least one report of a male with Down syndrome who fathered a child. Some women with Down syndrome, however, are capable of having babies.

Approximately 40% of women with Down syndrome are unable to become pregnant. The risk of a woman with trisomy 21 to have a child with Down syndrome is approximately 50%.

Health care team roles

Obstetricians, nurse practitioners, or family doctors often make an initial recommendation that a woman be screened for Down syndrome. Depending on the test, a physician, phlebotomist or ultrasonographer may obtain sample materials. A laboratory technician will process sample materials. A genetic counselor, physician or other person with specialized training usually provides test results to a couple or woman. Counselors must be available to assist a woman or couple to make appropriate decisions about their baby. Pediatricians, family doctors, internists, and geriatric physicians provide care throughout the life of an individual with Down syndrome. Other health professionals, including surgeons, eye specialists and hearing experts, provide services as needed.

Prevention

As of 2001, there is no known way to prevent Down syndrome.

Drug dosages

Definition

Drug dosage refers to the determination and regulation of the amount, frequency, and number of times a specific quantity of medication is to be administered. For legal purposes in the United States, a drug is considered to be any substance (other than a food or a device) intended for use in diagnosis, cure, relief, treatment, or prevention of disease, or to affect the structure or function of the body. However, a simple, working definition of a drug is any chemical that affects the processes of the mind or body, and the dose is the amount to be administered at one time.

Purpose

The selection of a drug for use in an individual requires two primary considerations: pharmacodynamics (what the drug does to the body) and pharmacokinetics (what the body does to the drug over time). Pharmacodynamics not only involves considering what the drug does as in lowering **blood pressure**, relieving **pain**, or fighting an **infection**, but where (the site) and how (mechanism of action) the drug acts on the body. Often, what the drug does is immediately obvious, but the exact site and mechanism of action may not be understood until after many years of use.

For a drug to work, it has to get to the place in the body where it is needed, and this requires the science of pharmacokinetics. Sufficient amounts of a drug must stay at the site of its required action until the job is completed, but not so much that severe side effects or toxic reac-

KEY TERMS

Conjugations—The joining of a chemical substance with another to form a new product.

Hydrolysis—The breaking up of a chemical compound by the addition of water.

Lipids—A group of substances composed of fatty, greasy, oily, and waxy compounds that are insoluble in water and soluble in nonpolar solvents or most organic solvents.

Metabolism—The sum of the physical and chemical processes by which living organized substance is built up and maintained and by which large molecules are broken down into smaller molecules to make energy available to the organism.

Oxidation—The chemical reaction whereby electrons are removed from the atoms of a substance for transferal.

Perfused—The act of the passage of a fluid through the vessels of a specific organ or tissue.

Phospholipids—Any lipid or fatty substance that contains phosphorus; the major lipids in cell membranes.

Reduction—The gaining of electrons during a chemical reaction.

Semi-permeable—Permitting passage only of certain molecules.

Therapeutic window—A drug's ability to maintain a specific level of action over a specific period of time.

tions are produced. Many drugs get to their site of action through the bloodstream. Therefore, how much time they need to work and how long their effects will last can depend on how fast they get into the bloodstream, how much gets into the bloodstream, how fast they leave the bloodstream, how easily and efficiently they are broken down (metabolized) by the **liver**, and how soon they are eliminated by the **kidneys** and intestines.

Drugs affect only the speed of biologic functions and do not change the basic character of existing processes nor generate new functions. This means that drugs can either speed up or slow down biochemical reactions in the body, as in how fast or slow a nerve may transmit a message, or how fast or slow a muscle may contract. Although drugs can change the rate of a biological

process, they cannot re-establish a system that is injured beyond repair.

Every person responds to a drug differently. Thus, it is difficult to determine what dosage of a drug should be administered to each individual. Since drugs undergo testing in animals and trials in humans, an average dose is determined from these studies. An appropriate response to a drug requires the appropriate concentration of the drug at the site of action. The appropriate concentration and dosage regimen depend on individuals' clinical state, the severity of their disorder, the presence of a diseased state, the use of other drugs, as well as other considerations. Drug administration must be determined by each individual's needs, which requires an accurate evaluation of drug dosage.

Precautions

All drugs can harm as well as help, so the safety and effectiveness (efficacy) of a drug are relative. Since most drugs cannot maintain a specific level of action for a certain period of time (therapeutic window), their effect can sometimes be either too strong or too weak, depending on the individual's condition who is receiving the drug.

Unwanted drug effects are called side effects or adverse reactions. A drug may affect several functions even though it is prescribed for only one. As an example, most **antihistamines** are targeted for the function of relieving allergy symptoms, yet one of the many side effects is sleepiness. In turn, this side effect is utilized to target the function of an inability to sleep when offered as a sleep aid.

The best drugs are both safe and effective. However, some drugs may be used despite having a very narrow margin of safety because there might be no safer alternative. Although it is impossible to know everything about every drug, understanding the general principles of drug action is an essential precaution in drug administration.

Description

Utilization of drug treatment for any condition requires the drug to be capable of getting into the body's system (administration), moving into the bloodstream (absorption), and traveling to the specific site where it is needed (distribution). Following the administration, absorption, and distribution, the drug leaves the body (elimination) either in the urine or by conversion to another substance.

Administration of drugs can occur by many different means. Drugs be taken by mouth (oral/p.o.); by injection into a vein (intravenous/IV); by injection into a muscle (intramuscular/IM); beneath the skin (subcutaneous/SQ);

placed under the tongue (sublingual); inserted in the rectum (rectal); instilled in the eye (ocular); sprayed into the nose (nasal); sprayed into the mouth (inhalation); applied directly to the skin for a local effect (topical); or applied to the skin for a systemic effect by a patch (transdermal).

Absorption is the process of drug movement from the administration site to the general (systemic) circulation. Although oral administration is the most convenient, the safest, the least expensive, and the most common route, it has its restrictions. The presence of other drugs and food in the **stomach** affect how drugs are absorbed. Some drugs must be taken on an empty stomach, while others should be taken with food.

For distribution into the general circulation, a drug taken orally is absorbed from the gastrointestinal tract by passing through the intestinal wall and then to the liver. Whereas a drug given IV immediately passes into the general circulation to produce a quicker and more consistent effect, a drug given by most other routes must travel across several semi-permeable **cell membranes** before reaching the systemic circulation. These membranes are biologic barriers that selectively prevent the passage of drug molecules and are composed of mostly cholesterol and phospholipids. These **lipids** provide stability to the membrane and determine its permeability characteristics. Drugs cross a biologic barrier by passive diffusion (moving from an area of high concentration to one of low concentration), facilitated passive diffusion (a carrier component combines with the drug to cause rapid diffusion across the membrane), active transport (the cell expends energy to move a drug), or pinocytosis (the cells ingest extracellular fluid and its contents).

Bioavailability refers to the rate and extent to which a drug is absorbed into the bloodstream and thereby gains access to the site of action. The properties of the actual dosage form of a drug, either tablet, capsule, suppository, transdermal patch, or solution, largely determine drug bioavailability.

Drug products may be chemically equivalent, containing the same compound in the same amount, but have dissimilar effects even at the same dose, due to different inactive ingredients, which affect absorption. When drug products contain the same active ingredients and also produce virtually the same **blood** levels over time, they are termed bioequivalent. If drug products given to the same person in the same dosage regimen produce the same therapeutic effect, they are therapeutically equivalent. Bioequivalent products are expected to be therapeutically equivalent.

A drug product is the actual dosage form of a drug. Drug products contain other substances (additives) that are adjusted to affect the rate and extent of the drug's

absorption. Some drug products are designed to release the active ingredient slowly over a long period of time and are called controlled-release dosage forms. This occurs by coating the drug product with a polymer (a chemical substance) of varying thickness that dissolves layer by layer at different times in the gastrointestinal tract. Other additives such as enteric coatings prevent the drug from irritating the stomach lining. Drugs filled with liquids are usually absorbed faster than those filled with solids.

Although a drug rapidly circulates through the body in the bloodstream, this does not mean that it immediately moves into the tissues. Drugs are distributed to different tissues at different rates, depending on their ability to cross membranes, the rate of blood flow to a particular tissue, and the tissue mass. Most drugs do not spread evenly throughout the body; some tend to stay in the plasma (watery tissue of the blood) and muscle, others concentrate in specific areas such as the kidneys, liver, and thyroid. A balance between entry and exit rates (distribution equilibrium) is reached more rapidly in highly vascularized areas than in areas that are poorly perfused. There are drugs that bind tightly to blood **proteins** and leave the bloodstream very slowly, and others that exit quickly to the tissues. Some tissues build up high levels of a drug and serve as reservoirs of extra drug, which prolongs their distribution. Those drugs that accumulate in fatty tissues exit slowly and will continue to circulate in the bloodstream for days following the last administration.

It is possible for drugs to reach the **central nervous system** (CNS) through the **brain** capillaries and the cerebral spinal fluid (CSF). However, despite the fact that the brain receives approximately one-sixth of the blood circulation, distribution of drugs to brain tissues is restricted. Fat-soluble drugs can enter the brain and exert their effects rapidly, but the water-soluble drugs enter the brain slowly. The CNS is well perfused so the major factor of drug distribution rate in it is permeability, whereas for most tissues, perfusion is the major determinant of distribution.

The liver is the principal site of drug **metabolism**, and some of the metabolites are active forms of the drug administered. An inactive substance that produces an active metabolite, once it is absorbed, is called a pro-drug. All drugs are either metabolized or excreted intact. Enzymes in the liver assist with chemical reactions (oxidation, reduction, hydrolysis), and some enzymes attach substances to the drugs, producing reactions called conjugations, which enable a drug to be excreted in the urine.

Excretion refers to the processes by which the body eliminates a drug without further chemical change, and

the major organ of excretion is the kidney. The kidneys filter drugs from the bloodstream and excrete them into the urine. Thus, the major limiting factor of excretion is kidney function, and decreasing kidney function is seen in the elderly, or people with high blood pressure, diabetes, and recurring kidney infections. A laboratory determination of kidney function permits the dosage of a drug to be altered as necessary. The liver does excrete some drugs through bile. These particular drugs enter the gastrointestinal tract and end up in the feces if they are not reabsorbed into the bloodstream or decomposed. Individuals with liver disease may need to have the drug dosage adjusted accordingly, although there is no corresponding liver function test comparable to that for kidney function. Likewise, some drugs can be excreted in breast milk, saliva, sweat, or exhaled air.

Once in the body, drugs can affect it in many ways. Interactions with other cells, tissues, or organs may result in side effects or adverse drug reactions. Many drugs bind or attach to cells by means of receptors on the cell surface. Receptors have a specific structure, which permits only those substances that fit it precisely to attach to it. The majority of cells have these surface receptors with which drugs can selectively bind to change the activity of the cell. These receptors possess a natural, physiologic purpose, and drugs take advantage of them.

A class of drugs called agonists activates or stimulates the receptors to trigger a response that either increases or decreases the cell's function. Another class of drugs called antagonists blocks the access of agonists to the receptors. Antagonists are used primarily to block or diminish cell responses to agonists normally present in the body, and this is usually in reference to neurotransmitters.

Other targets of drug action are enzymes, protein substances needed in the body to assist with the control of chemical reactions during metabolism. Drugs that target enzymes are classified as inhibitors or inducers (activators).

Affinity and intrinsic activity are two other drug properties that must be considered in dosage. Affinity refers to the attraction or strength of the bond between a drug and its target, regardless of whether it is a receptor or an enzyme. Intrinsic activity refers to the ability of the drug to produce its desired effect after it is bound to its target. Agonists drugs have both properties because they must bind effectively and produce a response. Antagonists drugs, however, only have an affinity for a target site since their purpose is to block agonists.

Other properties that are important in determining drug dosage include potency, efficacy, tolerance, and

resistance. Potency refers to the amount of drug needed to produce a certain effect; it is usually expressed in milligrams (mg). Greater potency does not necessarily mean that one drug is better than another because side effects, toxicity, duration of effectiveness, and cost must also be considered. Efficacy refers to the maximum therapeutic response that a drug can produce and, once again, this is only one factor in the consideration of which drug to use at what dosage. Tolerance to a drug can occur when the body adapts to the continued presence of the drug. It is also possible for tolerance to occur if the number of receptors decreases or their affinity for the drug decreases. The term resistance is generally used to refer to a situation in which an individual no longer responds well to a drug. In these cases, the drug dosage may be increased or an alternative drug may be utilized.

Preparation

Before administering a new drug or a medication that is prescribed on an as-needed basis, a patient must be assessed in terms of factors that may be pertinent. An initial prediction of increased risk for adverse drug effects can be made by the patient assessment. It is essential to double check the medication ordered, the dosage to be given, the times the drug is to be administered, how it is to be administered, the expiration date on the drug, and that the correct patient receives the correct drug. Many IV medications are now being mixed in the pharmacy to prevent errors in calculations for a patient. It is important that the health care provider discusses with the patient what the medication is, why it is being given, and reviews some potential side effects.

Aftercare

A patient should be continually assessed during the administration of a medication for signs and symptoms of any untoward reaction, as well as to determine if the medication has had the desired effect.

Complications

Adverse reactions are one of the main complications of drug administration. Some patients may experience an allergic reaction to a medication that could range from mild to severe. They may experience itching, exhibit a rash, have localized swelling, difficulty breathing, or suffer a complete vascular collapse. Other complications could include a resistance to the drug with a subsequent progression of the initial condition. If the patient's status does not seem to be improving, this should be reported to the physician or nurse practitioner. Severe side effects

could be detrimental to the patient, necessitating laboratory tests to monitor the patient's condition.

Results

Results expected with drug administration will vary according to why the drug was given. In all cases, it is essential to determine what end result is expected from the administration of a drug.

Health care team roles

The health care team shares responsibility for providing optimal intervention in the administration of drugs. Since nurses spend more time with patients and are more likely to focus on the patient as an individual, this places them in an optimal position to assess a patient's response to a drug. Any pertinent changes should be immediately reported to the physician or nurse practitioner. The nurse must also ensure that the patient is well informed about the drug being administered.

Drug interactions

Definition

Drug interactions are changes in the effect of one drug due to the effect of either another drug taken at the same time (drug-drug interactions) or food consumed while the drug is being taken (drug-food interactions).

Description

Some drugs are deliberately combined for administration because there are beneficial effects to be derived. Generally, drug interactions are unwanted and harmful. They may either serve to intensify or diminish the desired effect of a particular drug, or worsen its side effects. Although most drug-drug interactions involve prescription drugs, they can occur with nonprescription or over-the-counter (OTC) medications—the most common of these being aspirin, **antacids**, and decongestants.

Individuals under the care of more than one health care practitioner are at highest risk for drug interactions because each practitioner may not be aware of drugs being prescribed by the other. The patient needs to make each practitioner fully aware of all medications being taken. This includes prescription and nonprescription medications, and herbal remedies. A practitioner may not think to ask a patient about OTC medications or herbal supplements, and the patient may not think to inform their practitioner they are taking these substances because they do not think of OTCs or herbals as medications. The more drugs being consumed, the greater the risk of developing a drug interaction. This risk also increases with the amount of drug taken and the tendency of particular drugs to interact adversely with each other. The incidence of adverse drug reactions increases with the age of the patient; the risk is three times greater for older people than for younger adults.

When the effect of one drug in the body is altered by the presence of another, one drug may increase or decrease the effects of the other with harmful results. Two drugs taken together may produce a new and dangerous reaction, or they may be in opposition to each other in their actions. Two similar drugs taken together may produce an effect that is greater than would be expected from one drug. This effect is called potentiation. One drug may also affect the rate at which the **kidneys** excrete another drug by altering the acidity of the urine. This, in turn, affects the excretion of other drugs. **Vitamin C** in large doses can do this. Although not considered a drug by some, alcohol is a drug that does affect bodily processes and is often responsible for drug interactions. OTC drugs can interact with each other as well as with prescription drugs. For example, many cough medicines contain alcohol which, if taken with antihistamine medications, could increase sleepiness and decrease alertness.

Examples of drug interactions include:

- salt substitutes interacting with potassium-sparing diuretics (agents that promote urine secretion) to increase **blood** potassium levels and cause nausea,

Interactions between drugs and commonly used modalities

Modality	Use	Drugs with complementary/synergistic effects	Drugs with antagonistic effects
Cryotherapy: cold/ice packs, ice massage, cold baths, vapocoolant sprays	Decreased pain, edema, and inflammation	Anti-inflammatory steroids (glucocorticoids); nonsteroidal anti-inflammatory analgesics (aspirin and similar NSAIDs)	Peripheral vasodilators may exacerbate acute local edema.
	Muscle relaxation and decreased spasticity	Skeletal muscle relaxants	Nonselective cholinergic agonists may stimulate the neuromuscular junction.
Superficial and deep heat (local application): hot packs, parafin, infrared, fluidotherapy, diathermy, ultrasound	Decreased muscle/ joint pain and stiffness	NSAIDs; opioid analgesics; local anesthetics	—
	Decreased muscle spasms	Skeletal muscle relaxants	Nonselective cholinergic agonists may stimulate the neuromuscular junction.
	Increased blood flow to improve tissue healing	Peripheral vasodilators	Systemic vasoconstrictors (e.g., α -1 agonists) may decrease perfusion of peripheral tissues.
Systemic heat: large whirlpool, Hubbard tank	Decreased muscle/ joint stiffness in large areas of the body	Opioid and nonopioid analgesics; skeletal muscle relaxants	Nonselective cholinergic agonists may stimulate the neuromuscular junction.
Ultraviolet radiation	Increased wound healing	Various systemic and topical antibiotics	—
	Management of skin disorders (acne, rashes)	Systemic and topical antibiotics and anti-inflammatory steroids (glucocorticoids)	Many drugs may cause hypersensitivity reactions that result in skin rashes, itching.
Transcutaneous electrical nerve stimulation (TENS)	Decreased pain	Opioid and nonopioid analgesics	Opioid antagonists (naloxone)
Functional neuromuscular electrical stimulation	Increased skeletal muscle strength and endurance	—	Skeletal muscle relaxants.
	Decreased spasticity and muscle spasms	Skeletal muscle relaxants	Nonselective cholinergic agonists may stimulate the neuromuscular junction.

SOURCE: Ciccone, C.D. *Pharmacology in Rehabilitation*. 2nd ed. Philadelphia: F.A. Davis Co., 1996.

vomiting, **diarrhea**, muscle weakness, and possibly cardiac arrest

- decongestants interacting with diuretics to increase blood pressure
- antacids interacting with anticoagulants (blood thinning drugs) to slow down absorption of the prescribed drug or interacting with absorption of other drugs—such as the antibiotic tetracycline—and thus prolonging an infection
- aspirin increasing the effect of blood thinning drugs
- antihistamines increasing the sedative effects of barbiturates (sleeping pills), tranquilizers, and some **pain** relievers
- iron supplements binding with **antibiotics** in the **stomach**, preventing absorption of the antibiotic into the bloodstream
- antihypertensive medications mixed with digitalis (Lanoxin) resulting in abnormal **heart** rhythms
- anticoagulants mixed with sleeping pills resulting in decreased effectiveness of the anticoagulant
- antibiotics taken by women on the low-dose birth control pill causing decreased effectiveness of the pill

- nonsteroidal antiinflammatory drugs (NSAIDs) causing the body to retain salt and fluid that can oppose or antagonize the effectiveness of a diuretic
- beta-blockers, such as propranolol, counteracting certain drugs taken for asthma

Certain drug-food combinations can produce dangerous side effects as well. Food can speed up or slow down the action of a medication, and some drugs may prevent the absorption of **vitamins** and **minerals** from food. Drugs may also alter the way the body uses nutrients, as well as altering the **taste** sensation. Chemicals in cigarette smoke can increase the enzyme activity of some **liver** enzymes, which, in turn, reduces the effectiveness of some pain relievers and some drugs used for lung conditions. The antibiotic tetracycline is not absorbed appropriately if it is taken within an hour of drinking milk or eating other dairy products or foods containing **calcium**.

To help avoid drug interactions, patients should inform their health care practitioners of any medical problems they have or have had, maintain a list of drugs—both prescription and nonprescription—taken during the few weeks prior to their visit to their practitioner, and give the list to their practitioner. They should also advise their practitioner of any **allergies** or unusual reactions to drugs, food, or other substances, and make

KEY TERMS

Potentiation—Making effective or active, or more effective or active; synergistically augmenting the activity of one drug with another.

note of any special dietary or food restrictions. A woman should always inform her practitioner if she is pregnant, plans to become pregnant in the near future, and if breastfeeding.

Viewpoints

Although drug interactions can create serious health risks, they can be avoided with appropriate education (of the patient) and history-taking (by the health care practitioner). The health care practitioner needs to take the time to ask pertinent questions about an individual's history, including diet, nutritional intake, and medication regimen which should include nonprescription drugs and herbal remedies. Although it is often difficult for the practitioner to spend an appropriate amount of time with patients in this era of health care management, it could ultimately save time and money and prevent serious consequences to the health of the patient. Healthcare providers need to stay informed and up-to-date regarding drug-drug and drug-food interactions.

Professional implications

Healthcare professionals are capable of exerting a measurable impact on the lives of individuals who are taking drugs for either medical or nonmedical reasons. Education is the foundation for patient care with regards to potential drug interactions. It is the responsibility of the care provider to take the time to inform patients of potential interactions with drugs and food, as well as to take a complete patient history. A patient's family should be included in the educational process so they may recognize possible interactions by changes in behavioral patterns or demeanor.

Drug monitoring see **Therapeutic drug monitoring**

Drug overdose see **Overdose**

Drug testing

Definition

Drug testing is the assessing of drug use (or non-use) by a person. The drugs for which one tests fall into three main types: illegal drugs, alcohol, and performance-enhancing drugs. Illegal drugs include **marijuana**, cocaine, amphetamines, and phencyclidine (PCP, the hallucinogen known as "angel dust"). Alcohol is, of course, a legal drug for adults, but since such activities as driving under its influence are illegal, it is sometimes very important to test for the level of alcohol in the bloodstream. Performance-enhancing drugs may be legal, but their use by athletes may be forbidden by the rules of an athletic association sponsoring a competition, rules designed to be fair to all the players.

Description

One line of attack in the "war against drugs" in the United States involves compulsory drug testing. Specific drug-test laws vary from state to state, but **drug tests** are commonly administered in schools, athletic competitions, and the workplace. When results of some tests are being evaluated, it is important to keep in mind the fact that sometimes legitimate prescription drugs for such conditions as arthritis and **asthma** can produce test results that falsely suggest illegal drug use.

Some schools test students in general for drug use; others focus on student athletes because drug use increases the risk of sports-related injury, and also because the use of performance-enhancing drugs would give the athletes who use them an unfair advantage over the other athletes. The United States Supreme Court ruled in 1995 that schools may test entire teams of student athletes, even if individual team members are not suspected of using drugs. On the state level, courts are divided on the circumstances under which such testing can legally

A technician performs laboratory urine drug testing.

(Photograph by Edward L. Lallo. The Picture Cube. Reproduced by permission.)

occur. Some states provide more protection than others for the rights of students to privacy and due process.

In the 1970s, the issue of performance-enhancing drug use among athletes came into the forefront. Many athletes use performance-enhancing drugs (ergogenic drugs) such as anabolic steroids, growth hormone, and erythropoietin. Some athletes also use stimulants because of their ability to mask fatigue. Athletes are tested for use of forbidden drugs at many major meets.

The federal government laid the groundwork for drug testing in the workplace when, in the late 1980s, it initiated mandatory drug testing of federal employees, and began to require that government contractors establish drug-testing programs for their workers. Today, many large companies in the United States administer drug tests to their employees, but testing in smaller organizations is significantly less common.

Some workplace drug-testing policies are considerably stricter than others. Federal employees can be subject to compulsory random drug tests, as can private-sector employees with responsibility for the lives and safety of others. It is obviously not as dangerous to the public for the person raking leaves in a park to take illegal drugs

as for an airplane pilot, a truck driver, or a person producing atomic weapons. Much workplace testing is conducted under such circumstances as the following:

- Pre-employment. Employers offer employment on condition of a negative drug test.
- Reasonable suspicion. Employers test an employee after direct observation of drug use or possession, patterns of erratic behavior, or drug-related arrests.
- Post-accident. Employees involved in accidents are sometimes asked to take a drug test immediately after an incident to determine whether alcohol or drug use was a factor.
- Treatment follow-up. Employees returning to work after treatment for substance abuse are often subject to follow-up testing.

Urine is the most common sample used in drug testing. Urine tests for federal employees are first analyzed by laboratories certified by the Substance Abuse and Mental Health Services Administration (SAMHSA), and any samples that come up positive are double-checked by gas chromatograph mass spectrometry, the “gold standard” test that identifies the exact molecular structure of a substance. Some private employers also follow SAMHSA procedures and use federal laboratories for testing, but others use commercial drug-testing kits. These commercial kits have often been criticized for generating a high rate of false positives. The problems associated with urine testing have sparked interest in alternative techniques, such as the testing of hair, sweat, or saliva.

Viewpoints

SAMHSA advocates drug testing in order to help businesses achieve a drug-free workplace. A survey from the United States National Institute on Drug Abuse (NIDA) estimated that employee drug misuse cost the country billions of dollars in lost productivity, as well as in medical expenses and in worker-compensation claims. Mandatory drug testing in the workplace deters those who abuse drugs and alcohol from engaging in this unhealthy behavior at least while they are on the job, and it may deter non-users from ever starting to abuse drugs and alcohol. Also, it can sometimes help those with abuse problems to admit them and so to start getting help, but some abusers are in such deep denial that they cannot be helped in this way.

Opponents of these views point out problems with drug testing. Workplace testing may actually dampen company productivity because it is time-consuming, has the potential to violate the confidentiality that medical personnel are obliged to practice, and undermines staff morale and loyalty. More importantly, it may needlessly

KEY TERMS

Amphetamine—A chemical mixture that can strongly stimulate the central nervous system. Over time, users tend to need stronger doses, and eventually they may develop a physical dependence on it and thus become addicted.

Anabolic steroid—A synthetic or semisynthetic substance that promotes the production within the body of the proteins that build up tissues, especially muscle tissues.

Cocaine—An alkaloid chemical obtained from the leaves of the coca plant (or from some related species). It is addictive, it can cause mental and physical problems, and an overdose can lead to coma and death.

Ergogenic—Giving rise to, or enhancing, work, activity, functioning, and the like.

Erythropoietin—A protein produced mostly in the kidneys, and now available synthetically, that stimulates the production of red blood cells in the bone marrow.

False negative—A test result that erroneously gives a negative finding when the actual condition should have given a positive finding.

False positive—A test result that erroneously gives a positive finding when the actual condition should have given a negative finding.

Gas chromatograph mass spectrometry—A technique by which complex organic compounds are identified by the use of two sophisticated instru-

ments. First, a gas chromatograph heats the compounds until they vaporize into gases which ascend a column and emerge one at a time. Then, each separate fraction of these gases is sent to a mass spectrograph which identifies the fragments of the molecules according to their mass. One thus gets a kind of chemical fingerprint of the substance being tested, and checks in a data base of thousands of such fingerprints of known substances to see which substance one has just tested.

Growth hormone—A substance produced naturally in the body, and now available synthetically, that promotes the development of flesh and bone, and influences the metabolism of proteins, carbohydrates, and fats.

Hallucinogen—A drug that can cause false sensations, such as hearing voices when there are no voices and no other sounds that could reasonably be confused with voices, or seeing persons or things that are not present.

Marijuana—The dried leaves, stems, and flowers of plants of the cannabis family. It is often smoked, sometimes eaten. It can produce distorted perceptions (which the users consider to be a form of elevated consciousness) and sometimes causes outright hallucinations.

Phencyclidine—A chemical used legally as a veterinary anesthetic and illegally as a drug that alters consciousness (a psychedelic drug).

harm the careers of employees whose legitimate use of prescription medicines causes confusing or ambiguous test results. Also, it may identify substances at insignificant doses because of recreational drug use outside working hours, use that has no bearing on employee performance, according to civil-rights groups such as the American Civil Liberties Union (ACLU). The ACLU advises that employees in safety-sensitive positions such as airline pilots should indeed be tested for impairment, and that any individuals found to be impaired should then be referred to special programs called Employee Assistance Programs (EAPs). EAPs can in turn direct these persons to the appropriate substance-abuse programs. The ACLU also recommends more rigorous reference-checking to avoid hiring someone with a history of drug-abuse problems in the first place. However, if the

person no longer has a drug problem, such an approach could illegally and unfairly violate this person's rights.

Many health-care organizations that provide qualified support for drug testing oppose its more radical uses, such as random testing or testing without suspicion. The American Nurses Association (ANA) opposes random drug testing of health-care workers, viewing it in violation of the basic principle of "innocent until proven guilty," but provides qualified support for testing under reasonable suspicion, and with evidence that job performance has been impaired by alcohol or drug usage. Employees who initially test positive for drugs should be offered a reassessment of the test results and should be given the chance to explain what legitimate medications they are taking which might have produced false-positive results. Even when the drug use is confirmed, counseling

and treatment are recommended before any disciplinary action is taken, according to the ANA. The American Hospital Association (AHA) advocates pre-employment testing, suspicion-based testing, testing after certain incidents or injuries, and testing following drug rehabilitation, but not random testing without cause.

Some health-care organizations have also issued position statements on drug-testing policies in the community. The American Academy of Pediatrics has stated opposition to drug testing without cause as a prerequisite to student participation in school activities. And the American Medical Association (AMA) is opposed to the practice of reporting positive drug results for pregnant women to law-enforcement officials. Proponents say such practices protect unborn children, but the AMA states they are an invasion of medical confidentiality and a violation of the provider/patient relationship. Such practices may also discourage some women from seeking **prenatal care**.

Professional implications

Nurses may draw **blood** samples, for example, when testing for alcohol level. They must be certain that they have the **informed consent** of the person from whom they are drawing blood, or else that they have clear-cut legal authorization, such as a court order, to do so. In the case of testing of urine, hair, saliva, and sweat, nurses should instruct the person being tested and then properly store and label the specimen provided. Medical technologists or clinical-laboratory scientists are responsible for running the tests, for reporting the results accurately, and in some cases for estimating the margin of error or assessing the likelihood that the result is a false positive or a false negative. All health personnel must see that the results of such tests are disclosed only to those authorized to have them, and must otherwise maintain strict professional confidentiality.

Ann Quigley

Drug tests

Definition

Drug tests are analytical procedures that may be performed on **blood**, urine, or gastric fluid for the purpose of identifying an unknown drug or measuring the concentration of a specific drug.

Purpose

Drug tests are usually performed for three reasons. 1) To identify an abuse drug. The majority of drug abuse

involves one or more of the following substances and these comprise a typical drug of abuse panel: amphetamines, cannabinoids, cocaine, ethanol, opiates (morphine and codeine compounds), and phencyclidine (PCP). Over 85% of drug abuse cases involve those drugs or one of the following: barbiturates, benzodiazepines, methadone, propoxyhene, LSD, methaqualone, and antidepressants. 2) To identify a drug which may have been ingested or administered in a toxic or lethal dose either accidentally or on purpose. In addition to poisons such as pesticides and heavy metals such as arsenic, drugs are often implicated in accidental **overdose** and suicide situations. The three most commonly encountered drugs seen in overdose situations are ethanol, salicylate (aspirin), and acetaminophen. 3) To determine whether the amount of a drug in the blood is within therapeutic limits. This process, called **therapeutic drug monitoring** (TDM), is used to insure that the dose and dose interval of the drug are sufficient to maintain a therapeutic blood concentration throughout drug therapy without risk of toxicity. TDM is also performed to verify that a patient is complying with the physician's orders.

Description

Drug abuse testing

Drug screening may be performed on urine, blood serum or plasma, or gastric fluid, but urine is the sample of choice for symptomatic cases because drugs and their metabolites concentrate in the urine. Clinical or emergency department settings require the use of a screening method because the identity of the drug is not usually known. Drug screening methods may be designed to detect a class of related drugs. For example, a drug test for amphetamines may detect methamphetamine, dexamphetamine, methylenedioxymethamphetamine (Ecstasy), and phenylpropanolamine. The latter drug is a decongestant that sometimes cross reacts with the antibodies used in the amphetamine assay (analysis). Although drug screening may be sufficient to treat the patient, medicolegal implications are usually involved and this necessitates the need for positive sample identification and confirmatory **drug testing**. The confirmatory test need not be more specific than the screening test, but must utilize a different method of detection. This obviates the chance of a false positive test result caused by an interfering substance unless the interferent affects both methods. Drug screening programs are also used in occupational settings as a condition of employment, and extensively by the criminal justice system for criminal investigations and monitoring persons who have been convicted of drug related offenses. These situations require stringent adherence to procedures for documenting chain-of-custody of

the specimen and confirmatory testing. Federal drug testing worksites must follow the Department of Transportation (DOT) chain-of-custody procedures for collection and transport of urine samples for drug testing. Laboratories certified by the U.S. Substance Abuse and Mental Health Services Administration (SAMHSA) must use the gas chromatography with mass spectroscopy (GC-MS) method to confirm a positive drug screening test. This method is the gold standard for drug identification because it determines the mass spectrum of the drug which is a fingerprint of its chemical composition.

Specimen collection and transport

Urine specimens should be collected in a room with separate areas for workspace and toilet. The sink should be located in the workspace area. The patient or client must be positively identified via two forms of photoidentification or a passport. A form such as a DOT Custody Control Form should be used for chain-of-custody documentation. This form should include labels for the collection bottle and bag, and signature lines for all persons who will receive the specimen. At minimum the client must be observed entering and leaving the toilet area and should be instructed to remove outer garments and empty his or her pockets. The toilet should contain a bluing agent and the client should be instructed not to flush the toilet. The collection container should be unwrapped in the client's presence and affixed with a temperature measuring strip. The sample should be examined by the collector for adulteration and rejected if not within prescribed limits for volume (at least 30 mL) and temperature (90-100°F). An acceptable sample is labeled across the lid and side so the seal will be broken if the lid is removed. The laboratory should perform a test for urinary creatinine, pH, or specific gravity to check specimen integrity.

Blood samples are collected by venipuncture using standard precautions for reducing exposure to blood-borne pathogens. It is not necessary to restrict fluids or food prior to collection. Blood should be collected in tubes containing no additive. Risks of venipuncture include bruising of the skin or bleeding into the skin.

The EMIT principle

The most commonly used drug screening method is immunoassay. There are several immunoassay methods available including the enzyme multiplied immunoassay technique (EMIT), solid phase immunoassay fluorescence polarization immunoassay (FPIA), and cloned enzyme donor immunoassay (CEDIA). In addition, thin layer chromatography is sometimes used as a screening test. This method is more time consuming than immunoassay but is more comprehensive. The EMIT

method is the most commonly used platform for drug of abuse screening. All EMIT assays follow the same scheme regardless of the drug being tested. EMIT assays measure enzyme activity. In a typical EMIT assay, urine is mixed with an antibody specific for the drug (e.g., methadone) and an enzyme-conjugated form of the drug. The enzyme used in EMIT testing is glucose-6-phosphate dehydrogenase. If not bound by the antibody, the enzyme will catalyze the oxidation of glucose-6-phosphate in the reagent forming 6-phosphogluconate and NADH. The production of NADH causes an increase in the absorption of 340 nm light. If no drug is present in the urine sample, all of the antibody will bind to the enzyme-conjugated drug. The antibody will block the catalytic site of the enzyme preventing the formation of NADH. If the drug is present in the urine sample, it will bind to some of the antibody, reducing the amount of antibody available to bind to the enzyme-conjugated drug. Therefore, the activity of the enzyme will be proportional to the concentration of drug in the urine sample.

In order to give maximum sensitivity the concentration of antibody is less than the concentration of the enzyme-conjugated drug. The labeled drug competes with any drug in the urine for binding sites on the antibody. If no drug is present in the sample, there will still be some unbound enzyme-conjugated drug that will produce NADH. However, the rate of enzyme activity will be less than that of the cutoff calibrator solution.

The enzyme activity of the sample is compared to that of a cutoff calibrator. The concentration of drug in the calibrator is set to a level recommended by SAMHSA for a positive test result. If the patient's sample result is greater than that of the cutoff calibrator, the drug test is presumed to be positive. Results below the cutoff calibrator are interpreted as negative. Activity less than the cutoff can result from endogenous drug present at very low levels in the absence of substance abuse. For example, poppy seeds used in baking contain minute amounts of opiates that cause some reactivity with enzyme immunoassays for opiates. Generally, the level of opiate detected will be below the cutoff value. Typically, the low calibrator and positive and negative urine control samples are assayed at least once per day along with the urine specimens.

EMIT is approved by the FDA only for urine specimens. Samples should be collected in clean plastic containers and refrigerated if not run within one hour. They can be refrigerated for up to three days or frozen, if longer storage is required. The pH of the sample must be between five and eight.

Confirmatory drug testing

Confirmation of a positive drug test by immunoassay is performed by a chromatographic method. Confirmatory methods include gas chromatography (GC), gas chromatography with mass spectroscopy detection (GC-MS), thin layer chromatography (TLC), and high performance liquid chromatography (HPLC). The methods most commonly employed in clinical practice are GC and TLC. In forensic laboratories and SAMHSA approved **toxicology** laboratories confirmation is done using GC-MS. All chromatography techniques require extraction of the drug from the biological fluid. This is accomplished by adjusting the pH of the sample to minimize ionization of the drug and addition of an organic solvent. The nonionized drug molecules will be more soluble in the organic phase and can be separated from water-soluble interfering substances. Extraction also serves to concentrate the drugs. In general, a pH of nine promotes extraction of alkaline and neutral drugs, and a pH of 4.5 promotes extraction of neutral or acidic drugs. Most abuse drugs with the exception of barbiturates and some benzodiazepines are extracted at an alkaline pH. Chromatography is a method used to separate molecules of similar structure. The process of separation depends upon nature of the chromatographic medium. Separation can result from partitioning (solubility differences), adsorption, size exclusion, ion exchange, and affinity bonding.

Gas chromatography

Gas chromatography is performed using a glass column packed with a liquid separation medium such as polyethylene glycol or an open glass capillary that is coated with a liquid polymer separation medium. GC measures only those substances that are volatile or can be separated into volatile compounds. GC separates molecules primarily on the basis of solubility. The sample is introduced into the instrument injection port and is vaporized by a high temperature. The vapors are carried by an inert gas (usually nitrogen) into a temperature-controlled column where they separate based upon their boiling point. Molecules of low boiling move faster through the column and elute first. When the drugs leave the column they are most often detected by a process called flame ionization. A small hydrogen-air flame is used to excite the molecule, causing release of an outer shell electron. This produces a current that is proportional to the concentration of the molecules. The instrument produces a recorder tracing of a peak when a compound is detected. The peak height or area is proportional to the drug concentration. The time between introduction of the sample and the appearance of the peak is called the retention time. Under standardized conditions, the retention

times of unknown substances can be compared to those of drug standards to identify the drug in the sample. GC is the reference method for measuring ethanol in blood and is sufficiently sensitive and specific to identify most drugs extracted from biological samples.

GC-MS is a form of gas chromatography. The detector used is a mass spectrometer. This device usually uses an electron beam to break the eluted drug into ion fragments. The ions are kept apart by application of a vacuum and are separated according to their mass to charge (m/z) ratio in the mass analyzer, which is usually a quadrupole mass filter. This device produces alternating direct current voltage and radio frequency waves that attract and repel the ions. Ions of different m/z ratios move at different rates as the frequencies change and leave the filter at different times. The ions are detected by a dynode as they leave the filter. When the ion strikes the dynode it causes the element to release a shower of electrons. This current is used to produce a peak corresponding in height to the concentration of the ion. A recorder tracing of all of the ion fragments constitute the mass spectrum of the drug. As no two drugs have the identical mass spectrum this method conclusively identifies the drug. For drug identification the GC-MS is used in a mode called total ion chromatography, which displays the complete mass spectrum of the eluate and allows comparison to a computerized library of drug standards. For quantitative analysis the selected ion monitoring (SIM) mode is used. This mode measures the principal ions of the drug and can more accurately quantify the drug at lower concentrations.

When testing for abuse substances the timing of specimen collection is very important because drugs are metabolized and eliminated at different rates. Dosage, length of use, and individual differences in absorption, **metabolism**, and elimination cause the window of detection to vary. Approximate detection times are shown below for some commonly abused drugs:

- amphetamines: one to two days
- short acting barbiturates (eg. Seconal): one day
- long-acting barbiturates (eg. Phenobarbital): two to three weeks
- benzodiazepines: three days
- THC: three days for acute intermittent use; up to one month for heavy, chronic use
- cocaine: two to four days
- ethanol: three to four hours
- morphine and codeine: two days
- phencyclidine: one to two days
- propoxyphene: six to 48 hours

Therapeutic drug monitoring (TDM)

The same dose and dosing schedule for a drug can be therapeutic for some patients, and subtherapeutic or toxic for others. Age, gender, smoking, genetics, protein binding, concurrent medications, and renal and hepatic function cause variation in drug absorption, distribution, and clearance, which affects blood levels of the drug. The study of the behavior of a drug in the body is called pharmacokinetics. Pharmacokinetics describes the relationship between drug dose and blood concentrations. When two or more measurements are made after the drug reaches steady state, the results can be used to determine the dose and dosing interval needed to achieve the desired blood level. Tests for therapeutic drugs are performed for four reasons. 1) To determine whether the dose and dosing interval are able to maintain the desired blood level of the drug. 2) To permit empirical adjustment of the dose when the drug level falls outside the therapeutic range. 3) To verify that the patient is complying with the prescribed treatment. 4) To evaluate the magnitude of an intentional or accidental drug overdose.

In practice, only those drugs that have toxic potential near the therapeutic range need to be monitored. Drugs that should be monitored include many anticonvulsants, aminoglycoside **antibiotics**, antiasthmatics, antiarrhythmics, antineoplastics, antidepressants, and immunosuppressive drugs used in organ transplantation. As orally ingested drugs are metabolized and eliminated between doses, blood levels are time dependent. Shortly following absorption and distribution of the drug in the body, the blood level will peak. As the drug is metabolized and eliminated the blood level will fall until replaced by the next oral dose. When serial measurements of drug are plotted, the result is a dose response curve made up of repeating peaks and troughs. Accurate timing of sample collection is required to properly interpret blood drug test results. For most drugs, there is not a great difference between peak and trough blood drug levels, and measurement of trough drug concentration is sufficient to evaluate the patient. In cases where the trough-peak range is large, both trough and peak levels need to be considered. This is the case when monitoring aminoglycoside antibiotics. When measuring trough blood levels of a drug the sample should be collected just before the next dose is given. Collection time for peak blood levels depends upon the drug and route of administration. For aminoglycoside antibiotics peak levels are usually drawn 30 minutes following an IV (intravenous) dose and 60 minutes following an IM (intramuscular) dose.

KEY TERMS

Immunoassay—A method for measuring biological substances such as drugs, proteins, and hormones. It utilizes antibodies specific for the substance being tested.

Enzyme—A protein that accelerates the rate of a biochemical reaction.

Enzyme immunoassay—A procedure employing an enzyme bound to an antigen or antibody. The antibody binds to the antigen of interest and the enzymatic reaction measures the concentration of the antigen.

Chromatography—A technique used to separate closely related biological molecules which exploits one or more of the following differences: solubility, molecular size, adsorption, ion exchange, affinity bonding.

Gas chromatography—A chromatographic method that utilizes a gas for the carrier or mobile phase and a liquid for the stationary phase.

Gas chromatography with mass spectroscopy—A method that employs a gas chromatograph to separate the molecules and a mass spectrometer to identify and quantify the separated compounds.

High performance liquid chromatography—A chromatographic method that utilizes a liquid mobile phase or carrier and a liquid stationary phase. Sample is forced through the stationary phase by a high pressure pump.

Thin layer chromatography—A chromatographic method that uses a thin layer of silica gel and a liquid mobile phase which migrates upward through the silica gel by capillary action. Molecules are carried by the mobile phase and separate on the basis of solubility.

Therapeutic drug monitoring—The measurement of a drug in blood serum or plasma in order to determine the adequacy of dosing and prevent drug toxicity.

Trough level—A drug assay performed on a sample collected before the next dose is absorbed.

Peak level—A drug assay performed on a sample following complete absorption and distribution.

Therapeutic drug measurements

Both immunoassay and chromatographic methods are used to quantify therapeutic drugs. EMIT, CEDIA, and FPIA assays are the most commonly used immunoassays. Gas chromatography and high-performance liquid chromatography are the most commonly used chromatographic methods.

FLUORESCENCE POLARIZATION IMMUNOASSAY (FPIA). This method measures the plane polarized fluorescence of fluorescein-labeled antigen without the need for an enzyme conjugate. Fluorescein conjugated to a drug competes with the drug in the sample for a limited number of antibody molecules. Plane-polarized UV light is transmitted through the sample. Both the unbound and antibody-bound, fluorescein-labeled drug absorb the UV light and the fluorescein becomes excited. The unbound labeled drug is rotating rapidly and emits light that is unpolarized. The labeled drug that is bound by antibody rotates more slowly and will emit light that is plane polarized. The detector responds to plane-polarized light only because a polarizing filter is placed between the cuvet and detector. Antibody binds to more fluorescein labeled drug when there is less drug in the patient's serum. This slows down its rotation giving a greater plane polarized signal. Therefore, plane-polarized fluorescent intensity is inversely proportional to the drug concentration in the patient's sample.

CLONED ENZYME DONOR IMMUNOASSAY (CEDIA). A technique related to EMIT is CEDIA (cloned enzyme donor immunoassay). The method uses a drug conjugated to a fragment of the enzyme β -galactosidase which is called the enzyme donor (ED). The ED reagent also contains the substrate, chlorophenol red- β -D-galactopyranose. This is mixed with urine or serum and a second reagent containing a monoclonal antibody against the drug and a second fragment of β -galactosidase called the enzyme acceptor (EA). If drug is present in the sample it neutralizes the antibody. The two enzyme fragments associate forming an active enzyme which splits the substrate, liberating the red dye. Absorbance is directly proportional to drug concentration. If drug is not present, the antibody binds to the ED fragment preventing formation of active enzyme.

HIGH PERFORMANCE LIQUID CHROMATOGRAPHY (HPLC). HPLC is a chromatography method that uses liquid mobile and stationary phases. The mobile phase is usually a buffer to which a polarity modifier such as acetonitrile has been added. The stationary phase consists of a stainless steel column of silica gel that is bonded to a nonpolar liquid. The most common column packing for clinical use is octadecylsilane (C18). The stationary phase is less polar than the mobile phase, and this causes

compounds which are lower in polarity to be retained longer than more polar molecules. The column is packed very tightly to give thousands of surfaces upon which partitioning can occur. Therefore, a pump is used to move the mobile phase through the column. To obtain a flow rate of 1.5-2.0 mL/min it is not uncommon to develop a pressure of 1,200-2,500 pounds per square inch at the start of the column. The separated molecules enter an optical flowcell after eluting from the column. UV (ultra-violet) light is passed through the flowcell and a photomultiplier tube or photodiode array detects the transmitted light. When a drug enters the flowcell it will absorb a portion of the incident UV light causing an increase in absorbance (optical density). This signal is applied to a chart recorder, which produces a peak that is proportional in height and area to the concentration of the drug. HPLC is time consuming and is usually reserved for assays of drugs for which there is no available immunoassay. It has the advantage of being able to separate drug metabolites from parent compounds and separate compounds that are nonvolatile (for example, anabolic steroids).

Results

Results for drug of abuse tests should be negative (ie. below the low calibrator cutoff). Results for therapeutic drugs should fall within the published therapeutic range for the drug and treatment. Some typical therapeutic limits for commonly measured drugs are shown below:

- Acetaminophen: 10-30 mg/L; toxic level >200 mg/L.
- Amikacin: trough 1-4 mg/L; peak 25-35 mg/L; toxic trough >10 mg/L; toxic peak >35 mg/L.
- Carbamazepine: 4-12 mg/L; toxic level >15 mg/L.
- Digoxin: 1.5-2.0 µg/L; toxic level >2.5 µg/L.
- Ethosuximide: 40-100 mg/L; toxic level >150 mg/L.
- Gentamicin: trough 1-2 mg/L; peak 8-10 mg/L; toxic trough >2 mg/L; toxic peak >12 mg/L.
- Kanamycin: trough 4-8 mg/L; peak 25-35 mg/L; toxic trough >10 mg/L; toxic peak >35 mg/L.
- Lidocaine: 1.5 - 6 mg/L; toxic level >6 mg/L.
- Netilmicin: trough 1-2 mg/L; peak 8-10 mg/L; toxic trough >2 mg/L; toxic peak >12 mg/L.
- Phenobarbital: 15-40 mg/L; toxic level >40 mg/L.
- Primidone: 5-12 mg/L; toxic level >15 mg/L.
- Procainamide: 4-10 mg/L; toxic level >12 mg/L.
- Salicylates: 100-300 mg/L; toxic level >400 mg/L.
- Theophylline: 8-20 mg/L; toxic level >20 mg/L.
- Tobramycin: trough 1-2 mg/L; peak 8-10 mg/L; toxic trough >2 mg/L; toxic peak >12 mg/L.
- Valproic acid: 50 - 100 mg/L; toxic level >100 mg/L.
- Vancomycin: trough 5-10 mg/L; peak 20-40 mg/L; toxic peak >80 mg/L.

Health care team roles

Therapeutic drug tests are ordered by physicians. Blood and urine samples may be collected by a nurse or phlebotomist. In the case of drug of abuse testing performed on behalf of an employer or government agency, drug testing is supervised by a medical officer appointed by the institution. Urine samples are collected and transported by nontesting personnel who should have special training in chain-of-custody procedures. Drug testing is performed by a clinical laboratory scientist, CLS (NCA) or medical technologist, MT (ASCP) or by a clinical laboratory technician, CLT (NCA) or medical laboratory technician, MLT (ASCP). Clinical toxicologists, clinical chemists, and clinical pharmacologists may be responsible for interpreting therapeutic drug tests and recommending dosage adjustments to the physician. Psychiatrists, psychologists, nurses, and social workers who are trained in drug abuse treatment are involved in evaluation, treatment, and counseling of drug abusers.

Dynamic spatial reconstructor

Definition

The dynamic spatial reconstructor (DSR) is a unique computed tomography (CT)-based scanner valuable for three-dimensional imaging and visualization of high temporal resolution three-dimensional cardiac cycles. Developed in the 1970s and early 1980s, the DSR is the “multi-source, multi-detector high speed synchronous 3D CT scanner for high temporal and spatial resolution scanning of the **heart, lungs,** and circulation” according to the Mayo Clinic, where the scanner was developed and is located. It is considered a research prototype and is not available commercially.

Purpose

The DSR was developed as a non-invasive diagnostic device to detect **lung cancer** and heart disease in their early stages. It emerged as an answer to the tremendous challenge of using CT to provide 3D reconstruction of moving objects such as the cyclic motion of the beating heart. Due to its efficacy, it has become the standard in the field of three-dimensional real-time imaging by which other non-invasive imaging modalities are measured in their effectiveness for achieving various diagnoses.

Description

Only a single DSR exists, at the Mayo Clinic site (Rochester, Minnesota), due to its prohibitive cost and size. The physical machine comprises:

- a gantry 15 ft (4.57 m) in diameter and 20.5 ft (6.24 m) in length, weighing about 17 U.S. tons
- fourteen x-ray guns featured within a hemicylindrical arrangement (surrounding the patient or subject overhead and on the sides) and targeted at an adjacent hemicylindrical fluorescent screen
- fourteen rotating two-dimensional television cameras and eight video disc recorders for recording the x-rays
- electronics and software algorithms for image acquisition

The DSR is theoretically capable of acquiring image data for up to 240 contiguous 0.9 mm thick segments in time periods down as far as 1/60 of a second. The process can then be repeated as rapidly as 60 times per second. Due to limiting physical factors of the machine, however, these values are somewhat diminished in practice. The 14 rotating television cameras, possessing 240 scan lines apiece, receive x-ray photons from the 14 x-ray

point sources directly opposite them at a frequency of 1/60 second, which happens to be a physiologically appropriate frequency for internal investigations involving moving organs such as the heart.

Though the DSR is capable of diagnosing a myriad of heart and lung disorders, its cost (and thus limited capability for service) has prevented it from becoming a routinely useful clinically diagnostic tool. Nevertheless, over the years since its inception in 1983, the DSR has made possible the collection and analysis of unique, important data that has been especially employed in cardiac dynamics research and in assuring the legitimacy of other imaging modalities.

An example of typical research usage is estimating the spatio-temporal distribution of the velocity of the left ventricular wall from experimental data obtained on the DSR. Essentially, a dense velocity field may be computed by applying a differential technique. This velocity field is obtained by mathematically applying the three following assumptions to the images: conservation of mass, incompressibility, and smoothness of the velocity field. In the case of this study, the results were in terms of the evolution of the field over time and maximum velocities, which were found to be in good agreement with the known physiological behavior of the heart.

The DSR is not without its problems, however. In addition to its enormous cost and size, another difficulty plaguing the machine is that the gantry rotates only 1.5° per 1/60 second, which hinders the homogeneous distribution in orientation angle of images per time period.

In order to keep the DSR more modern, some alterations have been implemented over the years since its launch, such as converting the old cameras (image isocron) to CCD (charge coupled device) cameras, larger lenses, and utilizing digitized images with corresponding algorithms. The DSR has thus been used to examine cardiopulmonary mechanics and pulmonary ventilation. Studies have confirmed the functionality of volumetric CT (DSR) in accurately resolving lung volumes, cardiac chamber volumes, myocardial muscle mass, and regional lung density, among others.

Operation

In general, the greater the number of viewing angles used in collecting data tends to generate better images, at least up to a point. At least 4/60 of a second of scanning is typically desirable for creation of a reasonably good image reconstruction by the DSR. However, the DSR operator, or the research team doing the experiment, must consider the organ of interest in terms of its speed of movement within the body. This is so that interesting and

KEY TERMS

Computed tomography (CT)—Also known as CAT (computed axial tomography) scans. Computed tomography scans are completed with the use of a 360-degree x-ray beam and computer reconstruction of images using appropriate algorithms. Two-dimensional slices are acquired and stacked up computationally to yield a three-dimensional density map of areas of interest. These scans allow for high resolution cross-sectional views of body organs and tissues.

relevant data can be taken at an appropriate rate, based on the similarity between the DSR temporal resolution and the tissue velocities and periodicity, in order to obtain optimal images.

Maintenance

Maintenance is performed as needed on this unique instrument.

Health care team roles

The DSR is mainly a research machine, so health care roles are generally relegated to interpretation of data sets by a doctor or technician trained to work with the apparatus.

The DSR is used at its sole site in the Mayo Clinic. It is generally used by researchers in fields such as cardiac dynamics which require in vivo 3D data for specific studies or by doctors who wish to measure how well another imaging modality (i.e. electron CT) performs in comparison. It is used on humans as well as a wide range of animals for research.

Training

Very few people are needed to operate the DSR since there is only one. Operating the scanner requires very specialized training that would be provided by technicians and technologists on site at Mayo if the need arises for its use.

Dysarthria

Definition

Dysarthria is a group of speech impairments due to weakness, incoordination, spasticity, rigidity, or irregular movements caused by damage to the nervous system.

Description

Speech abilities depend on the coordinated function of muscles of respiration, phonation (larynx), and articulation. These functions are controlled by a complex neural circuitry involving the structures and pathways of the peripheral nervous system (cranial and spinal nerves) and **central nervous system** (cerebral cortex, basal ganglia, substantia nigra, cerebellum, brainstem). Damage to any portion of the speech neural circuitry can lead to dysarthria. As a result, speech may be distorted and difficult to understand. Dysarthria is frequently accompanied by **dysphagia**, or swallowing difficulty, as similar neural circuits are necessary for swallowing function. Depending on which portion of the nervous system is affected, dysarthria can be accompanied by other speech, language, motor and sensory disturbances. Dysarthria can occur in adults and children who have neurologic conditions affecting the speech circuitry.

Causes and symptoms

Many neurologic etiologies that affect the speech neural circuitry can lead to dysarthria. Among the most common etiologies are stroke, degenerative conditions (e.g., **Parkinson's disease**, amyotrophic lateral sclerosis, Huntington's disease, cerebellar degeneration, **multiple sclerosis**), trauma, **cerebral palsy**, tumor, infections, and toxic conditions. Because dysarthria can arise from so many different neurologic conditions, the prevalence of the disorder is difficult to estimate.

The symptoms of dysarthria vary depending upon which portion of the neural circuitry is damaged.

KEY TERMS

Articulation—The pronunciation of speech sounds.

Central nervous system—Portions of the nervous system within the confines of the meninges and bones.

Dysphagia—Swallowing difficulty.

Dysphonia—Hoarse, breathy, or strained voice.

Etiology—The cause or causes of a disease or condition.

Peripheral nervous system—Portions of the nervous system that exit the meninges; the nerves.

Phonation—Sound that emanates from the larynx; voice.

Prosody—Intonation and rhythm of speech.

Resonance—The nasal quality of speech.

Articulation may be slurred, imprecise, distorted, or irregular. The resonance quality of speech may be hypernasal (over nasally sounding) or hyponasal (under nasally sounding). The voice may be breathy, strained, hoarse, or strangled to the point of stopping. Selective dysphonia (strained or breathy voice quality) can be observed. The prosody or melody of speech may be flattened, excessive, or choppy. The rate of speaking is usually slowed, but some individuals may actually speak at an excessive rate. Respiration for speech may be weak or forced. Tremor, spasms, or excessive movements of the speech muscles may disrupt the flow of speaking. Different combinations of symptoms can lead to significant loss of speech intelligibility (how easily speech is understood). Patterns of these symptoms tend to be observed in relation to the part of the nervous system that is damaged.

Diagnosis

A physician will perform a clinical neurological examination to determine a diagnosis in individuals with suspected neurologic disease. When an accompanying speech disorder is noted, the physician will refer the patient to a speech-language pathologist trained in the administration of speech examination protocols to identify the pattern of dysarthria and determine a course of treatment if warranted. Although most dysarthria tests depend on the clinician's perceptual analysis and judgment of the patient's speech characteristics, some acoustic and physiologic measurements can be complet-

ed using computerized analyses. Clinicians evaluate patterns of speech characteristics related to articulation, resonance, phonation, respiration, and prosody to determine a course of intervention. Assessment of dysarthria, which occurs in acute through chronic stages of the neurologic condition, takes one to two hours to complete.

Treatment

Treatments provided by physicians that may improve aspects of dysarthria include pharmacologic treatments for neurologic conditions, surgical intervention (e.g., injection of botulinum toxin into the vocal folds), or prosthetic management (for example, palatal lift, a prosthesis used to improve speech for a patient with an incompetent soft palate). Patients with dysarthria often work with a speech-language pathologist who will use behavioral methods to alleviate the consequences of dysarthria for communication. When patients have a neurologic condition from which recovery is anticipated (e.g., stroke), clinicians will use drills and practice with speech activities to restore speech skills or identify strategies to improve speech intelligibility. In degenerative neurologic conditions, when it often becomes impossible to rehabilitate speech, patients with dysarthria may adopt alternative and augmentative communication strategies including writing, communication pointing boards, computers, or speech-generation devices to compensate for the severe speech impairment.

Prognosis

The prognosis for recovery of dysarthria relates to the nature of the neurologic disorder that has caused the disease. When patients develop degenerative neurologic conditions, speech is likely to deteriorate as well. When the patient has a static or recovering neurologic condition (e.g., stroke), some improvement in speech abilities is likely depending on the extent of the nervous system injury.

Health care team roles

Nursing and medical staff providing medical care for individuals with dysarthria implement strategies recommended by speech-language pathologists to foster communication with patients. The rehabilitation team (e.g., physical therapist, occupational therapist, physiatrist, social worker) assists with neurological recovery and implements strategies to maximize communication skills.

Prevention

The way to prevent dysarthria is to prevent the neurologic event that causes dysarthria.

Dysphagia

Definition

Dysphagia is a disorder of swallowing.

Description

Dysphagia is a disruption in the ability to move food or liquid from the mouth through the pharynx and esophagus into the **stomach** safely and efficiently. Swallowing disorders can occur at any point in the life span from infancy through old age. It is estimated that approximately 6,228,000 Americans over age 60 have dysphagia, and that it occurs in 32% of all patients in intensive care units. If untreated, dysphagia can result in **dehydration**, weight loss, malnutrition, **pneumonia**, and, in rare cases, death.

In order to understand dysphagia, it helps to understand the normal swallow. A normal swallow rapidly carries a bolus of food or liquid through the mouth, pharynx, and esophagus, leaving these structures substantially clear of residue at its completion. It involves a complex interaction of sensory stimuli and motor responses that encompass both voluntary and involuntary behaviors.

A normal swallow consists of four phases: the oral preparatory phase, the oral phase, the pharyngeal phase, and the esophageal phase.

The oral preparatory phase readies the food or liquid for swallowing. The lips close and seal to contain the material in the mouth. Solid food is chewed and mixed with saliva. The tongue gathers the liquid or solid material into a bolus and holds it. During this phase, the entry into the airway is open and nasal breathing continues.

The oral phase begins when the tongue starts to move the bolus backward toward the pharynx. It ends when the head of the bolus passes into the pharynx.

The pharyngeal phase begins when the bolus enters the pharynx and ends when it passes into the esophagus. In this phase, sensory stimuli interact with reflex and volitional movements to trigger the swallow response, which includes:

- elevation and retraction of the soft palate to prevent material from entering the nose
- elevation and forward movement of the hyoid and larynx, which moves them out of the path of the bolus as it travels downward, thus helping to prevent it from entering the airway below
- closure of the larynx, which stops respiration momentarily and prevents the bolus from entering the airway below
- retraction of the tongue base and contraction of the posterior pharyngeal wall, which build pressure to propel the bolus downward
- progressive top to bottom contraction of the pharyngeal constrictor muscles, placing additional downward pressure on the bolus
- opening of the pharyngoesophageal segment to allow the bolus to pass into the esophagus

The esophageal phase of the swallow begins when the bolus enters the esophagus and ends when it passes into the stomach. Muscular contractions push the bolus downward through the lower esophageal sphincter into the stomach.

Causes and symptoms

Causes

Dysphagia occurs when any element of the normal swallow is disrupted. Oral structural abnormalities, muscular weakness, or incoordination may interfere with holding material in the mouth, forming it into a cohesive bolus, and propelling it backward into the pharynx. Lack of control over the material in the mouth might cause it to fall over the back of the tongue prematurely, while the airway is unprotected, or it might result in material remaining in the mouth after the swallow, when it could fall into the pharynx. If the bolus enters the pharynx before or after the swallow, while the airway is open and unprotected, there is a danger that aspiration will occur. Similarly, structural abnormalities, weakness, or incoordination in the pharynx or larynx may interfere with protection of the airway during the swallow or with the downward propulsion and emptying of the bolus into the esophagus. Finally, structural abnormalities, weakness, or incoordination in the esophagus may interfere with the progress of the bolus through the esophagus into the stomach.

Common etiologies of dysphagia include:

- strokes
- head injuries
- cervical **spinal cord** injuries
- progressive neurologic diseases
- **head and neck cancer** and the surgery or radiation used to treat it
- congenital syndromes and abnormalities
- esophageal stenosis
- esophageal tumors
- esophageal motility disorders
- achalasia
- gastroesophageal reflux disease

Medications may also cause or exacerbate dysphagia. **Antipsychotic drugs** that cause extrapyramidal symptoms like tardive dyskinesia may cause dysphagia, and some anticholinergic drugs may impair swallowing ability.

Symptoms

Common symptoms of dysphagia include:

- inability to control food or saliva in the mouth
- residue in the mouth after the swallow
- coughing during or after the swallow

- gurgly or wet vocal quality associated with swallowing
- unexplained weight loss
- increased time to consume a meal
- complaints of globus
- recurring pneumonia
- heartburn

Diagnosis

Diagnosis of dysphagia generally involves a clinical screening evaluation (sometimes called a bedside evaluation) and an instrumental evaluation. The clinical screening evaluation includes review of the medical history; current medical status; examination of oral anatomy and oral motor functioning; perceptual evaluation of laryngeal functioning; and observation of eating and drinking unless the risk of aspiration is very high and the individual is deemed too medically fragile to tolerate it. If the clinical screening evaluation suggests the presence of a dysphagia, it is usually followed by an instrumental evaluation.

The instrumental evaluation that is most widely used for diagnosing oropharyngeal dysphagia is the videofluoroscopic modified barium swallow (MBS) study. The MBS study allows the observation of structures and movements as the individual swallows controlled amounts of various consistencies (usually thin and thick liquid, a paste or pudding consistency, and solid food) while seated in an upright position. It provides information about transit times through the mouth and pharynx, motility problems, and the presence and etiology of aspiration. The MBS is done in the radiology department and requires the patient's cooperation. Thus, it may be contraindicated for patients who are unable to cooperate with instructions, or who are too medically fragile to be transported.

Videoescopy, or flexible fiberoptic examination of swallowing (FEES), is another procedure used to examine for oropharyngeal dysphagia. A flexible scope is inserted through the nose into the pharynx, allowing observation of the pharynx before and after the pharyngeal swallow is triggered. It does not allow observation of the oral or esophageal phases of the swallow, and, because the image is blocked by the constriction of the pharynx around the scope during the pharyngeal swallow, the presence and etiology of aspiration may be inferred but cannot be observed. This procedure can be done at the bedside and requires minimal cooperation from the patient, making it useful for patients who cannot tolerate an MBS study.

KEY TERMS

Achalasia—Failure of the pharyngoesophageal segment to relax sufficiently to allow swallowed material to pass from the esophagus into the stomach.

Anterior faucial arches—Also called the glosso-palatine arches, these pillar-like structures run from the palate down to the tongue laterally in the back of the mouth.

Anticholinergic drugs—Drugs that affect the parasympathetic system.

Aspiration—Entry of food or liquid into the airway below the level of the true vocal folds. Aspiration of large amounts or of small amounts over a period of time may result in pneumonia.

Cervical auscultation—Listening to the sounds of swallowing, usually via a stethoscope.

Dilatation—The stretching of a structure by swallowing increasingly larger sized rubber catheters filled with mercury.

Electromyography—Measures the timing and amplitude of selected muscle contractions.

Esophageal stenosis—Narrowing of the esophagus.

Esophagus—The tube that carries food or liquid from the pharynx to the stomach.

Globus—The feeling that there is a lump in the throat.

Hyoid—A small bone at the root of the tongue to which many lingual muscles are attached. It provides a stable base for tongue movement.

Larynx—Commonly called the voice box, this structure of muscle and cartilage sits at the top of the trachea.

Manometry—Measures of pressure changes that occur in the pharynx and/or esophagus during the swallow.

Motility—Movement.

Pharyngoesophageal segment—Also called the cricopharyngeal muscle or the upper esophageal sphincter (UES), this segment is normally in tonic contraction in awake individuals to prevent air from entering the esophagus during respiration and to reduce the risk of reflux from the pharynx into the esophagus.

Pharynx—The hollow muscular tube, commonly called the throat, that runs from the base of the skull to the opening of the esophagus.

Reflux—Backward flow of food and stomach acid from the stomach into the esophagus.

Scintigraphy—A nuclear medicine test requiring the patient to swallow measured amounts of radioactive substance. It can reveal the amount of aspiration and residue, but does not allow visualization of structures or movements.

Tardive dyskinesia—A disorder characterized by abnormal involuntary movements.

The instrumental evaluation most frequently used for esophageal dysphagia is the standard barium swallow or upper gastrointestinal series. This differs from the MBS study in that the patient is required to swallow a much larger amount of barium, typically while lying in the prone position. It allows observation of structures and of the movement of the material through the esophagus and into the stomach. When gastroesophageal reflux disease is suspected, continuous pH monitoring that measures the pH level of the contents of the lower esophagus is considered the best single test for its diagnosis.

Other instrumental evaluations that are sometimes used, either alone or in combination with the more standard techniques, include: ultrasound of the oral cavity, scintigraphy, **electromyography**, cervical auscultation, and manometry.

Treatment

Treatment of oropharyngeal dysphagia depends on the etiology and the severity of the problem. An essential component of treatment is education of the patient, family, and other caregivers regarding the nature of the swallowing problem, its potential complications, and the importance of following recommendations to prevent such complications. Treatment may also involve one or more of the following:

- An **exercise** program to improve the strength, range of motion, speed, and/or coordination of movements.
- Diet modifications that eliminate food or liquids of consistencies that are at high risk of being aspirated.
- Teaching of specific postures or strategies designed to reduce or eliminate the risk of aspiration when swallowing.

- Use of an alternate means of feeding, such as a gastric tube, either temporarily while other treatment strategies are attempted, or permanently if other treatment is unsuccessful.
- Esophageal dysphagia is usually medically, rather than behaviorally, managed. Dilatation is the typical treatment for esophageal stenosis. Surgery is most often used for esophageal tumors. Medications are used to treat motility disorders. Achalasia may be treated with smooth muscle relaxant drugs, dilatation, or surgery. Gastroesophageal reflux disease may be managed through dietary and lifestyle modifications, specifically: decreasing or eliminating certain foods from the diet, elevating the head of the bed for sleeping, avoiding lying down within two hours of eating, and eliminating smoking. Drugs and surgery are also used to treat this disorder.

Prognosis

The prognosis for recovery from dysphagia varies from excellent to poor depending on its severity, etiology, and the ability of the individual to comply with treatment recommendations.

Health care team roles

Identification, diagnosis, and management of dysphagia is a multidisciplinary effort. In most settings, speech-language pathologists perform screening evaluations, collaborate with a physician (usually a radiologist or otolaryngologist) in instrumental evaluations, design and implement a treatment program for oropharyngeal dysphagia, and provide education to the patient, family, and other staff members. The dietitian monitors the patient's nutritional status. The nursing staff, often the first to recognize dysphagic symptoms, encourages daily compliance with the recommended treatment program. Occupational and physical therapists work on feeding, adaptive devices, and sitting balance. (In some settings an occupational therapist is the primary swallowing therapist.) Physicians monitor and treat the patient's overall medical status. They are typically the primary treatment providers for esophageal dysphagia.

Prevention

Prevention of dysphagia requires prevention of the conditions that cause dysphagia, such as stroke, head trauma, or head and neck **cancer**. Prevention of complications from dysphagia involves adherence to the individualized treatment program, which usually specifies the precautions that should be taken. Although these will vary for each individual, they generally include eating and drinking only those foods and liquids of the recommended consistencies, sitting upright for oral intake, taking small amounts at a slow rate, ensuring that the mouth is clear after a swallow and at the end of a meal, using recommended strategies on every swallow, maintaining good **oral hygiene**, and remaining upright for 30 minutes after eating or longer if there is an esophageal dysphagia.

Ear instillation

Definition

An ear instillation is a solution of topical medicine prepared for administration into the ear canal. Medicine instilled into the ear is absorbed through the skin of the ear canal and membranes of the eardrum.

Purpose

Ear instillations are used primarily to treat wax build-up and inflammations or infections of the ear.

Precautions

Do not place the medicine dropper tip or cotton swabs directly into the ear canal, as this can traumatize the skin of the ear canal. Do not touch anything with the tip of the medicine dropper to prevent contamination. If the patient experiences **pain** from eardrops, stop using the medicine and contact the physician.

Description

To instill eardrops, have the patient lie on his or her side with the affected ear up. Gently pull the lobe of the ear up and back to open the ear canal (down and back for children under the age of three). Hold the medicine dropper just above the entrance to the ear canal and squeeze out the correct number of drops. Release the ear and have the patient remain still for five minutes to allow absorption of the eardrops. Repeat the procedure on the other ear if ordered.

Preparation

The hands should be washed before administering ear drops. Check the medication label each time to avoid medication errors. Be sure it is the right medicine, the right dose (strength), the right time, the right person and the right method. Look at the expiration date on the label. Do not use outdated medicine. Warm the eardrops to body temperature by rolling the bottle in the hands for several minutes before the instillation.

Aftercare

Have tissues or a warm washcloth available to wipe off residual medicine that may drip out of the ear when the patient sits up. A small piece of clean cotton ball may be placed into the outer portion of the ear canal to absorb excess medicine if desired. Discard soiled tissues and cotton in a bag that can be closed and discarded. Wipe the tip of the ear dropper with a clean tissue and recap the bottle. The hands should be washed again after completing the procedure.

Complications

Excessive use of eardrops can cause irritation and inflammation of the skin and membranes of the ear.

Results

Ear instillations will produce the desired results within a few days. Contact the physician if the patient experiences ear pain at the time of medicine instillation, or if the condition does not improve.

Health care team roles

Ear instillations are usually administered by a licensed nurse (R.N. or L.P.N.) in the health care setting. The patient or members of the patient's family can be taught to instill ear medicines in the home setting.

Ear irrigation

Definition

Ear irrigation is the process of flushing the external ear canal with sterile water or sterile saline. It is used to treat patients who complain of foreign body or cerumen (ear wax) impaction.

Purpose

The purpose of ear irrigation is to remove earwax that is obstructing the ear canal or to remove a foreign object lodged in the ear canal. Ear irrigation is most commonly performed on those who experience a wax buildup that has impaired **hearing** and irritated the outer ear canal. Ear irrigation is performed in the emergency department as a first-line treatment for a foreign object in the ear canal, because it is less invasive than using an instrument. If the object is a live insect, oil is inserted into the ear to kill the insect; then, the ear canal is irrigated to remove the dead insect. Some foreign objects may be removed from the ear using irrigation alone, but most require a combination of both irrigation and the use of instruments by the physician.

Precautions

The ear canal should be examined with an **otoscope** prior to ear irrigation. Ear irrigation is contraindicated if the eardrum is ruptured, because the procedure may force **bacteria** through the perforation into the inner ear. Ear irrigation is also contraindicated in patients with **fever**

and ear **pain**, as these symptoms may indicate an inner ear **infection**. If a foreign object is made of vegetable matter (e.g., a bean or pea), irrigation is contraindicated because the water will cause the object to swell and complicate extraction of the object.

Description

Ear irrigation can be performed using a 50–60-cc syringe (20–30-cc syringe for children). Some nurses prefer to attach a large bore IV (intravenous) catheter (with the needle removed) to the syringe for easier direction of the fluid. Using this method, the fluid is aspirated into the syringe and squirted into the ear canal. Another method uses IV solution and tubing, with a disposable ear irrigation connector that fits onto and over the outer ear. When using this method, the IV is turned on and the fluid flows by gravity into the ear to create the irrigation. When using the IV method, the bag should be about 6 inches (15 cm) or less above the patient’s head to create the proper fluid pressure.

After positioning the patient, the earlobe of the affected ear should be held back, and up (back and down for an infant). The tip of the irrigation syringe or catheter should be placed at the entrance to the ear. The tissue of the ear should not be touched. The ear canal should not be occluded, or the solution will not be able to run back out of the ear. Gently aiming the flow of the irrigation solution towards the upper aspect of the external ear canal, the nurse should syringe or run in the IV fluid at a slow, steady rate, allowing the fluid to escape out of the ear canal and into the basin. If using a dental pik apparatus, the lowest setting should be used. Exerting too much pressure can force the foreign object or the wax occlusion deeper into the ear canal. The return fluid should then be checked before the syringe is refilled—or after 100cc of fluid for an adult, and 30cc of fluid for a child. The nurse should investigate whether the wax or foreign object has been flushed from the ear. When the occlusion has been removed, 500cc of irrigation fluid should be used for an adult—100cc for a child, or as ordered by the physician. The procedure should be interrupted if the patient complains of pain or dizziness.

Preparation

The patient should be positioned with his or her head bent slightly forward and tilted toward the unaffected ear. His or her shoulder and neck should be covered with a water-resistant pad and a bath towel. The patient should be given kidney-shaped basin to hold under the affected ear. Children, the elderly, or patients who cannot sit up may be positioned on the back with the head tilted slightly toward the unaffected ear. Again, the shoulder should be covered

and/or the pillow with a water resistant pad and a bath towel. If necessary, the nurse should obtain assistance to hold the basin under the ear during the ear irrigation.

The nurse should wash his or her hands and put on gloves. The normal saline or sterile water irrigation solution should be heated. This can be accomplished by placement of the solution bag (bottle) in hot water, or using a microwave. Then, the temperature of the solution should be checked before the irrigation is started. The solution should be body temperature or slightly warmer (98.6–100°F [37–37.8°C]). Cool irrigation solution is more likely to make the patient dizzy. If using an irrigation syringe, the cap should be removed, and the first 60 cc should be drawn into the syringe. If using an IV catheter, the needle should be removed and the plastic catheter attached to the syringe or the IV tubing. All air from the syringe and tubing must be removed. Further, when an ear irrigation kit is used, the pieces should be opened and assembled. The IV tubing must be primed and filled, and the irrigation apparatus should be connected. The patient should have a dry wash cloth on hand in case the irrigation fluid runs toward his or her face or eyes. The patient should be informed before the irrigation begins. The patient should be instructed to speak up if he or she experiences pain or discomfort.

Aftercare

The patient should tilt his or her head toward the affected ear for a few minutes. This will allow excess fluid to run out. The irrigation apparatus should be removed and the patient assisted with drying off. The outer ear should be wiped with cotton balls or cotton swabs. However, the swabs should not be placed into the ear canal. Irrigation fluid should be discarded into a hopper. Disposable equipment and gloves should be placed in a trash bag that can be sealed and discarded. Finally, the nurse should wash his or her hands once the procedure is completed.

Complications

Complications of an ear irrigation are rare, but may include trauma to the external ear canal, external ear infection, pain, nausea, or vertigo. Forceful irrigation with high pressure can rupture the eardrum and force bacteria into the inner ear.

Results

Proper ear irrigation will most often result in the removal of the impacted earwax. If the wax is not washed out with 500cc of irrigation fluid, ear drops containing peroxide will be prescribed by the physician; these are to

be used for several days, to soften the earwax before further irrigation. If **foreign bodies** cannot be removed with ear irrigation, suction or instruments to remove the foreign object may be employed by the physician.

Health care team roles

Ear irrigations are performed by a **registered nurse** (R.N.) in the health care setting. The patient or family of the patient may be taught, by the physician or nurse, to do ear irrigations in the home setting if a patient has frequent problems with ear wax build-up.

Echocardiography

Definition

Echocardiography is a diagnostic test that uses ultrasound waves to produce an image of the **heart** muscle and the heart’s valves.

Purpose

Echocardiography is used to diagnose certain cardiovascular diseases, and is one of the most widely used

Echocardiogram, in which one can see the four chambers of the heart. (Photograph by Ken Eward. *Science Source/Photo Researchers*. Reproduced by permission.)

diagnostic tests for heart disease. Ultrasound waves that rebound or echo off the heart can show the size, shape, and movement of the heart's valves and chambers, as well as the flow of **blood** through the heart. Echocardiography may show abnormalities such as a poorly functioning heart valve or damage to the heart tissue from a heart attack. Echocardiography is especially useful for assessing disorders of the heart valves. It not only allows doctors to evaluate the heart valves, but can also detect abnormalities in the pattern of blood flow. For example, echocardiography can show the backward flow of blood through partially open heart valves (that should be fully closed). This backward flow of blood through a valve is known as regurgitation. By assessing the motion of the heart wall, echocardiography can help detect the presence and assess the severity of **coronary artery disease**, as well as help determine whether chest **pain** is related to heart disease. Additionally, echocardiography can help detect hypertrophic cardiomyopathy, in which the walls of the heart thicken in an attempt to compensate for heart muscle weakness.

Echocardiography is also used to evaluate heart murmurs (abnormal heart sounds), determine the causes of congestive **heart failure**, assess enlarged hearts or hearts with septal defects (holes between pumping chambers), and to monitor the heart in patients with diseases that may affect heart function (e.g., lupus, lung diseases). The biggest advantage to echocardiography is that it is noninvasive (it doesn't involve breaking the skin or entering body cavities) and has no known risks or side effects. Echocardiography is often used in conjunction with other diagnostic tests for the heart, such as **electrocardiography**.

Echocardiography is usually performed in the cardiology department at a hospital, but may also be performed in a cardiologist's office or an outpatient imaging center. Because the ultrasound scanners used to perform

echocardiography are portable (handheld) or mobile, echocardiography can be performed in the emergency department or at the bedside of patients who cannot be transported to the cardiology department.

Precautions

Echocardiography is a safe, noninvasive procedure, and there are no special precautions.

Description

Echocardiography creates an image of the heart using ultra-high-frequency sound waves—sound waves that are too high in frequency to be heard by the human ear. The technique is very similar to ultrasound scanning commonly used to visualize the fetus during **pregnancy**.

An echocardiography examination generally lasts between 15-30 minutes. The patient lies bare-chested on an examination table. A special gel is spread over the chest to help the transducer make good contact and slide smoothly over the skin. The transducer, also called a probe, is a small handheld device at the end of a flexible cable. The transducer, essentially a modified microphone, is placed against the chest and directs ultrasound waves into the chest. Some of the waves get echoed (or reflected) back to the transducer. Since different tissues and blood reflect ultrasound waves differently, these sound waves can be translated into a meaningful image of the heart that can be displayed on a monitor or recorded on paper or tape. The patient does not feel the sound waves, and the entire procedure is painless.

Occasionally, variations of the echocardiography test are used. For example, Doppler echocardiography employs a special microphone that allows technicians to measure and analyze the direction and speed of blood flow through **blood vessels** and heart valves. This makes it especially useful for detecting and evaluating regurgitation through the heart valves. By assessing the speed of blood flow at different locations around an obstruction, it can also help to precisely locate the obstruction.

An **exercise** echocardiogram, or **stress** echo, is an echocardiogram performed during exercise, when the heart muscle must work harder to supply blood to the body. This allows doctors to detect heart problems that might not be evident when the body is at rest and needs less blood. For patients who are unable to exercise, certain drugs can be used to mimic the effects of exercise by dilating the blood vessels and making the heart beat faster.

During the examination the sonographer can take measurements and, using the ultrasound scanner's computer, make calculations, including calculating blood

flow speed. Most ultrasound scanners are equipped with videotape recorders or digital imaging/archiving devices to record the real-time examination, and with medical image printers to print out hard copies of still images.

Preparation

The patient removes any clothing and jewelry above the chest.

Aftercare

No special measures need to be taken following echocardiography.

Complications

There are no known complications associated with the use of echocardiography. There is a slight risk of having a heart attack during an exercise echocardiogram, due to the stress put on the heart during the test, mostly for patients with a history of heart attack or other risk factors.

Results

A normal echocardiogram shows a normal heart structure and the normal flow of blood through the heart chambers and heart valves. However, a normal echocardiogram does not rule out the possibility of heart disease.

An echocardiogram may show a number of abnormalities in the structure and function of the heart, such as:

- thickening of the wall of the heart muscle (especially the left ventricle)
- abnormal motion of the heart muscle
- blood leaking backward through the heart valves (regurgitation)
- decreased blood flow through a heart valve (stenosis)

Health care team roles

Echocardiography should be performed by a registered diagnostic cardiac sonographer—an ultrasonographer specially trained in cardiac ultrasound. The results should be interpreted by a cardiologist trained in the application of cardiac sonography. The Intersocietal Commission for the Accreditation of Echocardiography Laboratories provides a self-evaluation process for echocardiography labs to become accredited. Accreditation involves staff evaluation and training, equipment assessment, and peer review.

KEY TERMS

Doppler imaging—A mode of ultrasound imaging that uses the physics principle of the Doppler effect (sound frequency waves shift relative to the observer, allowing velocity measurement) to produce color or gray-scale images of blood flow velocity and heart motion.

Heart murmur—An abnormal sound originating from the heart, usually detected by stethoscope. Murmurs are often caused by abnormalities of the heart valves.

Lupus—Also known as systemic lupus erythematosus, it is an autoimmune disease that may affect connective tissues and possibly the heart.

Noninvasive—Pertaining to a diagnostic procedure or treatment that does not require the skin to be broken or a body cavity to be entered.

Regurgitation—Backward flow of blood through a partially closed heart valve.

Transducer—A device that converts electrical signals into ultrasound waves and ultrasound waves back into electrical impulses; also called a probe.

Ultrasound—Sound waves at high frequencies beyond the level of human hearing; frequencies of approximately 2 to 10 megahertz are often used for diagnostic ultrasound imaging.

Edema

Definition

Edema is the medical term for swelling. It is an abnormal retention of fluid in body tissue.

Description

Edema that is visible and localized often accompanies a soft-tissue injury, a sprain, or a fracture. However, it is also a component of generalized retention of fluid such as occurs in congestive **heart failure** (CHF). By weight, 60% of the human body is composed of water. In a remarkable process that is, under normal circumstances, a nearly perfect balance, water is exchanged between the **blood** and the tissues. As it circulates blood through the body, the pressure from the **heart** presses water out of capillaries and into body tissues. Osmotic (water-drawing) properties of certain blood **proteins** cause this process to reverse and fluid to be reabsorbed from the tissues back into the capillaries. To maintain equilibrium, the **kidneys** draw off excess fluid and salt, which are then excreted as part of the urine. When fluid is not released from the tissues, the result is edema.

Causes and symptoms

The causes and severity of edema cover a wide spectrum, including:

- mild edema that accompanies female hormone imbalance during the menstrual cycle
- allergies in which the chemical histamine is released by the **immune system**, resulting in fluid leaking into the tissues, which creates swelling
- injuries that do damage to capillaries, causing fluids to seep out into the tissue and not be reabsorbed by the damaged capillaries
- hormonal imbalance caused by taking certain hormonal medications such as **corticosteroids**, high estrogen contraceptives, or androgens (male hormones)
- beriberi (vitamin B₁ deficiency) and dietary protein deficiency, often found with malnutrition
- the venous congestion that accompanies cirrhosis of the **liver** and eventually decreases osmotic pressure
- kidney failure, which eventually allows salts and water to be retained in the tissues rather than being excreted
- nephritic syndrome, a condition in which large amounts of blood protein are lost and the blood loses its ability to draw fluid back out of the tissues
- congestive heart failure, a common condition, especially in the elderly, in which the heart functions less efficiently due to **coronary artery disease**, high **blood pressure**, or congenital or disease-caused abnormality in the heart

Other than traumatic injuries or allergic reactions, swelling typically develops quite slowly and often goes unnoticed at its onset. It is estimated that fluid in the body can increase by 15% without being visible. Frequently it is manifested at that point only by an increase in weight. When edema does become apparent, it is usually found in the lower part of the body, in the feet, ankles, legs, and lower back. A finger pressed into edematous skin will leave an imprint that slowly disappears as the fluid again refills that tissue.

Severe edematous conditions can cause fluid to gather in body cavities. Ascites, common with cirrhosis of the liver, is characterized by large amounts of fluid amassing in the peritoneal cavity of the abdomen. When liquid fills the pleural cavity adjacent to the **lungs**, it is termed pleural effusion; the liquid presses upon the lungs, causing difficulty in breathing. Pulmonary edema, which occurs when air sacs in the lungs become waterlogged, also causes respiratory complications.

Diagnosis

Diagnosis of the cause of edema is based upon **physical examination** and laboratory testing, plus a complete medical history. For patients with a history of CHF or

Gross lymphoedema in the arm of an elderly woman following radiotherapy treatment for breast cancer. (Photograph by Dr. P. Marazzi. National Audubon Society Collection/Photo Researchers, Inc. Reproduced by permission.)

kidney disease, weights are frequently taken to watch for fluid retention.

Treatment

The simple act of elevating the legs sometimes will reduce edema. However, the primary means of treating edema is in determining the cause of the fluid retention and attempting to remedy that. Giving **antihypertensive drugs** to people with high blood pressure will sometimes eliminate the edema. Often, though, the underlying cause of the edema is not easily remedied, such as in the case of CHF. Treatment of CHF may include:

- limiting the salt in the diet
- taking diuretics, medications that stimulate the kidneys to excrete the excess salt and water
- taking angiotensin-converting enzyme inhibitors (ACE inhibitors) and vasodilator drugs, which cause **blood vessels** to expand and allow blood to flow easier, decreasing the work required of the heart
- taking beta blockers, which improve the functioning of the left ventricle of the heart

- taking digitalis, a drug that expands the ability of the heart to pump blood through the body
- having surgery to replace abnormal heart valves; in extreme cases, heart transplant may be needed

Prognosis

The outcome for edema depends heavily upon its cause. The best outlook for the relief of edema is when the underlying condition is treatable.

Health care team roles

Edema is most often noticed by either the patient, by a primary care physician or nurse-practitioner during a routine examination, or by nursing staff caring for the patient in a health care facility or at home.

Both registered nurses (RNs) and licensed practical nurses (LPNs) must complete a prescribed course in nursing and pass a state examination. RNs typically have a degree in nursing. Good nursing care of the patient with edema will include observation, elevating the legs if the

KEY TERMS

Capillaries—The term for any of the vessels that carry blood between the smallest arteries, or arterioles, and the smallest veins, venules.

Congestive heart failure—A condition in which the heart cannot circulate enough blood to meet the needs of the body.

Corticosteroids—A group of medications that have similar properties to the corticosteroid hormones that the adrenal glands produce naturally.

Fracture—A partial break in a bone.

Histamine—A chemical present in cells that is released during an allergic reaction and that causes the symptoms of inflammation, including swelling.

Osmosis—The passage of a fluid such as water through a sieve-like tissue called a semipermeable membrane from a less concentrated, or weaker, solution to a more concentrated, or stronger one.

Soft-tissue injury—Damage to tissue that encloses bones or joints, such as muscles, tendons, or ligaments.

Sprain—The tearing or stretching of ligaments holding bone ends together in a joint, usually caused by sudden, violent pulling.

lower extremities are swollen, monitoring **vital signs** and weights, and providing education about the cause of the edema.

Clinical laboratory scientists have specialized training and must pass a state examination. They draw blood samples or do the necessary tests on fluids withdrawn from fluid-filled body cavities.

Radiologic technologists have specialized training and must pass a state examination. They take x rays and other tests to visualize and monitor the course of disease processes that contribute to the edema.

Prevention

Prevention of edema is dependent upon treatment of the basic reason for the edema. Losing weight, stopping smoking, and reducing **stress** can all aid in reducing blood pressure. Proper **nutrition** can help to maintain a healthy circulatory system.

Electroanalgesia

Definition

Electroanalgesia is a method of **pain management** that involves the introduction of a weak electric current at the site of **pain**.

Purpose

The purpose of electroanalgesia is to reduce or eliminate pain.

Precautions

There are few contraindications for the use of electroanalgesia. It should not be used with pregnant women or patients with **pacemakers**, **heart** problems, **hearing aids** or hearing-aid implants. The low-level current can often interfere with the working of pacemakers and **hearing** aids.

Description

Electroanalgesia is a relatively new treatment method (since the late 1960s) to mitigate or eliminate pain. The concept, however, dates to the time of Aristotle, when patients who were experiencing pain were urged to stand in shallow water on top of electric fish (probably rays). It was not until 1965 when Dr. Ronald Melzack and Dr. Patrick Wall suggested the gate control theory that a legitimate scientific basis for electroanalgesia was

found. This theory, and the endorphin release theory, became the foundational rationale of electroanalgesia.

The gate control theory is the most widely held explanation for why electroanalgesia works. It says that by stimulating nerve sensors in the skin through electricity, a gate is closed in a part of the **spinal cord**, preventing pain messages from being carried to the **brain**. The patient has no perception of pain, although the message of pain at its site of origin still exists.

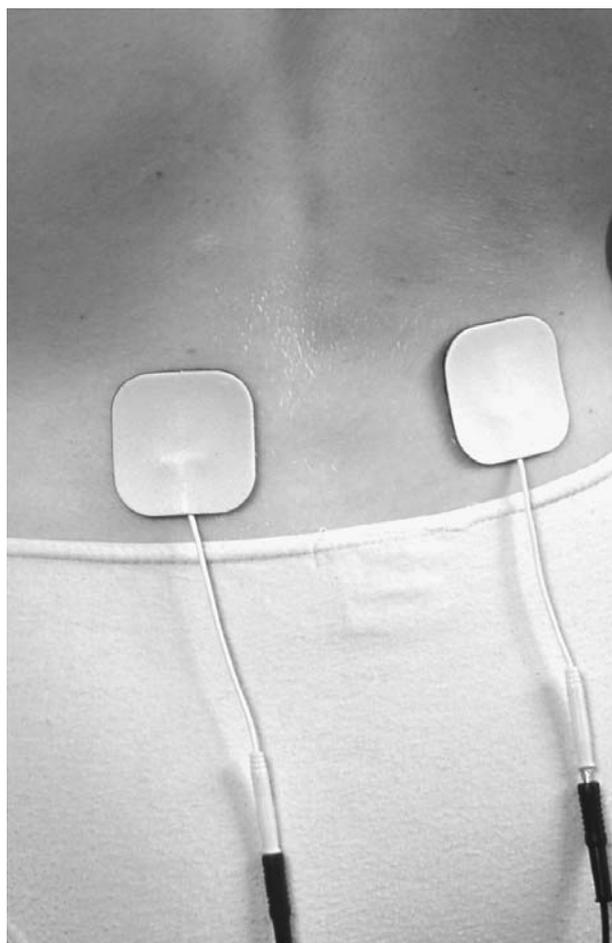

The endorphin release theory, in contrast, says that electricity stimulates the production of endorphins and enkaphalins—natural, morphine-like protein peptides—in the brain. These peptides block pain messages like conventional medications do but without the side effects associated with introducing pain control with opioids, for instance. Electroanalgesia cannot create a physical dependency like pain medications can.

Electroanalgesia may be used to relieve pain found in migraine and tension headaches, lower back, phantom limb syndrome, various forms of arthritis, **cancer**, angina pectoris, dysmenorrhea, posthepatic neuralgia, diabetic neuropathy, **bursitis**, sports injury, **wounds**, and after surgery. It can also be used to mitigate dental pain.

There are two forms of electroanalgesia: transcutaneous electrical nerve stimulation (TENS) and percutaneous electrical nerve stimulation (PENS). Electrical dental analgesia (EDA) is a form of TENS therapy and has been approved by the FDA since 1996.

TENS therapy uses one-inch (2.5 cm) diameter conductor electrode pads with adhesive backings. These electrode pads are placed on the skin near the site of the pain. The locus of the pain is the only reference for placement of these electrode pads. Studies have shown that endorphins are only released at pulse repetition rates (PPR)—or frequencies—of 8 Hz or less. Wider pulses spread the current over a greater area; most TENS units emit pulse widths ranging from 50–400 microseconds. Each TENS treatment will consist of the determined frequency (number of Hz) delivered for a certain length of time (perhaps one or two hours a day and sometimes more often at night) for a specified period of time (seven days; 14 days; 24 days). In low-frequency high-intensity stimulation, “quick probe treatments” may be delivered for 10 seconds each time; however, one “treatment” consists of several sets of five or six of these 10-second stimulations, and several “treatments” may be given consecutively. High-frequency TENS has been shown to suppress spontaneous and abnormal activity in a damaged nerve, and frequencies of 80 Hz or higher may be the treatment of choice in certain circumstances.

PENS therapy is a combination of acupuncture and electroanalgesia. In PENS treatment, fine stainless steel

An electrical current is passed between the two transcutaneous electrical nerve stimulation (TENS) pads on the skin. The current blocks the nerve signaling pathway and prevents pain signals from reaching the brain and being felt. (Photograph by Sheila Terry. Science Source/Photo Researchers. Reproduced by permission.)

acupuncture probes (rather than electrode pads) are attached to bipolar leads coming from an electrical generator. These probes are inserted into the soft tissue like acupuncture needles and the electricity running through them stimulates the pain sensors within and just beneath the skin. As with TENS, the level and length of stimulation, number of treatments, and number of treatment days, is determined. (In one study an alternating frequency of 15 Hz and 30 Hz was administered for 30 minutes three times a week.) Also as in TENS, the probes are inserted at or near the locus of pain rather than at traditional acupuncture points. Because a patient's skin is punctured, universal sterile procedures must be used.

A similar therapy to PENS is electroacupuncture. In this treatment method probes carrying the electric current are inserted at traditional acupuncture sites rather than at the pain locus.

KEY TERMS

Dysmenorrhea—Painful menstruation.

EDA—Electrical dental analgesia.

Endorphins—Natural, morphine-like substances in the brain.

Enkephalins—Natural, morphine-like substances in the brain.

PENS—Percutaneous electrical nerve stimulation.

TENS—Transcutaneous electrical nerve stimulation.

EDA is administered through small pads placed inside the mouth or on the outside of the cheeks. The patient controls the amount of electroanalgesic administered and feels only a pins-and-needles sensation rather than pain. Once the dental procedure is over and the EDA pads are removed, the patient has no residual numbing as often occurs with the use of local anesthetics.

Neither PENS nor electroacupuncture were approved by the FDA by 2001, and often are not covered by standard medical insurance. TENS and EDA have been approved. However, all of these electroanalgesic therapies should be used as a supplement to conventional treatment and should not be the primary or alternate course of treatment. Since pain is an indication of many serious conditions, pain should not be ignored or eliminated until the source of the disorder is found. Then, any number of pain management therapies including electroanalgesia may be used.

Preparation

There is no preparation for this procedure, except to identify the location of the pain. For TENS treatment, the patient should be given three separate treatments in the practitioner's office. An assessment of the patient's pain level after treatment, measured against a standard scale, must be discussed and recorded. The patient can then be instructed in the use of the apparatus for self-treatment at home. Once several treatments are completed, the patient should be evaluated. If the pain has stopped or reached a plateau, treatment should cease. If the pain is gone, even after only one minute of treatment during the first treatment, treatment should cease for that day. Often the patient feels immediate relief; sometimes, it is delayed over a day or two. It is important to remember that with progressive pathologies such as cancer and degenerative diseases like arthritis, pain most likely will return. The

patient will need repeated treatments which are often taken at home under the patient's control.

For PENS therapy, the patient receives treatment in the practitioner's office. The practitioner must locate the areas of pain and place the steel probes into the soft tissue at specific points near the pain.

Aftercare

With proper use, there is no need for aftercare from these procedures.

Complications

The only complications with electroanalgesic therapies are the risk of **infection** in invasive techniques (probes) and continuation of therapy after pain is eliminated or has reached its lowest threshold. In these instances, continuing treatment may cause the pain to return.

Results

Before treatments begin, the physician and patient must come to an agreement on the goals of therapy. Normal expected results are to diminish or eliminate pain; however, goals must be reasonable and workable according to the patient's condition. Often, patients report more freedom of movement, better sleep patterns, and considerable reduction in the need to use oral **analgesics** following electroanalgesic therapies.

Health care team roles

PENS therapists require special training in the use of the equipment and insertion of probes. There is an art to the therapy, much like the art associated with acupuncture.

TENS training is less delicate but still necessary. Since this therapy is relatively new, many physicians have written a prescription for a TENS unit, or given a unit to a patient without proper **patient education** about the use of the unit and the necessity for determining the appropriate frequency to obtain the necessary results. By administering the first three treatments in the office, the practitioner can determine the appropriate settings for the patient and his or her particular type of pain before sending the unit home with the patient.

Because dental patients control the amount of electronic anesthesia they receive, dentists and dental assistants must be trained in the use of the EDA units so they can instruct the patient how to dispense their individual level of pain suppression.

Electrocardiography

Definition

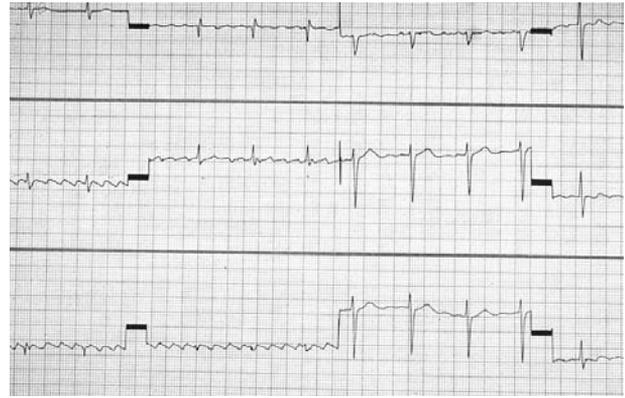

Electrocardiography is a commonly used, noninvasive procedure for recording electrical changes in the **heart**. The record, which is called an electrocardiogram (ECG or EKG), shows the series of waves that relate to the electrical impulses which occur during each beat of the heart. The results are printed on paper or displayed on a monitor. The waves in a normal record are named P, Q, R, S, and T, and follow in alphabetical order. The number of waves may vary, and other waves may be present.

Purpose

Electrocardiography is a starting point for detecting many cardiac problems. It is used routinely in physical examinations and for monitoring a patient's condition during and after surgery, as well as in the intensive care setting. It is the basic measurement used in **exercise** tolerance tests and is also used to evaluate symptoms such as chest **pain**, shortness of breath, and palpitations.

Precautions

No special precautions are required; however, patients are asked not to eat for several hours before a **stress test**.

An EKG strip indicating atrial flutter. (Custom Medical Stock Photo. Reproduced by permission.)

Description

The patient disrobes from the waist up, and electrodes (tiny wires in adhesive pads) are applied to specific sites on the arms, legs, and chest. When attached, these electrodes are called leads; three to twelve leads may be employed.

Muscle movement may interfere with the recording, which lasts for several beats of the heart. In cases where rhythm disturbances are suspected to be infrequent, the patient may wear a small Holter monitor in order to record continuously over a 24-hour period. This is known as ambulatory monitoring.

In 2001, the role of prehospital EKG in caring for patients with acute coronary syndromes was examined by the University of California San Diego School of Medicine, University of California San Diego Medical Center, San Diego, California, USA. Reported benefits of the prehospital 12-lead EKG include prompt initiation of reperfusion therapy (restoration of **blood** flow), and overall improved management and outcome of patients with acute **myocardial infarction**. Concerns remain regarding the best means of providing real-time field interpretation of the prehospital EKG and the potential for field time delay, triage concerns, and treatment of patients. Questions are raised regarding the overall clinical and cost benefit of expanding this resource.

Preparation

The skin is cleaned to obtain good electrical contact at the electrode positions and, occasionally, shaving the chest may be necessary.

KEY TERMS

Ambulatory monitoring—ECG recording over a prolonged period during which the patient can move around.

Arrhythmia or dysrhythmia—Abnormal rhythm in hearts that contract in an irregular way.

ECG or EKG—A record of the waves which relate to the electrical impulses produced at each beat of the heart.

Ectopic beat—Abnormal heart beat arising elsewhere than from the sinoatrial node.

Electrodes—Tiny wires in adhesive pads that are applied to the body for ECG measurement.

Fibrillation—Rapid, uncoordinated contractions of the upper or the lower chambers of the heart.

Lead—Name given the electrode when it is attached to the skin.

Reperfusion therapy—Restoration of blood flow to an organ or tissue; following a heart attack, quickly opening blocked arteries to reperfuse the heart muscles to minimize damage.

Aftercare

To avoid skin irritation from the salty gel used to obtain good electrical contact, the skin should be thoroughly cleaned after removal of the electrodes.

Complications

No complications from this procedure have been observed.

Results

Normal results

When the heart is operating normally, each part contracts in a specific order. Contraction of the muscle is triggered by an electrical impulse. These electrical impulses travel through specialized cells that form a conduction system. Following this pathway ensures that contractions will occur in a coordinated manner.

When the presence of all waves is observed in the electrocardiogram, and these waves follow the order defined alphabetically, the heart is said to show a normal sinus rhythm, and impulses may be assumed to be following the regular conduction pathway.

The heart is described as showing arrhythmia or dysrhythmia when time intervals between waves, or the order or the number of waves do not fit this pattern. Other features that may be altered include the direction of wave deflection and wave widths.

In the normal heart, electrical impulses—at a rate of 60–100 times per minute—originate in the sinus node. The sinus node is located in the first chamber of the heart, known as the right atrium, where blood reenters the heart after circulating through the body. After traveling down to the junction between the upper and lower chambers, the signal stimulates the atrioventricular node. From here, after a delay, it passes by specialized routes through the lower chambers or ventricles. In many disease states, the passage of the electrical impulse can be interrupted in a variety of ways, causing the heart to perform less efficiently.

Abnormal results

Special training is required for interpretation of the electrocardiogram. To summarize in the simplest manner the features used in interpretations, the P wave of the electrocardiogram is associated with the contraction of the atria. The QRS series of waves, or QRS complex, is associated with ventricular contraction, with the T wave coming after the contraction. Finally, the P-Q or P-R interval gives a value for the time taken for the electrical impulse to travel from the atria to the ventricle (normally less than 0.2 seconds).

The cause of dysrhythmia is ectopic beats. Ectopic beats are premature heart beats that arise from a site other than the sinus node—commonly from the atria, atrioventricular node, or the ventricle. When these dysrhythmias are only occasional, they may produce no symptoms or simply a feeling that the heart is turning over or “flip-flopping.” These occasional dysrhythmias are common in healthy people, but they also can be an indication of heart disease.

The varied sources of dysrhythmias provide a wide range of alterations in the form of the electrocardiogram. Ectopic beats, which begin in the ventricle, display an abnormal QRS complex. This can indicate disease associated with insufficient blood supply to the heart muscle (myocardial ischemia). Multiple ectopic sites lead to rapid and uncoordinated contractions of the atria or ventricles. This condition is known as fibrillation. In atrial fibrillation, P waves are absent and the QRS complex appears at erratic intervals, or “irregularly irregular.”

When the atrial impulse fails to reach the ventricle, a condition known as heart block results. If this is partial, the P-R interval (the time for the impulse to reach the ventricle) is prolonged. If complete, the ventricles beat

independently of the atria at about 40 beats per minute, and the QRS complex is mostly dissociated from the P wave.

Health care team roles

The electrocardiograph is conducted by a fully trained technologist and may be done in the cardiologist's office, a testing facility, or at a hospital patient's bedside. The technologist, or perhaps a nurse or nurse practitioner, will take the patients' medical history, educate them about the procedure they are about to undergo, and help them relax. The results of the electrocardiograph will be interpreted by a qualified physician, usually a cardiologist.

Electrocardiography unit

Definition

The **electrocardiography** unit, also called an electrocardiograph, is an apparatus that indirectly measures

the heart's electrical activity and records it as a graphic tracing.

Purpose

Electrocardiography is used to detect heart-function abnormalities. It indirectly detects the heart's electrical activity over time by measuring the electrical potential at the body's surface. If the heart's activity varies from normal, signs of this are seen in the surface electrical potentials. The electrocardiography unit produces a visual representation of the electrical potential, called an electrocardiogram (EKG or ECG), that is often recorded as a continuous line along a strip or special graph paper. When used to diagnose a **heart** ailment or check the effectiveness of a heart treatment, doctors, nurses, and other technicians read the strips, looking for telltale signs of various cardiac problems.

Because the electrical activity of the heart is the basis for its workings, many heart problems show up in an EKG tracing. The machine can detect **coronary artery disease**, where the **blood vessels** carrying **blood** to the heart have hardened and no longer work effectively; a heart attack, either current or previous; and arrhythmias, a heart beating at an abnormal speed or rhythm.

Description

The electrocardiography unit is a machine that transfers the very faint electrical signals of the heart into a visual representation of that activity. The unit commonly includes multiple electrodes and leads (often 12, but as few as three), a galvanometer to measure the electrical signal, an amplifier and filter to convert the faint electrical signal to one that can be seen, a computer screen or oscilloscope to display the output, and an ink-and-paper arrangement to produce hard copies of the signal.

In the simplest arrangement, three pairs of bipolar electrodes, where one is positively charged and the other negatively charged, are placed on particular areas of the patient's body. The electrodes are adhesive pads filled with conductive gel that are attached to the patient's skin. Wires called leads connect the electrodes to the unit. The electrical signal measured by each group of electrodes is also called a Lead. When used to identify the signal, the term is often capitalized.

Electrode placement

The first pair of electrodes has the positive electrode placed on the left arm and the negative on the right arm; this produces Lead I. The second pair has the positive electrode placed on the left leg and the negative on the right arm; this produces Lead II. Lead III comes from the

third pair, where the positive electrode is placed on the left leg and the negative on the left arm. If an imaginary line is drawn between each pair of these electrodes it forms a triangle where the electrical difference (measured in volts) can be detected across each side of the figure. This arrangement is known as Einthoven's triangle, after the inventor of the electrocardiograph.

Finer measurements of electrical potential can be made if additional sets of electrodes are used. The first additional set of electrodes is known as the augmented connections because the signals are significantly weaker than Leads I–III and have to be additionally increased, or augmented, by the machine. These Leads are unipolar, meaning that they measure the electrical difference between that electrode and a group of others. Lead aV_R measures the signal between the right arm (the positive electrode) and the average of the signals from the left arm and the left leg (two negative electrodes). Leads aV_L and aV_F are similarly arranged, with the left arm and the left leg having the positive electrode, respectively. All six of these limb leads measure electrical activity in the frontal plane of the heart, through the middle from top to bottom.

A second additional set of electrodes are the unipolar chest Leads, also known collectively as the modified chest Lead (MCL). These Leads measure electrical potentials across the horizontal plane of the heart. They are unipolar, measuring the electrical difference between the positive electrode and the average of the collective signal from the right arm, left arm, and left leg. There are six leads placed across the chest, numbered V1–V6 from the patient's right to left. V1 and V2 are put on either side of the sternum, in the fourth intercostal space (the space between the fourth and fifth rib). V4 is placed in the fifth intercostal space (between the fifth and sixth rib) on the line that divides the clavicle in half. V3 is placed halfway between V2 and V4. Both V5 and V6 are placed horizontal to V4, with V5 on the line that runs down the body from the inner armpit and V6 on the line that divides the armpit.

Waveform production

When the electrodes are placed as described, the electrical activity of the heart is printed in line patterns known as waves or waveforms. Waves come in two types—positive deflection (movement above the baseline or isoelectric line) and negative deflection (movement below the isoelectric line). Positive deflection is created when electrical activity flows toward the positive electrode; a negative deflection is produced when current flows away from the positive electrode (toward the negative). No heart activity produces a baseline or isoelectric

waveform. The isoelectric line is normally the beginning and ending of all waveforms.

EKGs are recorded on strips of graph paper that are fed through the machine at a constant rate (25 mm/sec or 1 in/sec) to allow for easy estimates of beats per time period and for points of comparison between the isoelectric line and the wave. At this standard feed rate, each small block of the graph paper represents 0.04 seconds, each larger dark box (having a 5×5 group of small boxes within it) is 0.2 seconds.

The normal heartbeat begins with an electrical impulse in the part of the heart with the fastest innate beat, the sinoatrial (SA) node. The electrical activity travels through the heart tissue, in a process known as depolarization, from the upper right of the organ to the lower left. Five major waves are produced: the P wave; the Q, R, and S waves (known as the QRS complex); and the T wave.

The P wave results from the depolarization of both atria and is a rounded, upward deflection that usually lasts about 0.10 seconds (about two small blocks of graph paper). The PR interval (PRI) is the time needed for the electrical impulse to travel from the atria to the ventricles. Normally, this lasts about three to five small squares (or 0.12 to 0.20 seconds).

The QRS complex has three recognized events and is the conduction of the impulse through the bundle of His and throughout the ventricles and atrial repolarization. The first downward deflection after PRI is the Q wave. It is followed by the largest deflection seen, the upward deflection of the R wave. Immediately after the R wave is a downward deflection called the S wave. The QRS complex generally happens in less than 0.12 seconds (three small squares) and all three waves are not always present, even in people with normal heart function.

The time interval between ventricular depolarization and repolarization is known as the ST segment and it is normally isoelectric (baseline). The full cycle is completed with the T wave, which is the result of the ventricles repolarizing. This wave is often a slightly asymmetrical, rounded positive deflection that finishes at the baseline.

Operation

To perform a resting EKG, the patient is placed on a table and the 12 electrodes are attached as described above. Sometimes, to improve connection, the areas of the skin where the electrodes will be placed are shaved or have conductive gel applied. Because some types of heart conditions are only evident when the heart is under **stress**, EKG analysis can also be performed with the patient on a treadmill.

An electrocardiography unit uses electrodes to measure the electrical activity of the heart and translates it into a line on paper and a computer screen. Doctors, technicians, and others can use the line tracing to look for a number of cardiac problems. (Custom Medical Stock Photo. Reproduced by permission.)

Sometimes a patient's symptoms occur at unpredictable intervals and are not **exercise** related. Heart activity can then be followed by a special portable EKG machine known as a Holter monitor. This EKG has three electrodes and stores the information for the monitoring period (generally from 24 hours to five days).

Diagnosing heart problems

In general, there are five aspects of the EKG that can reveal potential or present heart abnormalities: the heart rate, the heart rhythm, the P wave, the PR interval, and the QRS complex.

The heart rate is determined by counting the number of QRS complexes (for ventricular rate) or P waves (for atrial rate) over six seconds (30 large boxes on the graph paper). Normal is between 60 to 100 beats per minute (bpm). Less than 60 bpm is considered a slow or bradycardic rate and greater than 100 bpm is considered a fast, or tachycardic rate.

The heart rhythm, as revealed by the waveform pattern, can be classified either regular or irregular. To determine whether the ventricular rhythm is regular, a meas-

urement is made from R-to-R wave. A measurement from P-to-P wave determines the regularity of the atrial rhythm. If the interval is the same between waves, the rhythm is regular, if different, the rhythm is irregular.

Numerous changes in the P wave, PR interval, and QRS complex are possible. They depend on the actual damage to the heart, such as those that accompany a heart attack (**myocardial infarction** or MI). First, as the heart becomes ischemic, or starved for oxygenated blood, repolarization of the ventricles becomes abnormal; this depresses the ST segment more than 1 mm below baseline and the T wave becomes inverted. Next, if there is no treatment of the ischemia, actual damage to the heart tissue will occur. This can be seen through an elevation of the ST segment of more than 1 mm above baseline.

If the heart attack actually occurs (one or more coronary arteries becomes completely blocked), at least three possible indications can appear on the EKG. First, if it hasn't already happened, the ST segment will become elevated and the T wave will invert. Changes in the ST segment will remain for up to four weeks after the attack and the T wave could remain inverted for a year. If all

KEY TERMS

Bipolar—A type of lead having one positive and one negative electrode

Bradycardia—An abnormally slow heartbeat.

Bundle of His—A group of special heart muscle fibers that transmit electrical impulses to the ventricles, beginning the contractions that pump blood into the aorta and pulmonary artery.

Depolarization—The movement of an electrical charge through nerve or muscle tissue, changing its voltage.

Einthoven's triangle—The triangular arrangement of EKG electrodes on a patient, generally including the right arm, the left arm, and the left leg.

Electrode—The point of connection between the EKG unit and the patient.

Isoelectric—The baseline electrical level of the body.

Lead—A conductive connector between the electrode and the EKG unit or the signal derived from a group of electrodes.

Repolarization—The process in which a nerve or muscle cell returns to its normal electrical state after depolarization.

Tachycardia—An abnormally fast heartbeat.

Unipolar—A type of lead having one positive and multiple negative electrodes.

three of the layers of the heart have been affected by the attack, the Q wave will deflect more negatively. To be considered abnormal, the Q wave must be at least 0.04 seconds long (one small box) and be at least 25% of the height of the R wave. The Q wave will start large and shrink some over time, but will always be present after a so-called “Q-Wave” MI.

It is important to rule out artifacts as the cause of a patient's abnormal EKG. Common artifacts are patient movement, loose or defective electrodes, clammy skin, excessive chest hair, or improper grounding. The rule of thumb is to look to the patient and treat their distress, not what is showing on the monitor.

Maintenance

Electrocardiograph technicians are in charge of maintenance of EKG machines. Their tasks include

changing graph paper and ink, maintaining the electrodes and leads, and monitoring the machine for malfunction.

Health care team roles

Specially trained assistants known as electrocardiograph technicians often operate and maintain EKG machines in larger hospital and cardiology group practice settings. In small settings, nurses and medical assistants perform the test. A doctor usually does the final interpretation of the tracing.

Training

Many persons learn how to use an EKG machine through on the job training. However, training programs are available through outsourcing companies or in vocational and community colleges. The usual length of these college-based programs is 465 hours (four months). Program content includes classroom instruction in anatomy and physiology with an emphasis on the cardiac and vascular system, **medical terminology**, cardiovascular medications, patient care techniques, interpretation of cardiac rhythm, **medical ethics**, and a clinical practicum.

Electroencephalography

Definition

Electroencephalography, or EEG, is a neurological test that involves attaching electrodes to the head of a

patient to measure and record electrical activity in the **brain** over time.

Purpose

The EEG, also known as a brain wave test, is a key tool in the diagnosis and management of epilepsy and other seizure disorders. It is also used to assist in the diagnosis of brain damage and diseases such as strokes, tumors, encephalitis, mental retardation, and **sleep disorders**. The results of the test can distinguish psychiatric conditions (**schizophrenia**, paranoia, depression) from degenerative mental disorders such as Alzheimer's and Parkinson's diseases. An EEG may also be used to monitor brain activity during surgery to assess the effects of anesthesia, and also to determine brain death.

Precautions

An EEG is generally performed as one test in a series of neurological evaluations. Rarely does the EEG form the sole basis for a particular diagnosis.

Description

Before the EEG begins, a nurse or technologist attaches approximately 16 to 21 electrodes to the patient's scalp with a conductive, washable paste. The electrodes are placed on the head in a standard pattern based on head circumference measurements. Depending on the purpose for the EEG, implantable, or invasive, electrodes are occasionally used. Implantable electrodes include sphenoidal electrodes, which are fine wires inserted under the zygomatic arch, or cheekbone; Depth electrodes, or subdural strip electrodes, are surgically implanted into the brain and are used to localize a seizure focus in preparation for epilepsy surgery. Once in place, even implantable electrodes do not cause **pain**. The electrodes are used to measure the electrical activity in various regions of the brain over the course of the test period.

For the test, the patient lies on a bed, padded table, or comfortable chair and is asked to relax and remain still while measurements are being taken. An EEG usually takes no more than one hour, although long-term monitoring is often used for diagnosis of seizure disorders. During the test procedure, the patient may be asked to breathe slowly or quickly. Visual stimuli such as flashing lights or a patterned board may be used to stimulate certain types of brain activity. Throughout the procedure, the **electroencephalography unit** makes a continuous graphic record of the patient's brain activity, or brainwaves, on a long strip of recording paper or computer screen. This graphic record is called an electroen-

cephalogram. If the display is computerized, the test may be called a digital EEG, or dEEG.

The sleep EEG uses the same equipment and procedures as a regular EEG. Patients undergoing a sleep EEG are encouraged to fall asleep completely rather than just relax. They are typically provided a bed and a quiet room conducive to sleep. A sleep EEG lasts up to three hours, or up to eight or nine hours if it is a night sleep.

In an ambulatory EEG, patients are hooked up to a portable cassette recorder. They then go about normal activities and take normal rest and sleep for a period of up to 24 hours. During this period, the patient and patient's family record any symptoms or abnormal behaviors, which can later be correlated with the EEG to see if they represent seizures.

An extension of the EEG technique, called quantitative EEG (qEEG), involves manipulating the EEG signals with a computer using the fast Fourier transform algorithm. The result is then best displayed using a colored gray scale transposed onto a schematic map of the head to form a topographic image. The brain map produced in this technique is a vivid illustration of electrical activity of the brain. This technique also has the ability to compare the similarity of the signals between different electrodes, a measurement known as spectral coherence. Studies have shown the value of this measurement in diagnosis of Alzheimer's and mild closed head injuries. The technique can also identify areas of the brain having abnormally slow activity when the data are both mapped and compared to known normal values. The result is then known as a statistical or significance probability map (SPM). This allows differentiation between early **dementia** (increased slowing) or otherwise uncomplicated depression (no slowing).

Preparation

Full instructions should be given to EEG patients when they schedule their test. Typically, individuals on medications that affect the **central nervous system**, such as anticonvulsants, stimulants, or antidepressants, are told to discontinue their prescription for a short time prior to the test (usually one to two days). However, such requests should be cleared with the treating physician. Patients may be asked to avoid food and beverages that contain **caffeine**, a central nervous system stimulant. Patients may also be asked to arrive for the test with clean hair free of spray or other styling products to make attachment of the electrodes easier.

Patients undergoing a sleep EEG may be asked to remain awake the night before their test. They may be given a sedative prior to the test to induce sleep.

This woman is undergoing an electroencephalogram (EEG) to diagnose Alzheimer's disease. On the computer screen at the right are the colored scans of the electrical activity in her brain. Alzheimer's patients show a specific abnormality in their EEGs. (Photograph by Catherine Pouedras, Photo Researchers, Inc. Reproduced by permission.)

Aftercare

If the patient has suspended regular medication for the test, the EEG nurse or technician should advise the patient when to begin taking it again.

Complications

Being off medication for one to two days may trigger seizures. Certain procedures used during EEG may trigger seizures in patients with epilepsy. Those procedures include flashing lights and deep breathing. If the EEG is being used as a diagnostic for epilepsy (i.e., to determine the type of seizures an individual is experiencing) this may be a desired effect, although the patient needs to be monitored closely so that the seizure can be aborted if necessary. This type of test is known as an ictal EEG.

Results

In reading and interpreting brainwave patterns, a neurologist or other physician will evaluate the type of brainwaves and the symmetry, location, and consistency

of brainwave patterns. Brainwave response to certain stimuli presented during the EEG test (such as flashing lights or noise) will also be evaluated.

The four basic types of brainwaves are alpha, beta, theta, and delta, with the type distinguished by frequency. Alpha waves fall between 8 and 13 Hertz (Hz), beta are above 13 Hz, theta between 4 and 7 Hz, and delta are less than 4 Hz. Alpha waves are usually the dominant posterior rhythm in older children and adults when awake and relaxed. Beta waves are normal in sleep, particularly for infants and young children. Theta waves are normally found during drowsiness and sleep and are normal in wakefulness in children, while delta waves are the most prominent feature of the sleeping EEG. Spikes and sharp waves are generally abnormal; however, they are common in the EEG of normal newborns.

Different types of brain waves are seen as abnormal only in the context of the location of the waves, the patient's age, and the patient's conscious state. Overall, pathology typically increases slow activity, such as theta or delta waves, but decreases fast activity, such as alpha and beta waves.

Not all decrease in wave activity is abnormal, however. The normal alpha waves seen in the posterior region of the brain are suppressed merely if the patient is tense. Sometimes the addition of a wave is abnormal. For example, alpha rhythms seen in a newborn can signify seizure activity. Finally, the area where the rhythm is seen can be telling. The alpha **coma** is characterized by alpha rhythms produced diffusely, that is, by all regions of the brain.

Some abnormal beta rhythms include frontal beta waves that are induced by sedative drugs. Marked asymmetry in beta rhythms suggests a structural lesion on the side lacking the beta waves. Beta waves are also commonly measured over **skull** lesions, such as **fractures** or burr holes, activity known as a breach rhythm.

Usually seen only during sleep in adults, the presence of theta waves in the temporal region of awake, older adults has been tentatively correlated with vascular disease. Another rhythm normal in sleep, delta rhythms, may be recorded in the awake state over localized regions of cerebral damage. Intermittent delta rhythms are also an indication of damage of the relays between the deep gray matter and the cortex of the brain. In adults, this intermittent activity is found in the frontal region while in children it is in the occipital region.

The EEG readings of patients with epilepsy or other seizure disorders display bursts, or spikes, of electrical activity. In focal epilepsy, spikes are restricted to one hemisphere of the brain. If spikes are generalized to both hemispheres of the brain, multifocal epilepsy may be present. The EEG can be used to localize the region of the brain where the abnormal electrical activity is occurring. This is most easily done using a recording method, or montage, called an average reference montage. With this type of recording, the signal from each electrode is compared to the average signal from all the electrodes. The negative amplitude (upward movement, by convention) of the spike is observed for the different channels, or inputs, from the various electrodes. The negative deflection will be greatest as recorded by the electrode that is closest in location to the origin of the abnormal activity. The spike will be present but of reduced amplitude as the electrodes move farther away from the site producing the spike. Electrodes distant from the site will not record the spike occurrence.

A final kind of abnormal result is the presence of slower-than-normal wave activity, which can either be a slow background rhythm or slow waves superimposed on a normal background. A posterior dominant rhythm of 7 Hz or less in an adult is abnormal and consistent with encephalopathy. In contrast, localized theta or delta

KEY TERMS

Encephalitis—Inflammation of the brain.

Fast Fourier transfer—A digital processing of the recorded signal resulting in a decomposition of its frequency components.

Ictal EEG—An EEG done to determine the type of seizure characteristic of a person's disorder. During this EEG, seizure medicine may be discontinued in an attempt to induce a seizure during the testing period.

Sphenoidal electrodes—Fine wire electrodes that are implanted under the cheek bones, used to measure temporal seizures.

Subdural electrodes—Strip electrodes that are placed under dura mater (the outermost, toughest, and most fibrous of the three membranes (meninges) covering the brain and spinal cord); used to locate foci of epileptic seizures prior to epilepsy surgery.

Zygomatic arch—Cheekbone; a quadrilateral bone forming the prominence of the cheek; articulates with the frontal, sphenoid, and maxillary, and temporal bone.

rhythms found in conjunction with normal background rhythms suggest a structural lesion.

Health care team roles

Electroencephalography is often performed by specially trained electrodiagnostic technologists. Training for such a position can be on the job but often involves study at a one to two-year college or vocational program. A typical program would include:

- human anatomy and physiology
- neurology and neuroanatomy
- **neurophysiology**
- medical terminology
- computer technology and instrumentation

Certification of electrodiagnostic technologists specializing in electroencephalography and the related area of evoked potentials is available through the American Board of Registration of Electroencephalographic and Evoked Potential Technologists.

A physician such as neurologist, neurosurgeon, or internist does the final review and diagnosis based on the

results of the EEG. The doctor can be present for the testing or may review saved tracings. Other health care professionals, such as nurses, aid in **patient education** concerning this procedure.

Electroencephalography unit

Definition

The **electroencephalography** (EEG) unit is used to record the electrical output of the **brain** to produce a record called an electroencephalogram.

Purpose

Measurements taken by an electroencephalography unit are used to diagnose and classify disorders of the brain including seizures, encephalopathy, encephalitis, some psychiatric diseases, and brain death.

Description

The EEG unit includes a set of electrodes, amplifiers and filters, and a recording unit. Generally, surface electrodes are used for EEG recording, using 21 electrodes placed according to standard positions on the subject's scalp. However, implantable electrodes are also used for particular applications. For example, sphenoidal electrodes, which are fine wires inserted under the zygomatic arch, or cheekbone, are used when a patient is suspected of having temporal seizures. Depth electrodes, or subdural strip electrodes, are surgically implanted into the brain and are used to localize a seizure focus in preparation for epilepsy surgery.

The electrical signals from the brain are very weak, typically on the order of 10 to 100 microvolts. As a result, the amplifiers are used to increase the signal for display or recording, and the filters are used to eliminate artifacts and electrical noise produced by other sources such as muscles. The recording unit can be a paper and pen arrangement, although digital display is now standard.

Operation

The first step in performing an EEG is correct placement of the electrodes. The International Federation of Societies for EEG and Clinical Neurophysiology (IFSECN) has established a system of placement called the 10-20 Electrode Placement System. This system places the 21 electrodes at scalp positions that are at 10% and 20% of the head circumference, thus taking into account differing head size. Each electrode position is identified with a key letter that specifies the region of the brain and a positioning number. For example, prefrontal electrodes are labeled Fp, while central electrodes are C and occipital are O. Even numbers are on the right side of the head and odd numbers are on the left, with lower numbers anterior and higher numbers posterior. Midline electrodes are labeled with a "z" rather than a number.

Finding the exact point of placement of the electrodes involves measuring distances from various head landmarks, such as the nasion (the midpoint of the frontonasal suture) and the inion (the posterior occipital protuberance), and from one preauricular point (in front of the ear) to another. The electrodes are placed either at the intersection of these lines or at 10% or 20% of these various measurements about the head. For example, Cz is placed at the intersection of the nasion-inion line and the line that connects the preauricular points, while Fpz is 10% above the nasion and Oz is 10% above the inion. Standardized placement ensures that the results will be consistent and more easily compared to normal tracings.

The electrodes taped to this boy's scalp monitor his brain activity (brain waves) by detecting the electric impulses generated by the brain's activity. (Science Source/Photo Researchers. Reproduced by permission.)

Electrodes are applied to the head using electrode gel, which acts as a malleable extension of the electrode. Often, precleaning the scalp electrode site with a water-based, conductive agent is suggested for good contact. For long-term recordings, electrodes can be even more securely anchored using collodion (a mixture of pyroxilin, ether, and alcohol). This mixture quickly dries to a clear, tenacious film using compressed air.

Once the electrodes are attached, the machine is calibrated in two phases, through square-wave calibration and biological calibration. Square-wave calibration involves sending a standard pulse and altering the time constants of the low-frequency filters (LFF) and high-frequency filters (HFF) such that the resulting wave has the desired square-wave shape. Standard settings for LFF is 1 Hertz (Hz) and for HFF is 70 Hz. (Frequencies below 1 Hz can be artifacts due to sweat or other sources. The EEG typically does not have components above 70 Hz.)

Biological calibration involves sending one channel (the signal from a pair of electrodes) through all the amplifier inputs and comparing the signal with the displayed response; the two are adjusted until they are identical. Other adjustments that may be needed are damping the pen and setting sensitivity, which is usually started at 7 microvolts per millimeter and adjusted depending on the amplitude of the signal.

Generally, recordings are taken for at least 20 minutes to obtain an artifact-free result. The EEG unit records a series of waveforms that are not intrinsically normal or abnormal but must be interpreted based on the patient's age, awake-sleep state, and topographical location of the wave. Information can also be determined by looking for missing right-to-left symmetry. Further tests include the response of the subject to stimulation (such as visual flash or hyperventilation) or state changes (drowsiness or sleep). Although not always abnormal, the

KEY TERMS

Collodion—A syrupy liquid used to attach EEG electrodes to the scalp for long-term monitoring.

Inion—The bump of bone located on the back lower part of the head, a landmark used for measurements in the placement of EEG electrodes.

Nasion—The midpoint of where the frontal and nasal bones of the skull meet, a landmark used for measurements in the placement of EEG electrodes.

Sphenoidal electrodes—Fine wire electrodes that are implanted under the cheek bones, used to measure temporal seizures.

Subdural electrodes—Strip electrodes that are placed under dura mater (the outermost, toughest, and most fibrous of the three membranes [meninges] covering the brain and spinal cord); used to locate foci of epileptic seizures prior to epilepsy surgery.

Zygomatic arch—Cheekbone; a quadrilateral bone forming the prominence of the cheek; articulates with the frontal, sphenoid, and maxillary, and temporal bone.

presence of spikes and sharp waves can also aid in the diagnosis of the patient.

Maintenance

Electrodiagnostic technologists are in charge of daily maintenance of EEG machines. The tasks include changing graph paper and ink (if necessary), maintaining the electrodes and leads, and monitoring the machine for malfunction. Repair often involves outsource contracts or the use of personnel from the hospital engineering department.

Health care team roles

The EEG unit is often run by specially trained electrodiagnostic technologists, although sometimes it is done by nurses or other allied health professionals. Nurses are often used to supervise patients during extended EEG monitoring for seizure study. Neurologists and other physicians make the final diagnosis based on the results of EEG studies.

Training

Training to run an EEG unit can be on the job but often involves study at a one- to two-year college or vocational program. The formal postsecondary school training in this area is offered by hospitals and two-year community colleges. As of 2001, there were 12 formal programs approved by the Joint Review Committee on Education in **Electroneurodiagnostic Technology** of the Commission on Accreditation of Allied Health Programs (CAAHP). The programs usually last from one to two years with laboratory training, and often include the following classroom courses:

- human anatomy and physiology
- neurology and neuroanatomy
- neurophysiology
- medical terminology
- computer technology and instrumentation

Electrolyte balance

Definition

Electrolytes are positively or negatively charged particles that readily dissolve in water. The predominant positively charged electrolytes in the body are sodium, potassium, **calcium**, and magnesium, while negatively charged electrolytes include chloride, phosphates, and bicarbonate.

Description

Salts are chemical compounds composed of atoms that carry electrical charges. Dissolved in water, the components in a salt exist as ions. Collectively, these ions are called electrolytes. Electrolytes are dissolved in different compartments of body water including: the serum portion of the **blood**, inside the cells (intracellular), and outside the cells (extracellular). The concentration of these electrolytes varies considerably from one area to the other. However, there is a narrow concentration limit of these electrolytes that the body must maintain within each of these compartments. The body transfers electrolytes intracellularly and extracellularly as required to maintain electrolyte balance. Electrolyte concentrations of extracellular fluid can be measured in a blood sample.

Function

The kidney filters electrolytes in blood and maintains a balance by excreting the proper amount in the urine. An electrolyte's concentration in a solution of dissolved salts can be measured as the amount in milliequivalents (mEq) per volume of solution (i.e. per liter). Electrolytes have many functions and roles in the body. The concentration of electrolytes must be maintained within a narrow range within the blood, otherwise deleterious physiological effects may occur. Several of the most important electrolytes will be discussed individually in the following sections.

Role in human health

Sodium balance

The largest portion of the body's sodium reserves is in the extracellular fluid, which includes the blood plasma. The **kidneys** function to control the sodium excreted in the urine; thus the level of sodium in the body is relatively constant on a daily basis. An upset between intake of sodium (through dietary consumption) and output (in urine and sweat) creates an imbalance, affecting the total amount of sodium in the body. Variations in the total

amount of sodium are related to the volume of water found in the blood.

A decrease in the overall amount of sodium does not necessarily cause the concentration of blood sodium to fall, but may decrease blood volume. Low blood volume, such as occurs with hemorrhage, signals the kidneys to conserve both water and sodium through stimulation of aldosterone. This helps to return blood volume toward normal, by increasing the amount of extracellular fluid sodium. With an excess of sodium in the body, blood volume may rise. This increase in blood volume initiates an accumulation of extracellular fluid, often in the feet, ankles, and lower legs, resulting in a condition known as **edema**.

The body maintains extracellular fluid sodium concentration homeostasis through the thirst mechanism and regulation of kidney water excretion by antidiuretic hormone (ADH). When sodium concentration—as opposed to too much total sodium—is too high, thirst prompts water intake and, at the same time, the ADH signals to the kidneys to conserve water, by increasing water absorption by the organs and passing less water into the excretory system.

Common disorders

The electrolytes involved in disorders of salt balance are most often sodium, potassium, calcium, phosphate, and magnesium. The concentration of blood chloride is usually similar to the blood sodium concentration, while bicarbonate is related to **acid-base balance**.

Sodium balance

HYPONATREMIA. The most common electrolyte disorder is hyponatremia, it occurs in almost 1% of all patients hospital admissions. Hyponatremia is a condition characterized by low sodium in the blood, below 136 mEq per liter of blood. In hyponatremia, the sodium concentration has been overdiluted by an excess of water or a loss of sodium in the body. Hyponatremia may result from intravenous administration of water to hospitalized patients or can also occur with small amounts of water consumption in those who have impaired kidney function and several other conditions such as **liver cirrhosis**, **heart failure**, underactive **adrenal glands** as with Addison's disease, and various antidiuretic hormone disorders. Over 50% of hospitalized patients with **AIDS** have been reported to suffer from hyponatremia. Lethargy and confusion are typically the first signs of hyponatremia. Muscle twitching and seizures may occur as hyponatremia progresses with risk of stupor, **coma**, and death in the most severe cases. Due to the effects on the **central nervous system**, mortality risk is considerably greater in

acute hyponatremia than in chronic hyponatremia. Other factors that reduce survival are the presence of debilitating illnesses such as **alcoholism**, hepatic cirrhosis, **heart** failure, or malignancy.

HYPERNATREMIA. Hyponatremia is a condition characterized by a high concentration of sodium in the blood, above 145 mEq per liter of blood. There is too little water compared to the amount of sodium in the blood, often resulting from a low intake of water. Profuse sweating, vomiting, **fever**, **diarrhea**, or abnormal kidney function may result in hyponatremia. With age, there is a decreased thirst sensation; therefore, hyponatremia is more common in the elderly. Aging reduces the kidney's ability to concentrate urine; therefore, taking diuretics may further exacerbate hyponatremia. Hyponatremia is very serious, particularly in the elderly. Almost half of individuals hospitalized for this condition will die, although it is often secondary to other illnesses.

Major causes of high sodium levels include:

- limited water access, particularly when combined with any other cause
- excess water loss due to profuse sweating, vomiting, fever, diarrhea
- disorders of other electrolytes
- head trauma or neurosurgery involving the pituitary gland
- use of drugs including lithium, diuretics, demeclocycline
- diabetes insipidus
- sickle cell disease

As with hyponatremia, the major symptoms of hyponatremia result from **brain** dysfunction. Severe hyponatremia can lead to confusion, muscle twitching, seizures, coma, and death. The effects on central nervous system hyperosmolality and the seriousness of the underlying illness lead to greater mortality in acute hyponatremia compared to chronic hyponatremia.

Calcium balance

The body's calcium reserves are predominately stored in bones, although the blood and cells also contain calcium. Calcium is necessary for proper functioning in many areas of the body including nerve conduction, **muscle contraction**, and enzyme functions. Like other electrolytes, the body controls calcium levels both in blood and cells. Calcium from the diet is absorbed in the gastrointestinal tract while the excess is excreted in the urine. A minimum of 500-1000 mg of calcium is required daily in order to maintain a normal calcium concentration. Normally, the body transfers calcium to the blood from the bones to maintain calcium homeostasis. If cal-

cium intake falls short of the requirement, too much calcium will be mobilized from the bones, weakening the bones and contributing to **osteoporosis**.

Parathyroid hormone and calcitonin regulate the amount of calcium in the blood. There are four **parathyroid glands** located in the neck that increase secretion of parathyroid hormone when the calcium concentration falls too low. Consequently, the gastrointestinal tract is stimulated to absorb more calcium from the blood, release a greater amount of calcium from the bones, and to excrete less in the urine. At the same time, parathyroid hormone induces the kidneys to activate **vitamin D** which increases uptake of calcium from the gastrointestinal tract. Calcitonin is a hormone produced by the parathyroid, thyroid, and thymus glands. It acts to lower the calcium concentration in blood by enhancing uptake of calcium into the bones.

Common disorders

Calcium balance

HYPOCALCEMIA. A low calcium blood level is referred to as hypocalcemia. Calcium is measured in extracellular fluid in two forms: total calcium concentration and ionized calcium concentration. About 50% of the total calcium concentration in the plasma exists in ionized form, which is the form that has biological activity at **cell membranes**. The remainder is either bound to the plasma **proteins** (about 40%) or complexed in the non-ionized form (about 10%) with anions such as phosphate. In hypocalcemia the total calcium concentration falls below 2.4 mEq/l in the extracellular fluid. Hypocalcemia can result from a number of problems. The most common reason is an inability to mobilize calcium from the bones or a chronic loss of calcium in the urine.

Other causes of hypocalcemia include:

- low blood albumin concentration
- hypoparathyroidism
- vitamin D deficiency
- renal failure
- magnesium depletion
- acute pancreatitis
- hypoproteinemia
- septic shock
- hyperphosphatemia
- drugs such as those used to treat hypercalcemia; anti-convulsants
- excessive secretion of calcitonin

An abnormally low blood calcium concentration may not produce any symptoms. However, over time the lack of calcium in the blood can affect brain function causing neurologic symptoms such as **memory** loss, depression, confusion, delirium, and hallucinations. Once calcium levels return to normal, these symptoms are reversible. Very severe cases of hypocalcemia can lead to seizures, tetany, and muscle spasms in the throat, affecting breathing. The condition is usually first discovered during routine blood tests because often there are no symptoms evident.

HYPERCALCEMIA. A high calcium blood level is referred to as hypercalcemia. The blood calcium concentration rises above 10.5 mg per deciliter of blood. Increased gastrointestinal tract absorption or increased intake of calcium may lead to hypercalcemia. Individuals who consume large amounts of calcium or who take calcium containing **antacids** can develop hypercalcemia. Absorption of calcium can be increased in the gastrointestinal tract with an **overdose** of vitamin D. The condition is usually first discovered during routine blood tests because hypercalcemia often doesn't have any symptoms at all.

If symptoms occur, typically the earliest are:

- constipation
- loss of appetite
- nausea and vomiting
- abdominal pain

Large amounts of urine may be produced by the kidneys. Due to excess urine production, fluid levels in the body decrease and may lead to dehydration. Severe hypercalcemia may induce brain dysfunction symptoms such as weakness, confusion, emotional disturbances, delirium, hallucinations, and coma. Additionally, abnormal heart rhythms and death may follow. In chronic conditions, **kidney stones** or calcium-containing crystals that can cause permanent damage may form.

Potassium balance

Potassium plays a major part in cell **metabolism** and in nerve and muscle cell function. Most of the body's potassium is located intracellularly, not extracellularly or in the blood. Too high or low concentrations of blood potassium can have serious effects such as an abnormal heart rhythm or cardiac arrest. The potassium concentration in the blood is maintained with the assistance of intracellular potassium. Like other electrolytes, potassium balance is regulated through gastrointestinal tract absorption of potassium in food, and by excretion of potassium by the kidneys. Some potassium is lost in the gastrointestinal tract, but most is lost through urine.

Some conditions and drugs influence potassium balance intracellularly, also affecting blood concentrations.

High sources of dietary potassium are:

- bananas
- melons
- tomatoes
- oranges
- potatoes and sweet potatoes
- green leafy vegetables such as spinach, turnip greens, collard greens, kale etc.
- most peas and beans
- potassium supplements
- salt substitutes (potassium chloride)

Common disorders

Potassium balance

HYPOKALEMIA. A low potassium blood level is referred to as hypokalemia. It occurs when the blood potassium concentration falls below 3.8 mEq per liter of blood. Hypokalemia is common in the elderly. Common causes include decreased intake of potassium during acute illness, nausea and vomiting, and treatment with thiazide or loop diuretics. About 20% of patients receiving thiazide diuretics develop hypokalemia, which is dose-dependent but usually mild. Since several foods contain potassium, hypokalemia is not typically due to a low intake. It is usually due to malfunction of the kidneys or abnormal loss through the gastrointestinal tract. People with heart disease have to be especially cautious regarding hypokalemia (particularly when taking digoxin), because they are prone to developing abnormal heart rhythms.

Potassium usually can be replaced relatively easily by eating foods rich in potassium or by taking potassium salts (potassium chloride) orally.

HYPERKALEMIA. A high level of potassium in the blood is referred to as hyperkalemia. It occurs when the blood potassium concentration rises above 5.0 mEq per liter of blood. Hyperkalemia typically results when the kidneys excrete too little potassium.

Some common causes are due to:

- drugs which block potassium excretion (angiotensin converting enzyme [ACE] inhibitors, triamterene, and spironolactone)
- Addison's disease
- kidney failure

KEY TERMS

Antidiuretic hormone (ADH)—A hormone that encourages the kidney to retain water when body stores are low.

Bicarbonate—A salt of carbonic acid produced by neutralizing a hydrogen ion.

Dehydration—A deficit of body water that results when the output of water exceeds intake.

Diuretic—An agent or drug that eliminates excessive water in the body by increasing the flow of urine.

Edema—An increase in blood volume instigates an accumulation of extracellular fluid resulting in swelling of the feet, ankles, and lower legs.

Electrolyte—A substance such as an acid, bases, or salt. An electrolyte's water solution will conduct an electric current and ionizes. Acids, bases, and salts are electrolytes.

Homeostasis—An organism's regulation of body processes to maintain internal equilibrium in temperature and fluid content.

Hypoparathyroidism—A condition resulting from an absence or deficiency in parathyroid hormone. It is characterized by hypocalcemia and hyperphosphatemia.

Tetany—A general stiffening and spasms of the muscles that can occur in severe cases of hypocalcemia.

- a sudden release of potassium from the cell reservoir in such cases as when a large amount of muscle tissue is destroyed (crush injury) or severe burn injuries, or an overdose on crack cocaine

The kidney's ability to excrete potassium is overwhelmed due to a rapid influx into the blood, resulting in life-threatening hyperkalemia. Generally, hyperkalemia is more dangerous than hypokalemia. A blood potassium concentration above 5.5 mEq/liter starts to affect the electrical conducting system in the heart. If the concentration continues to increase, the heart rhythm becomes irregular which may cause the heart to eventually stop.

Mild hyperkalemia often may not produce any symptoms. Symptoms may include an irregular heartbeat that could be experienced as palpitations. Hyperkalemia is typically first diagnosed during a routine blood test or by examining changes in an electrocardiogram. Severe

deficiencies may lead to muscular weakness, twitches, and **paralysis**.

Magnesium balance

Magnesium influences the function of many enzymes. Dietary intake is essential to maintain normal levels. The body's magnesium stores are predominately found in bone with little appearing in the blood. Excess is excreted in the urine or stool.

Common disorders

Magnesium balance

HYPOMAGNESEMIA. A low level of magnesium in the blood is known as hypomagnesemia. The level of magnesium in the blood decreases below 1.6 mEq per liter of blood. Metabolic and nutritional disorders are usually the culprit of hypomagnesemia, most often when intake of magnesium is decreased during starvation or intestinal malabsorption compounded with greater kidney excretion.

Symptoms of hypomagnesemia may include:

- loss of appetite
- nausea and vomiting
- sleepiness
- weakness
- personality changes
- muscle spasms
- tremors

When hypomagnesemia occurs along with hypocalcemia, the magnesium must be replaced before successful treatment of the calcium disorder.

HYPERMAGNESEMIA. A high level of magnesium in the blood is referred to as hypermagnesemia. The blood magnesium concentration rises above 2.1 mEq per liter of blood. Hypermagnesemia is quite rare unless people with kidney failure are given magnesium salts or consume magnesium-containing drugs such as antacids. Weakness, low **blood pressure**, and impaired breathing can result and the heart may stop if the concentration increases above 12 to 15 mEq per liter.

Phosphate regulation

Phosphorus occurs in the body almost solely in the form of phosphate, which is composed of one phosphorus and four oxygen atoms. Phosphate is found mostly in bones, although a significant amount is found intracellularly. It plays a role in energy metabolism and acid-base regulation, and it is used as a building block for DNA. Phosphate is excreted in the urine and stool.

Sources of phosphate include:

- spinach, turnip greens, collard greens, kale, and other green leafy vegetables
- milk and dairy products
- nuts
- chocolate
- many peas and beans
- dark-colored soft drinks

Electrolyte tests

Definition

Electrolytes are positively and negatively charged ions that are found within the cells and extracellular fluids, including **blood** plasma. A test for electrolytes includes the measurement of sodium, potassium, chloride, and bicarbonate. These ions are needed to assess renal, endocrine, and acid-base function, and are components of both renal function and comprehensive metabolic biochemistry profiles. Other important electrolytes routinely measured in serum or plasma include **calcium** and **phosphorus**. These are measured together because they are both affected by bone and parathyroid diseases, and often move in opposing directions. Magnesium is another electrolyte that is routinely measured. Like calci-

um, it will cause tetany (uncontrolled muscle contractions) when levels are too low in the extracellular fluids.

Purpose

Tests that measure the concentration of electrolytes are needed for both the diagnosis and management of renal, endocrine, acid-base, water balance, and many other conditions. Their importance lies in part with the serious consequences that relatively small changes that diseases or abnormal conditions may cause. For example, the reference range for potassium is 3.6-5.0 mmol/L. Potassium is often a STAT test because values below 3.0 mmol/L are associated with arrhythmia, tachycardia, and cardiac arrest, and values above 6.0 mmol/L are associated with bradycardia and **heart failure**. Abnormal potassium cannot be treated without reference to bicarbonate, which is a measure of the buffering capacity of the plasma. Sodium bicarbonate and dissolved carbon dioxide act together to resist changes in blood pH. For example, an increased plasma bicarbonate indicates a condition called metabolic alkalosis, which results in too high a blood pH. This may cause hydrogen ions to shift from the cells into the extracellular fluid in exchange for potassium. As potassium moves into the cells, the plasma concentration falls. The low plasma potassium, called hypokalemia, should not be treated by administration of potassium, but by identifying and eliminating the cause of the alkalosis. Administration of potassium would result in hyperkalemia when the acid-base disturbance is corrected. Sodium measurements are very useful in differentiating the cause of an abnormal potassium. Conditions such as the overuse of diuretics (drugs that promote lower **blood pressure**) often result in low levels of both sodium and potassium. On the other hand, Cushing's disease (adrenocortical hyperfunction) and Addison's disease (adrenocortical insufficiency) drive the sodium and potassium in opposing directions. Chloride levels will follow sodium levels with the exception of acid-base imbalances, in which chloride may move in the opposing direction of bicarbonate. In essence, diagnosis and management of a patient with an electrolyte disturbance is best served by measuring all four electrolytes.

Description

Sodium is the principal extracellular cation and potassium the principal intracellular cation. Sodium levels are directly related to the osmotic pressure of the plasma. In fact, since an anion is always associated with sodium (usually chloride or bicarbonate), the plasma osmolality (total dissolved solute concentration) can be estimated using the following formula: Osmolality in

milliosmoles per kilogram water = serum sodium \times 2 + Glucose/18 + BUN/2.8 where BUN is the blood urea nitrogen concentration. Since water will often follow sodium by diffusion, loss of sodium leads to **dehydration** and retention of sodium leads to **edema**. Conditions that promote increased sodium, called hypernatremia, do so without promoting an equivalent gain in water. Such conditions include diabetes insipidus (water loss by the **kidneys**), Cushing's disease, and hyperaldosteronism (increased sodium reabsorption). Many other conditions, such as congestive **heart** failure, cirrhosis of the **liver**, and renal disease result in renal retention of sodium, but an equivalent amount of water is retained as well. This results in a condition called total body sodium excess, which causes **hypertension** and edema, but not an elevated serum sodium concentration. Low serum sodium, called hyponatremia, may result from Addison's disease, excessive diuretic therapy, the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), **burns**, **diarrhea**, vomiting, and **cystic fibrosis**. In fact, the diagnosis of cystic fibrosis is made by demonstrating an elevated chloride concentration (greater than 60 mmol/L) in sweat.

Potassium is the electrolyte used as a hallmark sign of renal failure. Like sodium, potassium is freely filtered by the kidney. However, in the distal tubule sodium is reabsorbed and potassium is secreted. In renal failure, the combination of decreased filtration and decreased secretion combine to cause increased plasma potassium. Hyperkalemia is the most significant and life-threatening complication of renal failure. Hyperkalemia is also commonly caused by hemolytic anemia (release from hemolysed red blood cells), diabetes insipidus, Addison's disease, and digitalis toxicity. Frequent causes of low serum potassium include alkalosis, diarrhea and vomiting, excessive use of thiazide diuretics, Cushing's disease, intravenous fluid administration, and SIADH.

Calcium and phosphorus are measured together because they are both likely to be abnormal in bone and parathyroid disease states. Parathyroid hormone causes resorption of these **minerals** from bone. However, it promotes intestinal absorption and renal reabsorption of calcium and renal excretion of phosphorus. In hyperparathyroidism, serum calcium will be increased and phosphorus will be decreased. In hypoparathyroidism and renal disease, serum calcium will be low but phosphorus will be high. In **vitamin D** dependent rickets (VDDR), both calcium and phosphorus will be low; however, calcium is normal while phosphorus is low in vitamin D resistant rickets (VDRR). Differential diagnosis of an abnormal serum calcium is aided by the measurement of ionized calcium (i.e., calcium not bound by protein). Approximately 45% of the calcium in blood is bound to protein, 45% is ionized, and 10% is complexed to anions

in the form of undissociated salts. Only the ionized calcium is physiologically active, and the level of ionized calcium is regulated by parathyroid hormone (PTH) via negative feedback (high ionized calcium inhibits secretion of PTH). While hypoparathyroidism, VDDR, renal failure, hypoalbuminemia, hypovitaminosis D, and other conditions may cause low total calcium, only hypoparathyroidism (and alkalosis) will result in low ionized calcium. Conversely, while hyperparathyroidism, malignancies (those that secrete parathyroid hormone-related protein), multiple myeloma, **antacids**, hyperproteinemia, dehydration, and hypervitaminosis D cause an elevated total calcium, only hyperparathyroidism, malignancy, and acidosis cause an elevated ionized calcium.

Serum magnesium levels may be increased by hemolytic anemia, renal failure, Addison's disease, hyperparathyroidism, and magnesium based antacids. Chronic **alcoholism** is the most common cause of a low serum magnesium owing to poor **nutrition**. Serum magnesium is also decreased in diarrhea, hypoparathyroidism, **pancreatitis**, Cushing's disease, and with excessive diuretic use. Low magnesium can be caused by a number of **antibiotics** and other drugs and by administration of intravenous solutions. Magnesium is needed for secretion of parathyroid hormone, and therefore, a low serum magnesium can induce hypocalcemia. Magnesium deficiency is very common in regions where the water supply does not contain sufficient magnesium salts. Magnesium acts as a calcium channel blocker, and when cellular magnesium is low, high intracellular calcium results. This leads to hypertension, tachycardia, and tetany. Unfortunately serum total magnesium levels do not correlate well with intracellular magnesium levels, and serum measurement is not very sensitive for detecting chronic deficiency because of compensatory contributions from bone. Ionized magnesium levels are better correlated with intracellular levels because the ionized form can move freely between the cells and extracellular fluids.

Measurement of electrolytes

Electrolytes are measured by a process known as potentiometry. This method measures the voltage that develops between the inner and outer surfaces of an ion selective electrode. The electrode (membrane) is made of a material that is selectively permeable to the ion being measured. For example, sodium electrodes are made from a special glass formula that selectively binds sodium ions. The inside of the electrode is filled with a fluid containing sodium ions, and the outside of the glass membrane is immersed in the sample. A potential difference develops across the glass membrane that is dependent upon the difference in sodium concentration (activity) on the inside

and outside of the glass membrane. This potential is measured by comparing it to the potential of a reference electrode. Since the potential of the reference electrode is held constant, the difference in voltage between the two electrodes is attributed to the concentration of sodium in the sample. Ion selective membranes can be made from materials other than glass. For example, the antibiotic valinomycin is used to make potassium-measuring electrodes. Neutral carrier ionophores selective for lithium, calcium, and magnesium are also used for measurement of these substances in laboratory medicine. Ion selective electrodes can be used to measure whole blood, serum, or plasma since they respond to the electrolyte activity in the water phase of the sample only. One important aspect of electrolyte measurement is an artifact (erroneous result) called pseudohyponatremia that may occur when sodium is measured using a diluted blood sample. This happens when the plasma contains excessively high **lipids** or protein. These solids displace plasma water from the specimen, resulting in a low measurement of sodium that does not occur with an undiluted sample.

Total calcium and magnesium are usually measured by colorimetric procedures called dye binding assays. Calcium is displaced from protein by dilute acid or alkali and reacts with a dye (arsenazo III or cresolphthalein complexone) to form a colored product. When cresolphthalein complexone is used, 8-hydroxyquinoline is added to bind magnesium which also reacts with this dye. Magnesium is commonly measured by its reaction with a dye called Calmagite. A calcium chelator such as EGTA is added to prevent interference from calcium. Both calcium and magnesium may be measured by atomic absorption spectrophotometry. This procedure is more complex than colorimetric methods, but is also more accurate. Phosphorus is measured by reacting it with ammonium molybdate at an acid pH. The rate of ammonium phosphomolybdate formation is measured at 340 nm and is proportional to the inorganic phosphorus concentration (mono- and dihydrogen phosphate) of the sample.

Precautions

Electrolyte tests are performed on heparinized whole blood, heparinized plasma, or serum, usually collected from a vein or capillary. Venipuncture is performed observing **universal precautions** for the prevention of transmission of bloodborne pathogens. In order to prevent hemoconcentration, the tourniquet must be removed from the arm as soon as the blood starts to flow. The needle gauge must be sufficient in width to prevent mechanical damage to the red blood cells that will result in hemolysis (rupture of the membrane of the red blood cells). Because the concentration of potassium, magne-

sium, and phosphorus within red blood cells is much higher than in the plasma, hemolysis will cause falsely elevated results for these analytes. Plasma is often preferred over serum for measuring potassium, as the process of blood clotting can release potassium from platelets. Heparin is the only anticoagulant acceptable for electrolyte testing, as all other anticoagulants act by chelating calcium. Samples for ionized calcium should be collected using balanced (low) heparin which has a concentration of 20 U/mL. Higher concentrations bind calcium. Ionized calcium samples should be transported and stored on ice under anaerobic conditions and measured within 30 minutes of sample collection as pH changes in the blood will affect the ionized calcium.

Special procedures are followed when collecting a sweat sample for electrolyte analysis. This procedure, called pilocarpine iontophoresis, uses electric current applied to the arm of the patient (usually an infant) in order to convey the pilocarpine to the sweat glands where it will stimulate sweating. Care must be taken to ensure that the collection device (macroduct tubing or gauze) does not become contaminated and that the patient's parent or guardian understands the need for the electrical equipment employed.

Preparation

Usually no special preparation is necessary by the patient. Samples for calcium and phosphorus and for magnesium should be collected following an eight-hour fast.

Aftercare

Discomfort or bruising may occur at the puncture site, or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Applying warm packs to the puncture site relieves discomfort.

Complications

Minor temporary discomfort may occur with any blood test, but there are no complications specific to electrolyte testing.

Results

Electrolyte concentrations are similar whether measured in serum or plasma. Values are expressed as mmol/L for sodium, potassium, chloride, and bicarbonate. Magnesium results are often reported as milliequivalents per liter (meq/L) or in mg/dL. Total calcium is usually reported in mg/dL and ionized calcium in mmol/L. Since

KEY TERMS

Tetany—Inappropriately sustained muscle spasms.

severe electrolyte disturbances can be associated with life-threatening consequences such as heart failure, **shock**, **coma**, or tetany alert values are used to warn physicians of impending crisis. Typical reference ranges and alert values are cited below.

- Serum or plasma sodium: 135-145 mmol/L Alert levels: less than 120 mmol/L and greater than 160 mmol/L.
- Serum potassium: 3.6-5.4 mmol/L (plasma, 3.6-5.0mmol/L); Alert levels: less than 3.0 mmol/L and greater than 6.0 mmol/L.
- Serum or plasma chloride: 98 - 108 mmol/L.
- Sweat chloride: 4-60 mmol/L.
- Serum or plasma bicarbonate: 18-24 mmol/L (as total carbon dioxide, 22-26 mmol/L); Alert levels: less than 10 mmol/L and greater than 40 mmol/L.
- Serum calcium: 8.5-10.5 mg/dL (2.0-2.5 mmol/L); Alert levels: less than 6.0 mg/dL and greater than 13.0 mg/dL.
- Ionized calcium: 1.0-1.3 mmol/L.
- Serum inorganic phosphorus: 2.3-4.7 mg/dL (children, 4.0 - 7.0 mg/dL); Alert level: less than 1.0 mg/dL.
- Serum magnesium: 1.8-3.0 mg/dL (1.2-2.0 meq/L or 0.5-1.0 mmol/L).
- Ionized magnesium: 0.53-0.67 mmol/L.
- Osmolality (calculated) 280-300 mosm/Kg.

Health care team roles

A physician orders electrolyte tests and interprets the results. A nurse or phlebotomist usually collects the blood sample by venipuncture. In some instances the nurse performs the electrolyte test using a point-of-care instrument consisting of a single use cartridge of ion-selective electrodes and a battery operated analyzer. In the laboratory setting electrolyte tests are performed by clinical laboratory scientists/medical technologists or clinical laboratory technicians/medical laboratory technicians. Nurses, nurse practitioners, and physician assistants may find themselves involved in explaining results to patients and advising them regarding treatment or dietary correction of any problems identified.

Electromyography

Definition

Electromyography (EMG) is used to detect, process, and record electrical muscle activity in order to aid in the diagnosis of neuromuscular disease.

Purpose

EMG is performed most often to help diagnose different neuromuscular diseases causing weakness. EMG can determine whether a particular muscle is responding appropriately to stimulation, and whether a muscle remains inactive when not stimulated. Although EMG is a test of the motor system, it may help identify abnormalities of nerves or spinal nerve roots that may be associated with **pain** or numbness. EMG may also be useful in determining the cause of certain symptoms, including numbness, atrophy, stiffness, fasciculation, cramps, deformity, and spasticity. EMG results can help determine whether symptoms are due to a muscle disease or a neurological disorder, and, when combined with clinical findings, usually allow a confident diagnosis.

EMG can help diagnose many muscle and nerve disorders, including:

- muscular dystrophy
- congenital, mitochondrial, and metabolic myopathies
- myotonias
- compression neuropathies, such as carpal tunnel syndrome
- peripheral neuropathies
- radiculopathies

- nerve lesions
- amyotrophic lateral sclerosis (Lou Gehrig's disease)
- polio
- spinal muscular atrophy
- Guillain-Barré syndrome
- ataxias
- myasthenias

EMG is also used in gait and motion analysis. EMG is performed dynamically (while the patient executes certain movements) to evaluate gait and movement problems. Clinical applications include assessment of patients with **cerebral palsy**, traumatic **brain injury**, **spinal cord injury**, motor neuron lesions, evaluation of athletic injuries, examination of gait abnormalities associated with stroke, and preoperative assessment of patients having corrective orthopedic surgery.

EMG is one of the tests administered during **polysomnography** studies. EMG is used to measure neuromuscular activity during sleep to aid in the diagnosis of **sleep disorders**, such as restless legs syndrome.

Precautions

No special precautions are needed for this test. Patients with a history of **bleeding disorders** should consult with their treating physician before the test. If a muscle biopsy is planned as part of the diagnostic work-up, EMG should not be performed at the same site, as it may affect the microscopic appearance of the muscle.

Description

EMG is performed using an electromyography unit consisting of electrodes and a computer-based recording unit. Electrodes are used to detect electrical activity generated by stimulating the muscles. Muscles are stimulated by signals from nerve cells called motor **neurons**. This stimulation causes electrical activity in the muscle, which in turn causes contraction. This electrical activity is detected by the EMG electrode and recorded by the electromyography unit computer.

During an EMG test, the electrode is applied or inserted into the muscle to be tested. Surface, needle, and fine-wire electrodes may be used, depending on the type of stimulation required. Needle electrodes may cause some discomfort, similar to that of an injection. Recordings are made while the muscle is at rest, and then during the contraction. The person performing the test may move the limb being tested, and direct the patient to move it with various levels of force. The electrode may be

Electromyography is often used in biofeedback therapy and in diagnosing neuromuscular disorders. (Custom Medical Stock Photo. Reproduced by permission.)

repositioned for further recording. Other muscles may be tested as well. A typical session lasts from 30–60 minutes.

A slightly different test, the nerve conduction velocity test, is often performed at the same time with the same equipment. In this test, stimulating and recording electrodes are used, and small electrical shocks are applied to measure the ability of the nerve to conduct electrical signals. This test may cause mild tingling and discomfort similar to a mild shock from static electricity. Evoked potentials may also be performed for additional diagnostic information. Nerve conduction velocity and evoked potential testing are especially helpful when pain or sensory complaints are more prominent than weakness.

Preparation

No special preparation is needed. The doctor supervising and interpreting the test should be given information about the symptoms, medical conditions, suspected diagnosis, neuroimaging studies, and other test results.

Aftercare

Minor pain and bleeding may continue for several hours after the test. The muscle may be tender for a day or two. Pain-relieving medications may be prescribed to relieve muscle soreness.

Complications

There are no significant risks to this test, other than those associated with any needle insertion (pain, bleeding, bruising, or **infection**).

Results

The end result of an EMG test is an electromyogram, a computer display or printout of EMG waveforms.

KEY TERMS

Fasciculation—Small involuntary muscle contractions visible under the skin.

Motor neurons—Nerve cells that transmit signals from the brain or spinal cord to the muscles.

Motor unit action potentials—Spikes of electrical activity recorded during an EMG that reflect the number of motor units (motor neurons and the muscle fibers they transmit signals to) activated when the patient voluntarily contracts a muscle.

Nerve conduction velocity testing (NCV)—A type of test that uses an electromyography unit to evaluate electrical potentials from peripheral nerves by measuring how long it takes for a nerve impulse to reach a muscle after stimulation with an electrical current.

Polysomnography—A group of studies (that includes EMG) performed while a patient is sleeping to diagnosis sleep disorders.

There should be some brief EMG activity during needle insertion. This activity may be increased in diseases of the nerve and decreased in long-standing muscle disorders where muscle tissue is replaced by fibrous tissue or fat. Muscle tissue normally shows no EMG activity when at rest or when moved passively by the examiner. When the patient actively contracts the muscle, spikes (motor unit action potentials) should appear on the recording screen, reflecting the electrical activity within. As the muscle is contracted more forcefully, more groups of muscle fibers are recruited or activated, causing more EMG activity.

The interpretation of EMG results is not a simple matter, requiring analysis of the onset, duration, amplitude, and other characteristics of the spike patterns.

Electrical activity at rest is abnormal; the particular pattern of firing may indicate denervation (for example, a nerve lesion, radiculopathy, or lower motor neuron degeneration), myotonia, or inflammatory myopathy.

Decreases in the amplitude and duration of spikes are associated with muscle diseases, which also show faster recruitment of other muscle fibers to compensate for weakness. Recruitment is reduced in nerve disorders.

Health care team roles

EMG is performed by clinicians with special training in electroneurodiagnostic medicine. Usually, a neu-

rologist or psychiatrist conducts the EMG study. Some physical therapists trained in EMG may also administer the test. A trained electroneurodiagnostic technologist prepares patients for EMG testing, obtains medical histories, maintains equipment, records and calculates test results, and assists with testing.

Electroneurodiagnostic technology

Definition

The practice of electroneurodiagnostic (END) technology involves the use of devices such as an electroencephalograph (EEG) unit to evaluate the function of a

patient's **brain** or other component of the nervous system in order to diagnose tumors, strokes, epilepsy, sleep problems, and other nervous disorders.

Description

END technologists use various devices to aid in the evaluation and examination of the nervous system. These devices receive and record the electrical impulses produced by the brain or other parts of the nervous system. Characteristic changes in the nerve impulses can determine whether a patient has an organic basis for a mental or behavioral problem, such as a tumor or **Alzheimer's disease**. The devices can also diagnose particular diseases such as neuropathies (disease of the nerves), myopathies (diseases of the muscles), epilepsy, or stroke. These tests can evaluate the condition of critically ill patients, to determine the presence of cerebral death, and help assess the probability of a patient recovering from a **coma**.

One test commonly performed by END technologists is **electroencephalography**. This test monitors the electrical output of the brain, displays it on a monitor, and records it on a strip of paper for review by a neurologist or other physician. The technologist is often responsible for taking the patient's medical history, helping the patient relax by explaining the procedure of the test, and applying the electrodes to the designated sites on the person's head. To get medically useful results, the technologist must use the appropriate machine settings and correct for interference coming from sources other than the patient's brain.

EEG studies can be done within the hospital or clinic, or on an ambulatory basis (typically over a 24-hour period) while the patient continues everyday activities. For ambulatory monitoring, the technologist is responsible for **patient education** and answering questions, correctly attaching the electrodes, and upon completion of the monitoring, removing the recorder and obtaining a read-out. Technologists review the entire read-out and select specific areas for examination by the neurologist.

Another specialized form of EEG is long term monitoring for epilepsy (LTME). This procedure is used to accurately diagnose the type of seizure occurring in patients who are not responding to medication. In many cases, the patient is admitted to the hospital for 24-hour-a-day monitoring so that seizures can be captured on videotape and EEG recording. Monitoring is performed to diagnose seizure type or to localize seizure onset within the brain for possible epilepsy surgery. Technologists place electrodes on the patient's head, as in a standard EEG, and behavior is recorded by closed circuit camera

onto videotape. Additional wire electrodes are sometimes inserted near the ear by the neurologist; these electrodes provide better information about temporal lobe seizures than scalp electrodes alone. Antiepileptic drugs are generally reduced or tapered off before or during the admission, which can last from one to several days. Often a family member is asked to stay with the patient, so that a seizure alarm can be triggered.

A second group of procedures commonly performed by END technologists are evoked potential tests. These tests separate the response of the patient's nervous system to various specific stimuli from background activity and record the results. The technologist is responsible for attaching electrodes to the patient and setting the machine to deliver the desired type and intensity of stimulus. Often the technologist performs a step-wise increase in the intensity of the stimulus and records the response of the patient's brain, spinal nerves, or sensory receptors to the input. Commonly, the stimulus is magnetic or electrical in origin, although visual and auditory stimuli are also used.

Technologists also perform nerve conduction studies (NCS), in which an electrode is placed over a peripheral nerve and a muscle, and a record is made of the response of the muscle to stimulation of the nerve. Various nerve and muscular problems have characteristic responses to repeated or increased intensity of stimuli, and the results from these tests can aid in differential diagnosis. NCS is often performed in conjunction with an electromyogram. That test is performed by a physician, although the END technologist can help with the process.

Another test often performed by END technologists is electronystagmography (ENG). ENG records the electrical potentials of the eyes. This test is used to document induced or spontaneous nystagmus, involuntary rapid movements of the eyeballs. An ENG can differentiate between inner ear and **central nervous system** causation for complaints of dizziness.

A subset of END technologists specialize in administering sleep disorder studies and are called polysomnographic technologists. During these testing procedures, called **polysomnography**, technologists monitor brain waves, respiration, and **heart** activity. They must understand the usual effect upon each of these systems with the different stages of sleep. Often a detailed report of each evening's readings is required for review by the supervising physician, separating the recorded results into the various sleep stages. As the primary medical personnel present for overnight monitoring, they may also have additional responsibilities in overseeing the well-being of patients staying at the sleep center.

KEY TERMS

Electroencephalography—The recording of changes in electric output in various areas of the brain using electrodes commonly placed on the scalp.

Electronystagmography—The electronic recording of eye movements that can document induced or spontaneous nystagmus.

Evoked potential testing—The electronic measurement of sensory and physical responses to specific stimuli.

Nerve conduction studies—The electronic measurement of the muscular response to the stimulation of a particular nerve.

Polysomnography—The recording of changes in electric output of the brain, in respiration, and in heartbeat during sleep.

Technologists' duties may also include clerical and technical work such as scheduling appointments, ordering supplies, and maintaining equipment. More senior END technologists may have administrative duties such as supervising and training less experienced technicians, managing the END laboratory, arranging work schedules, and keeping records. Additionally, some more senior personnel can perform research or have teaching duties.

Work settings

END technology is practiced in general hospitals, psychiatric hospitals, health maintenance organizations (HMOs), and in private clinic or office practice settings. In the hospital, technologists may work within a dedicated room in the neurology department, may push portable equipment to the patient's bedside, or may do both kinds of monitoring. One area of rapid growth is the performance of intraoperative neurodiagnostic tests by END technologists. These tests require an understanding of the effects of anesthesia on brain activity and involve working in the operating room with general and neurosurgeons.

Education and training

Although many current END technologists were trained on the job, employers are now favoring candidates who have completed formal training in the area. Some hospitals require applicants for trainee positions to have postsecondary training, whereas others only expect

a high school diploma. Employers will look for courses taken in health, biology, anatomy, and mathematics in applicants for training positions. Often those who do not have formal training are transfers from other allied health professions, such as licensed practical nurses.

The formal postsecondary school training in this area is offered by hospitals and two-year community colleges. As of 2001, there were 12 formal programs approved by the Joint Review Committee on Education in Electroneurodiagnostic Technology of the Commission on Accreditation of Allied Health Programs (CAAHP). The programs usually last from one to two years with laboratory training, and often include the following classroom courses:

- human anatomy and physiology
- neurology and neuroanatomy
- neurophysiology
- medical terminology
- computer technology and instrumentation

Training to perform polysomnograms may require a full year of additional study.

Advanced education and training

The American Board of Registration of Electroencephalographic and Evoked Potential Technologists awards the credentials of Registered EEG Technologist, Registered Evoked Potential Technologist, and Certification in Neurophysiologic Intraoperative Monitoring (CNIM). These certifications are based on the successful completion of both an oral and a written exam. On-the-job training is required to sit for the exam. Continuing education hours are required every two years for certificate renewal and the certificates are good for 10 years. The Board of Registered Polysomnographic Technologists certifies polysomnographic technologists as Registered Polysomnographic Technologists, which involves on-the-job training and a passing score on a written examination.

Continuing education opportunities are available through various organizations including the American Society of Electroneurodiagnostic Technologists and the American Association of Electrodiagnostic Medicine.

Future outlook

The *2000-01 Occupational Outlook Handbook* of the U.S. Department of Labor states that demand for this occupation will grow more slowly than average through the year 2008. Reasons for the slower growth include more sophisticated equipment and cross-training of other

allied health professionals to perform these procedures. However, states with high concentrations of older patients, such as Florida, anticipate a better than average growth in this allied health area.

Electroneurography

Definition

Electroneurography is the measurement of the speed of conduction of impulses down a peripheral nerve. The test is done to detect and roughly quantify the extent of nerve damage.

Purpose

Electroneurography, also known as nerve conduction studies (NCS), nerve conduction velocity (NCV), or stimulation myelographic study (SMS), is used to detect the presence of a neuropathy in a particular nerve. Anatomically, there are three conditions that significantly decrease nerve conduction velocities:

- demyelination (loss of myelin covering of the nerve)

- conduction blocks (damage that stops continued movement of nerve impulse)
- axonal loss (nerve cell death)

Electroneurography is used to detect and evaluate a wide variety of diseases or conditions involving nerve damage. It is a routine test after traumatic nerve damage such as **carpal tunnel syndrome** or to investigate suspected peripheral nerve dysfunctions or neuropathies. Nerve problems caused by viral infections such as HIV-1 or HSV-1 are also common indications for this procedure. Electroneurography can detect nerve damage that occurs as a side effect of systemic problems, including **diabetes mellitus**, B vitamin deficiency, multiple nutrient deficiency due to malabsorption of digested food, kidney failure, amyloidosis, and **alcoholism**.

Electroneurography can also evaluate nerve damage caused by several bacterial infections or toxicities such as diphtheria, leprosy, and botulism **poisoning**. This test is also used to diagnose and follow the progression of many diseases of the nervous and muscular systems such as amyotrophic lateral sclerosis (ALS), myasthenia gravis, muscular dystrophies, and **multiple sclerosis (MS)**.

Precautions

There are no contraindications for this test. It is non-invasive and very low risk.

Description

Electroneurography is based on the observation that when a nerve is electrically stimulated, a reaction will occur somewhere down the nerve or in the muscle served by the nerve. By using appropriate electrode placement, the reaction to the electrical stimulus is recorded. Examining the characteristics of the reaction and the timing of the reaction reveals both the velocity of conduction and the latency (time between stimulus and response) of the tested nerve.

This test requires that the nerve being tested is relatively close to the skin surface, although needle electrodes can be used to test deep nerves. Two sets of electrodes are used to perform the test, stimulating and recording. Normally, the stimulating electrodes are metal or felt pads placed on the surface of the skin, about 0.6 to 1.1 inches (1.5 to 3 cm) apart. Correct placement requires a strong understanding of neurological anatomy and varies from nerve to nerve. Conduction cream can be applied to maximize the effectiveness of the connection. Usually, the cathode (typically the black-colored electrode) is placed down the nerve from the anode (typically the red-colored electrode) in the direction of conduction.

The test works most effectively if maximal stimulation of the nerve is achieved. This is determined through step-wise increases in the stimulus output, and setting the stimulus 25–50% above this level. However, the greater the stimulation, the greater the chance of the stimulus being perceived as painful by the patient. Nevertheless, the duration of the discomfort is relatively short, and less than maximal stimulation produces results that cannot be interpreted and are therefore not medically useful. Stimulation is most difficult in patients who are obese, edemic (retaining water), or have unusually thick or calloused skin. Increasing stimulus duration, altering the placement of the cathode, or using needle electrodes can overcome stimulation problems.

Recording electrodes are placed according to the type of response that is being sought. If muscular reaction is the goal, the active recording electrode is placed over the belly (thickest area) of the muscle being tested, while the second recording electrode, called a reference electrode, is placed on a tendon. Placement is correct if the graphic representation of the response shows an initial negative deflection (upwards) in the graph of the response. If a nerve is being tested, the active electrode is placed directly over the nerve. The reference electrode is placed distally (pointing away from the electrode). Recording electrodes that test motor response are often metal, circular discs, while sensory recording electrodes come in many shapes such as buttons, rings, clips, discs, or bare wire.

The test will run from about 20 minutes to about two hours, depending on the number of nerves being tested and if **electromyography**, a test commonly performed in conjunction with electroneurography, is being done. The cost of the test is about \$500 and is usually covered by insurance.

Preparation

Low body temperature can greatly distort the results of electroneurography. Particularly in cold weather, it is important to warm the muscles being tested and to maintain normal body temperature throughout the testing procedure.

Aftercare

There are no aftercare procedures for this test. Patients may immediately resume normal activities.

Complications

There are no complications resulting from this test.

Results

Among the possible results from this test are measurements of motor response, sensory nerve response, and nerve conduction velocities.

Motor response

The motor (muscular) response is characterized by its waveform, amplitude, duration, and distal latency. The waveform is relatively simple, with a large negative deflection (upwards) followed by a large positive deflection (downward), producing a peak, although the exact shape depends on the placement and type of electrode. The amplitude (expressed in millivolts) is the value from the baseline to the peak of the negative response. Amplitude value depends on the number and synchronization of the muscle fibers that are being stimulated. The use of a maximal stimulation of the nerve ensures all possible fibers will be recruited.

The duration of the motor response is the time from the beginning of the negative deflection to the completion of the positive deflection. In disease states, along with decreased amplitude, the duration of the response will be increased if the muscle fibers do not fire together. The distal latency is the time it takes from stimulus to the beginning of the negative deflection, and is measured in milliseconds. If bilateral measurements are taken, this value will be increased on the side having damage to the nerve or neuromuscular junction. Each motor response characteristic is more difficult to read if electrode placement covers more than one muscle, emphasizing the need to isolate one muscle whenever possible.

Sensory nerve response

Like motor response, sensory nerve responses, or action potentials, are characterized by a particular waveform, amplitude, duration, and distal latency. The normal waveform includes a negative deflection (upward), a larger positive deflection (downward), followed by a negative rebound back to baseline, forming an S-shaped wave, although the exact shape differs with the type of electrodes, placement, or the use of three electrodes. Amplitude is measured from the peak of the negative response to baseline and is measured in microvolts.

Like motor responses, high amplitude and short duration in a sensory nerve response indicate large numbers of axons firing simultaneously. Disease states can reduce amplitude and increase duration. Distal latency is measured from stimulus to negative peak and is expressed in milliseconds. When taking sensory nerve

responses, it is important to isolate the recording electrodes away from innervated muscles, as the motor response will swamp the much smaller sensory nerve response.

Nerve conduction velocity

Nerve conduction velocities to a muscle can be calculated if it is possible to stimulate a nerve in two places along its length. Two latency measurements are made, a distal latency and a proximal latency (in milliseconds, msec). The distance between the two stimulation points is then measured (in millimeters, mm) and divided by the difference between the two latency values. This value is the conduction velocity of the nerve in meters per second. For sensory nerves, only one stimulation point is used, and the velocity is calculated by dividing the distance between the active and reference electrodes (in mm) by the latency (in msec).

Once results have been calculated, these are compared to a table of standard values. Tables have been devised that sort results by different characteristics such as the patient's age, sex, height, nerve length, or a combination of these factors. An example of a commonly used table is one published by the Cleveland Clinic Foundation. This table sorts results by patient age and is based on standard electrode distances for the measurement of different nerve velocities. In general, demyelination is indicated if conduction velocities have fallen below 50% of normal. Even significant loss of axons commonly reduces conduction velocities by only about 30%, based on a loss of the fastest conducting fibers.

When analyzing the results of this test, it should be taken into consideration that electroneurography tests the best surviving nerve tissue. This characteristic means that results can be normal despite extensive nerve damage. Nevertheless, abnormal results can provide extremely useful information, including distinguishing between demyelination and loss of axons and pinpointing the exact location of a nerve injury.

Health care team roles

Electroneurography is often performed by specially trained electrodiagnostic technologists. Training for such a position can be on the job but often involves study at a one- to two-year college or vocational program. A typical program would include:

- human anatomy and physiology
- neurology and neuroanatomy
- neurophysiology
- medical terminology

KEY TERMS

Amplitude—The distance from the baseline to the peak of the motor or sensory response represents the approximate number of healthy muscle fibers or nerves available.

Demyelination—Loss of the insulating cover of the nerve cell. Demyelination significantly reduces measured nerve conduction velocity.

Latency—The amount of time between stimulus and motor or sensory nerve response.

Waveform—The shape of the electrical response recorded by the active recording electrode.

- computer technology and instrumentation

Certification of electrodiagnostic technologists specializing in electroneurography and the related area of evoked potentials is available through the American Board of Registration of Electroencephalographic and Evoked Potential Technologists.

A physician such as a neurologist, neurosurgeon, or internist does the final review and diagnosis based on the results of electroneurography. The physician can be present for the testing or may review saved tracings. Other health care professionals such as nurses aid in **patient education** concerning this procedure.

Electronic fetal monitoring

Definition

The electronic fetal monitor (EFM) is a device that records an unborn baby's **heart** rate and the presence or absence of the mother's uterine contractions.

Purpose

The EFM is used to assess fetal well being during routine prenatal visits. It is also used during labor and delivery when high-risk factors exist or when a clinical condition develops beforehand that places the fetus at risk. High risk factors for EFM during labor include:

- low gestational age
- high maternal age
- placenta or cord problems
- meconium in the amniotic fluid
- hypertension
- proteinuria
- facial nerve palsy

A fetus having trouble in labor often exhibits characteristic changes in heart rate after a contraction (late decelerations). Trouble is also indicated by significant slowing of the heart rate during a contraction (variable deceleration). If the fetus is not receiving enough oxygen to withstand the stress of labor, and delivery is many hours away, a cesarean section (C-section) may be necessary.

Description

The monitor produces a continuous paper record of the fetal heart rate (FHR) and records uterine contractions. FHR is captured on the top part of the paper print-out; uterine activity, when monitored, appears on the lower part of the tracing.

Electronic fetal monitoring can be performed externally or internally. The external ultrasound approach is non-invasive and uses sensors (electrodes) placed on the mother's abdomen with an elastic belt. Another belt holds the contraction monitor.

External electronic fetal monitoring includes a non-stress test, which measures FHR accelerations with normal movement of the fetus. Sometimes the fetal movement is encouraged by giving the mother a small meal or something to drink. Fetal acoustic stimulation and moving the fetus by rubbing the abdomen gently may also be used.

Two contraction stress tests, which measure the placenta's ability to provide enough oxygen to the fetus during pressure, are also used with electronic fetal monitoring. The nipple stimulation contractions **stress test** involves the mother self-stimulating her nipple while contractions and FHR are monitored. Another test, called oxytocin stimulation, involves the administration of the hormone oxytocin intravenously until three uterine contractions are observed within ten minutes, during which time the FHR is monitored.

Sometimes, it is difficult to hear the baby's heartbeat with the monitoring device. Other times, the monitor may show subtle signs of a developing problem. In either case, the physician may recommend the use of an internal monitor, which provides a more accurate record of the baby's heart rate. The internal monitor (or fetal scalp electrode) uses an electrode attached to the baby's scalp through the cervix during an internal vaginal exam. The internal monitor can only be used when the cervix is dilated.

In 1995, a technical bulletin issued by the American College of Obstetricians and Gynecologists (ACOG) reported that the prudent use of intermittent auscultation (listening) of fetal heart rate is equivalent to continuous electronic fetal monitoring in a low-risk **pregnancy**. Intermittent auscultation involves listening to the FHR every 15 minutes during active labor until complete cervical dilation. From complete dilation to delivery, the FHR should be obtained every five minutes and timed to obtain the FHR during a contractions and for 30 seconds afterwards. In complicated pregnancies, however, continuous EFM is recommended during labor. EFM is used in most deliveries directed by physicians.

Preparation

There are no special preparations required for external fetal monitoring. Preparation for placement of an internal scalp lead (ISL) is the same as for a routine vaginal exam.

Complications

In general, no risks are associated with external fetal monitoring. However, the test can initiate labor and is generally not given to mothers at risk for **preterm labor** or with a condition that requires a cesarean section. Internal monitoring poses risks associated with improper placement of the electrodes.

Some data indicate that EFM leads to unnecessary C-sections. Another drawback includes loss of maternal mobility when used during labor, which may slow labor.

A fetal monitoring belt can be used to monitor a fetus through the abdominal wall and uterus. (Custom Medical Stock Photo. Reproduced by permission.)

Results

The normal fetal heart rate (FHR) ranges from 120 to 160 beats per minute (bpm). Just as an adult's heart rate rises with movement, FHR rises when the baby moves. A reactive heart rate tracing (also known as a reactive non-stress test, or NST) is considered a positive sign of fetal well being. A non-reactive NST may or may not imply fetal well being. The monitor strip is considered to be reactive when the FHR rises at least 15 to 20 bpm above the baseline heart rate for at least 20 seconds. This must occur at least twice in a 20-minute period.

Results are considered abnormal if the FHR drops below 120 or rises above 160 for sustained periods. In either of these cases the baby may be exhibiting fetal distress. A mean FHR of less than 110 bpm may indicate bradycardia (slow heart beat). A mean FHR of over 160 bpm may indicate a tachycardia (rapid beating of the heart). However, some babies who are having problems may not exhibit such clear signs.

During a contraction, the flow of oxygen from the mother through the placenta to the baby is temporarily stopped. It is as if the baby has to hold its breath during

each contraction. Both the placenta and the baby are designed to withstand this condition. Between contractions, the baby should be receiving more than enough oxygen to do well during the contraction.

One sign that a baby is not getting enough oxygen between contractions is a drop in the baby's heart rate after the contraction (late deceleration). The heart rate recovers to a normal level between contractions, only to drop again after the next contraction. This is a more subtle sign of distress. Trouble is also indicated by significant slowing during a contraction (variable decelerations).

Fetal monitoring is not a perfect test. Fetal assessment in labor is subject to differences in interpretation and consequent intervention; therefore, institutional policies and procedures should be followed.

Health care team roles

Electronic fetal monitoring is primarily conducted by specialists in obstetrics and gynecology. Qualified registered nurses and **advanced practice nurses** may assist in or conduct electronic fetal monitoring.

KEY TERMS

Auscultation—Listening to sounds within organs to help in diagnosis in treatment.

C-section—A cesarean section; delivery of a baby through an incision in the mother's abdomen instead of through the vagina.

Late deceleration—Transient fetal bradycardia exceeding 100 beats per minute which reaches its height more than 30 seconds after the peak of the uterine contraction.

Non-stress test—A record of the fetal heart rate in the absence of contractions (stress).

Reactive stress test—A positive sign of fetal well being. The FHR rises at least 20 beats per minute above the baseline heart rate for at least 20 seconds, occurring at least twice in a 20-minute period.

Variable deceleration—Fetal bradycardia below 100 beats per minute denoting compression of the umbilical cord at the height of a uterine contraction.

Training

Applying the external monitor is simple, but requires practice in the proper placement of the monitoring devices. The interpretation of the tracings, however, requires continued vigilance in education and clinical practice. Training should include instruction in auscultation, electronic FHR monitoring, and evaluation of uterine activity.

Electrophysiology study of the heart

Definition

An electrophysiology study (EPS) of the **heart** is a nonsurgical analysis of the electrical conduction system (normal or abnormal) of the heart. The test employs cardiac catheters and sophisticated computers to generate electrocardiogram (EKG) tracings and electrical measurements with exquisite precision from within the heart chambers.

Purpose

An EPS can be performed solely for diagnostic purposes or to pinpoint the exact location of electrical signals (cardiac mapping) in conjunction with a therapeutic procedure called catheter ablation. A cardiologist may recommend an EPS when the standard EKG, Holter monitor, event recorder, **stress test**, echocardiogram, or angiogram cannot provide enough information to evaluate an abnormal heart rhythm, called an arrhythmia.

An EPS offers more detailed information about the heart's electrical activity than many other noninvasive tests because electrodes are placed directly *on* heart tissue. This placement allows the electrophysiologist to determine the specific location of an arrhythmia and, oftentimes, correct it during the same procedure. This corrective treatment is considered a permanent cure; in many cases, the patient may not need to take heart medications.

EPS may be helpful in assessing:

- certain tachycardias or bradycardias of unknown cause
- patients who have been resuscitated after experiencing sudden cardiac death
- various symptoms of unknown cause, such as chest **pain**, shortness of breath, fatigue, or **syncope** (dizziness/fainting)
- response to anti-arrhythmic therapy

Precautions

Pregnant patients should not undergo EPS because of the exposure to radiation during the study, which may harm the growing baby. Patients who have **coronary artery disease** may need to be treated prior to EPS. EPS is contraindicated in patients with an acute **myocardial infarction**, as the infarct may be extended with rapid pacing. The test is also contraindicated for patients who are uncooperative.

Description

The rhythmic pumping action of the heart, which is essentially a muscle, is the result of electrical impulses traveling throughout the walls of the four heart chambers. These impulses originate in the sinoatrial (SA) node (specialized cells situated in the right atrium, or top right chamber of the heart). Normally, the SA node, acting like a spark plug, spontaneously generates the impulses, which travel through specific pathways throughout the atria to the atrioventricular (AV) node. The AV node is a relay station sending the impulses to more specialized muscle fibers throughout the ventricles (the bottom chambers of the heart). If these pathways become damaged or blocked or if extra (abnormal) pathways exist, the heart's rhythm may be altered (too slow, too fast, or irregular), which can seriously affect the heart's pumping ability.

The patient is transported to the x-ray table in the EPS lab and connected to various monitors. Sterile technique is maintained. A minimum of two catheters is inserted into the right femoral (thigh) vein in the groin area. Depending on the type of arrhythmia, the number of catheters used and their route to the heart may vary. For certain tachycardias, two more catheters may be inserted in the left groin and one in the internal jugular (neck) vein or in the subclavian (below the clavicle) vein. The catheters are about 2 mm in diameter, about the size of a spaghetti noodle. The catheters used in catheter ablation are slightly larger.

With the help of fluoroscopy (x rays on a television screen), all the catheters are guided to several specific locations in the heart. Typically, four to 10 electrodes are located on the end of the catheters, which have the ability to send electrical signals to stimulate the heart (called pacing) and to receive electrical signals from the heart; but not at the same time (just as a walkie-talkie cannot send and receive messages at the same time).

First, the electrodes are positioned to receive signals from inside the heart chambers, which allows the doctor to measure how fast the electrical impulses travel in the patient's heart at that time. These measurements are

called the patient's baseline measurements. Next, the electrodes are positioned to pace. That is, the EPS team tries to induce (sometimes in combination with various heart drugs) the arrhythmia that the patient has previously experienced so the team can observe it in a controlled environment, compare it to the patient's clinical or spontaneous arrhythmia, and decide how to treat it.

Once the arrhythmia is induced and the team determines it can be treated with catheter ablation, cardiac mapping is performed to locate the precise origin and route of the abnormal pathway. When this is accomplished, the ablating electrode catheter is positioned directly against the abnormal pathway, and high radio-frequency energy is delivered through the electrode to destroy (burn) the tissue in this area.

Pediatric patients present challenges in EPS. In 2001, an analysis of 45 pediatric patients who underwent electrophysiologic study was conducted. The researchers concluded that success rates and the prevention of complications in children may be increased by using ultrasound guidance for access of the internal jugular vein for coronary sinus cannulation (insertion of a tube for the transport of fluid) during EPS. Access was successfully obtained in all 45 of the patients without major complications using this technique.

Preparation

The following preparations are made for an EPS:

- The patient may be advised to stop taking certain medications, especially cardiac medications, that may interfere with the test results.
- The patient is kept fasting for six to eight hours prior to the procedure. Fluids may be permitted until three hours before the test.
- **Blood** tests usually are ordered one week prior to the test.
- The patient undergoes conscious sedation (awake but relaxed) during the test.
- A local anesthetic is injected at the site of catheter insertion.
- Peripheral pulses are marked with a pen prior to catheterization. This permits rapid assessment of pulses after the procedure.

Aftercare

The patient needs to rest flat in bed for several hours after the procedure to allow healing at the catheter inser-

KEY TERMS

Ablation—Removal or destruction of tissue, such as by burning or cutting.

Angiogram—X ray of a blood vessel after special x-ray dye has been injected into it.

Bradycardia—Relatively slow heart action, usually considered as a rate under 60 beats per minute.

Cardiac catheter—Long, thin, flexible tube, which is threaded into the heart through a blood vessel.

Cardiologist—Doctor who specializes in diagnosing and treating heart diseases.

Echocardiogram—Ultrasound image of the heart.

Electrocardiogram—Tracing of the electrical activity of the heart.

Electrode—A medium, such as platinum wires, for conducting an electrical current.

Electrophysiology—Study of how electrical signals in the body relate to physiologic function.

Event recorder—A small machine, worn by a patient usually for several days or weeks, that is activated by the patient to record his or her EKG when a symptom is detected.

Fibrillation—Rapid, random contraction (quivering).

Holter monitor—A small machine, worn by a patient usually for 24 hours, that continuously records the patient's EKG during usual daily activity.

Stress test—Recording a patient's EKG during exercise.

Supraventricular tachycardia—A fast heart beat that originates above the ventricles.

Tachycardia—Fast heartbeat.

Thrombophlebitis—Venous inflammation with the formation of thrombus (a clot in the cardiovascular system).

tion sites. The patient often returns home either the same day of the test or the next day. Someone should drive the patient home.

Patient education

To minimize bleeding and pain, instruct the patient to keep the extremity in which the catheter was placed immobilized and straight for several hours after the test.

Complications

EPS and catheter ablation are considered low-risk procedures. There is a risk of bleeding and/or **infection** at the site of catheter insertion. Blood clot formation may occur and is minimized with anti-coagulant medications administered during the procedure. Vascular injuries causing hemorrhage or thrombophlebitis are possible. Cardiac perforations are possible. If the right internal jugular vein is accessed, the potential for puncturing the lung with the catheter exists and could lead to a collapsed lung.

Because ventricular tachycardia or fibrillation (lethal arrhythmias) may be induced in the patient, the EPS lab personnel must be prepared to defibrillate the patient as necessary.

Patients should notify their health care provider if they develop any of these symptoms:

- numbness or tingling in the extremities
- heavy bleeding
- change in color and/or temperature of extremities
- loss of function in extremities

Results

Normal findings indicate that the heart initiates and conducts electrical impulses within normal limits.

Abnormal findings include confirmation of arrhythmias, such as:

- supraventricular tachycardias
- ventricular arrhythmias
- accessory pathways
- bradycardias

Health care team roles

The relatively simple EPS is performed in a special laboratory under controlled clinical circumstances by cardiologists, nurses, and technicians with special training in electrophysiology.

Electrosurgery machines

Definition

The electrosurgery machine produces high radiofrequency energy sufficient to induce cutting and/or coagulation in body tissues by an electrode during (electro)surgery.

Purpose

The instrument is designed to provide the correct electrical waveforms to deliver to the site of surgery in order to coagulate **blood vessels** and to cut tissues smoothly. Surgeons may use the electrosurgery tool instead of, or in conjunction with, a conventional scalpel. When used properly, the electrosurgery unit damages tissue considerably less than the scalpel, with the added ability to stem bleeding safely.

Description

Commercial electrosurgery machines may differ significantly, but comprise multiple components, which include:

- the electrode(s)

- the electrosurgical unit (ESU), which generates the radiofrequency current
- dispersive pads/electrodes for electrical current dispersion and foot pedals for operation in cut or coagulation mode

A complete circuit must be connected for current to flow, as in any circuit. In the case of electrosurgery, the circuit comprises the electrosurgical power unit, the active electrode (where cutting or coagulation transpire), the dispersive electrode (also known as the "return electrode," for return of current), and the path of least resistance through the patient's own body from the active electrode to the return electrode. When the circuit is complete and current can flow through it without too great of a resistance, the electricity that causes coagulation and cutting is readily applied to appropriate sites at the surgeon's discretion.

The low frequency power input of the wall (i.e. 60 Hz in the United States) is converted by the ESU to a high-frequency (on the order of 400,000 to 1,000,000 Hz) alternating current output that yields the therapeutic effects of electrosurgery. Safety is important with all electrical equipment; consequently the ESU should be grounded to a true earth ground that is electrically isolated from other grounds in the operating room, so that neither the surgeon nor the patient are shocked or electrocuted.

The high-frequency current is transmitted to the patient via the active electrode, which is insulated along its length until the electricity-emitting tip is reached, and which may take the form of:

- a one-piece electrode
- a pencil handpiece
- forceps
- suction tips

The complete circuit discussed above may be achieved through either bipolar or monopolar modalities. Bipolar surgery is as the title implies, involving the use of two poles, or electrodes. The electrodes (active and return) are fixed upon a forceps-shaped tool. When pinched, the surgeon may apply current that traverses only the tissue in between the two electrodes, thereby coagulating it (unless the tissue is completely desiccated, in which case some current may leak into surrounding tissue). Carrying low-voltage current and affecting little tissue, the bipolar instrument is considerably safer than the monopolar device. Neurosurgeons usually opt for the bipolar tool over monopolar for this reason and for its inherent delicacy, among others.

The monopolar instrument is often used in place of the bipolar for three main reasons: it is easier to use, it

KEY TERMS

Coagulate—To clot or cause hemostasis; in electrosurgery, to cause tissue dehydration without cutting.

Hemostasis—Stoppage of bleeding.

possesses the added capability of cutting tissue, and it is able to coagulate larger **blood** vessels. The active electrode, which may be in shape of a blade, loop, ball, needle, or pencil, can be disposable or reusable. Current emitted from this electrode is dispersed over a large area of padding by one of two types of dispersive electrode: conductive or capacitive. This can prove difficult, and is one reason why bipolar is the safer choice. Any erroneous selection or misuse of dispersive pads can result in a dangerous predicament for both the patient and the surgeon. While systems in use as of 2001 generally retain a number of alarms and warning systems built in, health care personnel must remain aware of the dangers implicit in using the equipment.

Operation

Three modes of operation are available, and can be produced on command, dependent upon the waveform issued by the ESU:

- **Cutting:** A high-frequency alternating current yields smooth, rapid cuts that evoke little to no hemostasis. The current stimulates cells to swell and explode.
- **Fulguration:** Sparking the tissue to lead to coagulation. There is no tissue-electrode contact; rather, voltage is raised in order to incite a spark between electrodes in order to coagulate the tissue in between.
- **Desiccation:** The drying out of cells leading to coagulation. Stems from direct contact with the active electrode and leaves a soft brown eschar, or scab.

It is key for all health care personnel involved in electrosurgery to be educated about the specific ESU and electrodes used by physicians at their location. The power settings on the ESU unit do not necessarily correspond to the quantity of power delivered. Thus, personnel must know not to equate numerical power settings with specific units unless explicitly labeled that way, i.e. one must not equate a power setting of “1” with 1 watt (or 100 watts) of power. Even if the amount of power is not known in watts, medical personnel must have an intuitive idea of what the different power settings mean in terms of the ability to cut, to coagulate, and for safety.

Most machines make it easier with the ability to pre-program cutting and coagulation settings so that the surgeon and staff can move swiftly and accurately between settings during surgery.

Smoke can also be an issue with electrosurgery, so many units as of 2001 come equipped with smoke evacuation and filtration systems, which the staff must also learn how to operate through reading manufacturers’ manuals.

Maintenance

Most maintenance on the electrosurgery power unit is generally performed by trained biomedical equipment technicians or biomedical engineers unless nursing staffers are adequately trained. The electrodes, however, must be cleansed and sterilized by the staff immediately following each surgery if they are not disposable.

Health care team roles

Most of the electrosurgical machine configuration and settings are handled by nursing staff and technicians. Often the operating room (O.R.) personnel know more about setting up the machine, its safety controls, and its handling than the surgeons using the equipment. This is because surgical residents are not formally trained in electrosurgical use; thus, since O.R. nursing personnel are usually trained by the manufacturer’s sales representatives, the surgeons tend to rely on nursing staff to set up and manage the equipment. It is therefore very much an integral aspect of the staff’s responsibility to alert surgeons to possible dangers, especially electrical, inherent in using the electrosurgical machine. The electrode insulation mentioned above is a key element in electrosurgical safety, so staff should remain alert for inadequate or defective insulation.

Training

Health care personnel are generally trained by the sales representatives of the electrosurgery unit’s manufacturer to set up and properly maintain the equipment. Without care and knowledge of the electrosurgery apparatus, great harm can be caused to patients undergoing surgery. Special attention should be paid to the manual since each ESU model is unique.

Electrotherapy

Definition

Electrotherapy is the use of electrical stimulation for therapeutic purposes. Specifically, electrotherapy uses energy waves that are part of the electromagnetic spectrum to produce desired physiological and chemical effects in the body.

Purpose

Electrotherapy is used for three therapeutic purposes: (1) to relieve **pain**; (2) to stimulate physiochemical changes; and (3) to stimulate **muscle contraction**.

Pain relief

Electrotherapy is used to manage both acute and chronic pain. In the gate model of pain, the neural fibers that carry the signal for pain and those that carry the signal for proprioception (body position) are mediated through the same central junction. Because signal transmission along pain fibers is slower than transmission along proprioception fibers, the gate model suggests that intense stimulation of proprioception fibers can block the slower-moving pain signals. Some forms of electrotherapy attempt to stimulate these proprioception fibers to reduce the sensation of pain. Other forms of electrotherapy alleviate pain by introducing **analgesics** and anti-inflammatory medications via electric current to the painful area.

Various types of pain are indications for electrotherapy, including:

- post-operative incision pain
- fracture pain
- pain associated with labor and delivery
- foot pain

- pain associated with tendinitis
- pain associated with certain types of arthritic inflammation
- back and neck pain

Stimulation of physiochemical changes

Electrotherapy is also used to induce physiological and chemical changes. Some forms of electrotherapy induce these changes by introducing heat into the deep tissues; this deep heating increases **blood** flow to and from the problematic region and improves drainage. Other forms of electrotherapy are thought to stimulate the body's production of **corticosteroids** and **vitamin D**. Still others are believed to promote wound healing by stimulating intracellular activity.

Indications for the forms of electrotherapy that induce physiochemical changes include:

- inflammatory orthopedic conditions
- bronchitis
- otitis media
- sinusitis
- prostatitis
- certain immunoregulated dermatologic conditions such as psoriasis
- open lesions and certain types of skin ulcers

Stimulation of muscle contraction

Electrotherapy is used to stimulate the contraction of muscles during rehabilitation. This type of electrical stimulation is used to prevent muscle atrophy and to re-educate muscles after trauma or surgery. This form of electrotherapy can also be used to relieve muscle spasms.

Indications for electrotherapy to stimulate muscle contraction include:

- healthy innervated muscle at risk of atrophy from immobilization or injury
- denervated (lacking natural neural connection) muscle that might atrophy or degenerate
- low back spasm

Precautions

Although each modality of electrotherapy has its specific set of contraindications, cardiac **pacemakers** are a general contraindication for electrotherapy. Electrical signals from electrotherapy devices can interact with the electrical signals from pacemakers and interfere with pacemaker functioning. Pacemaker disruption is particu-

larly acute with such modalities as diathermy and electrical nerve stimulation. However, less interference may occur with such radiation modalities as infrared, ultraviolet, and cold laser treatments (these modalities are discussed in detail below in the Description section).

Contraindications for pain relief electrotherapy include:

- undiagnosed pain (pain is a symptom that might signal a serious condition that may need to be treated directly)
- current use of narcotic medications that can desensitize patients to stimuli
- patient hyposensitivity in particular areas of the body
- pregnancy, except when electrotherapy is used to relieve pain of labor and delivery

For the use of electrotherapy to stimulate physiochemical changes, contraindications include:

- acute inflammation
- hemorrhage
- foreign bodies or metallic implants
- patient hyposensitivity in particular areas of the body
- recent treatment with ionizing radiation therapies
- pulmonary tuberculosis
- severe diabetes
- lupus erythematosus
- photosensitivity or current use of photosensitizing drugs

For the use of electrotherapy to stimulate muscle contraction, contraindications include:

- new fracture
- hemorrhage
- phlebitis

Description

Pain relief

For **pain management**, the two commonly used modalities of electrotherapy are transcutaneous electrical nerve stimulation (TENS) and iontophoresis. TENS relieves pain by stimulating proprioception nerve fibers to block the transmission of competing pain signals. Although both proprioception and pain receptors respond to electrical stimulation, there is some evidence that the proprioceptive nerves respond to different kinds of waveforms from the forms that stimulate pain receptors; TENS uses the electrical waveforms that target proprioceptors.

Electrodes are generally placed at points of pain, trigger points, acupuncture points, or over nerve roots. Parameters determining the character of the TENS stimuli are selected; these parameters include the waveform, frequency, duration, and amplitude of the wave. The duration of each TENS session is usually one hour. A typical patient is prescribed TENS four times daily for initial pain control. With continued use and as pain decreases, the frequency of TENS sessions can gradually be reduced to two sessions or one session daily.

The use of TENS for pain management is covered by insurance, but only for specific types of pain for limited time periods. TENS is typically well-covered for acute postoperative pain management, but TENS use for chronic pain complaints varies by insurer. Although the use of TENS to relieve labor and delivery pain has been documented overseas, this application of TENS is generally not approved by insurers in the United States.

A second form of electrotherapy used for pain relief is iontophoresis. Iontophoresis refers to the transdermal (through the skin) introduction of ionic compounds using direct current. This method of pain management is sometimes covered by insurance. In the United States, iontophoresis is almost always administered using dedicated iontophoresis devices. These machines allow for the fine-tuning of treatment parameters such as the amplitude of the current, the duration of treatment, and the automated ramping up and down of current at the start and end, respectively, of each treatment session. Iontophoresis units also come equipped with electrodes embedded in fiber pads or gel that carry the desired drug. For pain management, the drugs used in iontophoresis are analgesics and anti-inflammatory compounds, and include such medications as dexamethasone, lidocaine, and salicylate.

To begin iontophoresis, the delivery electrode containing the drug is placed in the area where pain is reported. Whether a drug is placed at the site of a negative or a positive electrode depends on the drug's ionic charge. Lidocaine has a positive charge and is placed with a positive delivery electrode, while the negatively-charged compounds of dexamethasone and salicylate are used with a negative delivery electrode.

After securing the delivery electrode, a second electrode, of opposite polarity, is placed on the body at a fixed distance (determined by the particular iontophoresis unit) away from the first electrode. Lead wires are attached to the electrodes, with the positive lead attached to the positive electrode and the negative lead to the negative electrode. The intensity of the electric current is then slowly increased until the predetermined level is reached, and this level is maintained throughout the main treatment session.

Treatment “dosages” are given in terms of milliamperes-minutes—that is, the product of the amplitude of the current (in milliamperes, mA) and the duration of treatment (in minutes). For example, a treatment consisting of two mA for 30 minutes would be a dose of 60 mA-min. Note that such a recommended dose would also allow the therapist to administer a treatment session of three mA for 20 minutes. In general, dosages range from 40 to 80 mA-min, with current intensity ranging from one to four mA, and treatment duration ranging from 20 to 40 minutes.

Stimulation of physiochemical changes

Diathermy and radiation are two forms of electrotherapy that are used to induce physiological and chemical changes in the body. Diathermy refers to the use of high-frequency electromagnetic waves (greater than 10 MHz) as therapeutic stimuli. Shortwave diathermy uses waves of 13, 27, or 45 MHz, while microthermy uses waves of up to 2450 MHz in frequency. Both forms of diathermy generate heat in deep muscle tissue, although microthermy is believed to be absorbed more by superficial fatty tissue.

The patient is placed between the electrodes, and the power level is adjusted until the patient reaches resonance (as determined by automated measurement systems) with a pre-established heating level. Each diathermy session lasts 10–30 minutes, depending on the size of the target area. The heat generated by diathermy is believed to improve blood circulation, relax muscular tension, and promote drainage in the target areas. Because of the lack of large controlled studies of diathermy, it may not be covered by insurance.

Radiation therapies in the context of electrotherapy include infrared, ultraviolet, and cold laser therapies. Infrared therapies—heat lamps, moist heat packs, and chemical heat packs—are used to apply superficial heat to improve circulation in target areas. Ultraviolet lamps are thought to stimulate the body’s production of corticosteroids and vitamin D. For some therapies, ultraviolet radiation is used in conjunction with photosensitive or photoactivated medications. Cold laser treatments—most commonly, the directing of a low-powered helium-neon laser beam over the target area—are used to facilitate wound healing. Cold laser may also be used for pain relief, with the laser directed at acupuncture points, trigger points, and nerve roots. Typically, ultraviolet and cold laser treatments do not exceed two minutes, while infrared treatments can last between 10 and 30 minutes.

Infrared or heat therapies are viewed as conventional treatments and are covered by insurers as part of a short-term **physical therapy** regimen. Ultraviolet thera-

pies, however, are only covered for very specific dermatological conditions such as disabling psoriasis. Cold laser treatments are categorized as investigational, or experimental, therapy and are not covered. Large uncontrolled trials have shown some benefits of cold lasers in promoting wound healing, but smaller controlled trials have shown little or no benefit. Studies of the pain-relieving effects of cold laser suggest no benefit beyond that which can be obtained through conventional treatments.

Stimulation of muscle contraction

The use of electrical stimulation to stimulate muscle contraction is known as neuromuscular electrical stimulation (NMES) or functional electrical stimulation (FES). NMES/FES therapies apply pulses of electrical current to target muscle groups to stimulate active motion, strengthen muscles, and prevent muscle atrophy.

In NMES/FES, electrodes are placed initially on the belly of the muscle that is to be stimulated. AC electrical stimulation is then applied at low levels (threshold levels for muscle movement). Based on muscle responses to the threshold stimulation, electrode positions are adjusted until the motor points of the muscle (optimal positions for generating muscle movement) are found. Electrodes are then secured at these optimal positions.

After the electrodes have been placed, parameters for NMES/FES are programmed into the electrical stimulator unit. Parameters include the amplitude of the electrical pulse, the duration of each pulse, the frequency of pulses, the duration of on/off (activation/rest) periods during the treatment session, ramping modulation (gradual increases and decreases) in stimulation, and duration of the treatment session. The maximum pulse amplitude recommended for NMES/FES is generally the maximum amplitude that can be tolerated by a given patient. Regarding pulse duration, there remains some ambiguity about the optimal duration time of each pulse; current practices suggest that pulse duration be set between 50 and 1000 microseconds. Pulse frequency tends to range from 30 pulses per second to 100 pulses per second. Since continuous electrical stimulation leads to early muscle fatigue, treatment sessions include rest periods between activation periods. The duration of “on” (activation) periods is typically 10–15 seconds; “off” (rest) periods can last up to one or two minutes. Treatment sessions may last between 10 and 20 minutes, and usually do not exceed one hour.

Electrical stimulation can begin after parameters are set. In general, the intensity of the stimulation is increased from contraction to contraction within a given session, and is also increased from session to session, depending on how well the patient tolerates the increases.

KEY TERMS

Denervation—A lack of nerve input into a muscle, organ, or other body part that normally receives neural input.

Innervation—The presence of nerve input into a muscle, organ, or other body part.

Osteogenesis—New bone growth.

NMES/FES is usually approved by insurers for post-surgical rehabilitation and rehabilitation after immobilization (after a limb has been in a cast or splint). This form of electrotherapy is typically not approved for **spinal cord** injuries or for muscles that have been denervated.

Preparation

Preparation for electrotherapy requires first that the physical therapist clarify the problem area and condition with the patient. The physical therapist then selects the appropriate therapeutic modality for the complaint and determines the relevant parameters for each electrotherapeutic modality.

The skin of the target area must be clean. For modalities requiring electrodes, the skin of the target area must also be free of lesions. For TENS therapy, conduction gels are used on the surface of the skin; otherwise, moisture on the tips of the electrodes is sufficient. For ultraviolet therapies, a small area of the skin should be tested to determine the minimal erythema (reddening of the skin) dosage prior to treatment. For some ultraviolet therapies, a photosensitizing medication is given prior to treatment.

If pain relief is the goal, the patient should discontinue the use of pain medications that might obscure the effect of electrotherapy. For iontophoresis, the patient must be queried on possible sensitivities; for example, an allergy to dexamethasone would rule out the use of dexamethasone as an anti-inflammatory ionic substance.

Aftercare

Patient comfort should be monitored throughout the therapeutic session. After treatment, the patient should be queried about excessive levels of discomfort. Excessive discomfort should serve as a guide for modulating electrotherapy parameter settings in the future.

In the case of such direct electrical stimulation as NMES/FES, the skin under the probes should be massaged with a neutral cream after treatment.

Complications

After treatment, the patient should be checked for **burns** from electrodes or poorly placed wires. Heat burns are possible with almost all electrotherapy modalities. These types of burns occur when there is a buildup of heat in regions where electrical resistance is high. Causes of these high-resistance burns include electrodes being placed in sclerotic (scarred) areas; electrodes being placed in areas with wrinkled or folded skin or other areas where electrode contact is poor; or electrodes being poorly moistened.

A complication of iontophoresis is chemical burn. Chemical burns occur when too much sodium hydroxide accumulates at the negative electrode. A pink lesion is apparent immediately after treatment, which becomes an oozing wound two to three hours later. This type of burn can be treated with **antibiotics** and a dressing, but tends to heal slowly. This complication can be prevented by decreasing the intensity of the current or by increasing the area of the negative electrode so that the current is dispersed over a larger area.

Complications arising from cold laser treatment include **dehydration**, protein coagulation (clumping), and thermolysis (melting). While dehydration is reversible, protein coagulation and thermolysis are not. The typical cause of these complications is the use of cold laser at excessively high power.

Results

TENS and iontophoresis should result in a reduction of pain and/or reduced symptoms of inflammation. There may be a concomitant increase in range of motion.

If diathermy and radiation are used, improved drainage may be reported. In addition, depending on the specific therapy, improvement in skin conditions and wound healing are expected. The reduction of pain and inflammation may also be reported.

NMES/FES should maintain or improve muscle strength. If the electrical stimulation is used to alleviate muscle spasm, relief from spasm is an expected result.

Health care team roles

Because the physical therapist has typically received training in electrotherapy during his/her course of studies, he/she is the primary care provider during electrotherapy. The physical therapist delivers the therapeutic care and monitors the patient during electrotherapy. If the patient has been referred by a physician or other health care provider and the provider requests briefings, the

therapist reports on the effects of the therapy and on the patient's progress.

Element deficiencies *see* **Mineral deficiency**

Elimination diet

Definition

An elimination diet functions as a test, determining whether patients may have a sensitivity to certain foods. Initially, patients stop eating foods suspected of causing illness. Then, after a suitable period of time (often 10–14 days), they review their symptoms. If significant improvement has occurred, it is assumed that an allergy or intolerance to certain foods may be involved. These suspect foods are then reintroduced to the diet, one by one. When symptoms return (usually within three days), the problematic food is identified and removed from the diet.

Benefits

Elimination diets are potentially useful in identifying hard-to-detect food intolerances that proponents believe are responsible for a wide range of ailments. These include constipation, headaches, migraine, infections of the ear or sinuses, frequent colds, post-nasal drip, chronic nasal congestion, sore throats, chronic cough, eczema, **hives**, acne, **asthma**, **pain** or stiffness in the muscles or joints, **heart** palpitations, indigestion, ulcers of the mouth, **stomach**, or duodenum, **Crohn's disease**, **diarrhea**, yeast infections, urticaria, **edema**, depression, **anxiety**, hyperactivity, weight change, and generalized fatigue.

Description

The following lists of appropriate and inappropriate foods for an elimination diet represent general guidelines. Elimination diets vary according to practitioner and the specific symptoms or allergy.

Foods that may be prohibited in an elimination diet include those containing:

- Additives: monosodium glutamate, artificial preservatives, sweeteners, flavors, or colors.
- Alcohol: beer, ale, stout, porter, malt liquors, wine, coolers, vodka, gin, rum, whiskey, brandy, liqueurs, and cordials.
- Citrus fruits: oranges, calamondins, tangerines, clementines, tangelos, satsumas, owaris, lemons, limes, kumquats, limequats, and grapefruit.
- Commonly eaten foods: anything consumed more than three times weekly, as well as foods that are craved or that cause a feeling of weakness.
- Corn: as well as corn syrup or sweetener, corn oil, vegetable oil, popcorn, corn chips, corn tortillas.
- Dairy products: milk, milk solids, cheese, butter, sour cream, yogurt, cottage cheese, whey, and ice cream.
- Eggs: both yolks and whites.
- Gluten: any pasta, breads, cakes, flour, or gravies containing wheat.
- Honey.
- Maple syrup.
- Sugar: candy, soft drinks, fruit juices with added sugar or sweetener, cakes, cookies, sucrose, fructose, dextrose, or maltose.

Foods that may be allowed include:

- Cereals: puffed rice or millet, oatmeal, or oat bran.
- Daily multivitamin: this is especially important during extended dieting to replace missing nutrients.
- Fats and oils: soy, soy milk, soy cheese, sunflower oil, safflower oil, flaxseed oil, olive oil, and sesame oil.
- Fruits and vegetables: typically, anything except corn and citrus fruits. Some practitioners suggest fruit be consumed in moderation, and preferably whole as opposed to juices.
- Grain and flour products: rice cakes or crackers, rye or spelt bread (both must be 100% with no added wheat), kasha, rice, amaranth, quinoa, millet, oriental noodles, other exotic grains.
- Legumes: soybeans, string beans, black beans, navy beans, kidney beans, peas, chickpeas, lentils, tofu.

KEY TERMS

Anaphylactic shock—An extreme allergic reaction characterized by swelling, constriction of the bronchi, circulatory collapse, heart failure, and even death.

Urticaria—Itchy pustules that may be caused by a hypersensitivity to food, drugs, or other substances.

Canned beans should be avoided unless they are free of preservatives and sugar.

- Seeds and nuts: must not contain sugar or salt. Nut butters are allowed if they meet this requirement and are organic.
- Water: two quarts daily. Preferably bottled, as tap water contains potential allergens including fluoride and chlorine.
- Other: honey, white vinegar, salt, pepper, garlic, onions, ginger, herbal teas, coffee substitutes, spices or condiments (mustard, ketchup) that are free from sugar, preservatives, and citrus. These products can commonly be found at health food stores.

An important complement to any elimination diet is a food diary, in which all dietary consumption is recorded, along with any subsequent symptoms. Patterns should be evident after about one month of record keeping.

Precautions

As with all therapies, anyone considering an elimination diet should weigh the potential benefits against the risks. The decision, according to some, is comparable to deciding to take a prescribed medication, and should be done only under the supervision of a competent medical practitioner.

Elimination diets should never be used by individuals with severe food **allergies**, as reintroducing a suspect food may provoke an asthma attack, anaphylactic **shock**, or other dangerous reaction. Generally, an elimination diet will be used only when symptoms are believed to be related to just one or two suspect foods.

Patients need to know that following a strict elimination diet is not an easy matter. It is extremely important to read packaged-food labels carefully, because many processed foods contain monosodium glutamate, sugar, and other substances that may be prohibited. It is almost impossible for elimination-diet patients to eat in restaurants, at school, or at the homes of friends. The resulting

isolation must be considered as part of the decision to undertake an elimination diet. Patients should also consider whether they have sufficient time for the extra planning, shopping, and food preparation involved.

Elimination-diet patients should be vigilant to replace any nutrients missing from their restricted diet. For example, **calcium** supplements may be advisable for someone eliminating dairy products from the diet. Needless to say, any prescribed medications should be continued during any diet.

Putting a very young child on an elimination diet may endanger the child's **nutrition** and normal growth. A breastfeeding mother may harm both her own health and that of her infant if she undertakes an elimination diet during **lactation**.

Side effects

The most significant side effects of an elimination diet are nutritional disorders resulting from a prolonged, highly restrictive diet, and the risk of a serious reaction as suspect foods are re-introduced to the diet. Some proponents also caution that patients consuming a very limited variety of foods risk becoming allergic to those very foods. For these reasons, professional supervision and substitution of missing nutrients are both essential.

Research and general acceptance

Elimination diets are widely used by medical doctors, but considerable differences of opinion exist over the range of illnesses that may be caused by food allergies or intolerances. Many physicians and researchers question the role of allergies in migraine, rheumatoid arthritis, **osteoarthritis**, and other conditions. Some doctors suggest that elimination diets should be used only after other diagnostic methods have been tried, including history-taking, skin tests, blind food challenges, and radioallergosorbent testing.

Training and certification

Because of the risks involved, elimination diets should be undertaken only under competent medical supervision. Some patients may wish to consult an allergy specialist.

Emergency medical technicians

Definition

An emergency medical technician-paramedic is a licensed and/or certified out-of-hospital health-care provider. EMTs represent the uppermost level of prehospital health care providers and serve as managers of prehospital treatment teams. They work under the direction of a physician—often by two-way radio—to evaluate and manage acutely ill or injured patients in ambulance services or other life-support units.

Description

The emergency medical system is a complex emergency response structure that has strict guidelines for its certification levels of health professionals. Emergency medical technicians are classified under four levels of prehospital certification: First Responder; Emergency Medical Technician-Basic (EMT-B); Emergency Medical Technician-Intermediate (EMT-I), and Emergency Medical Technician-Paramedic (EMT-P). Education and training varies across the four levels, with the emergency medical technician-paramedic having the highest level of training. An emergency medical technician has developed independent reasoning and training to make rapid assessments and interventions that can save people's lives. The EMT-P is considered an extension of the emergency room physician to the patient in the field and has the greatest amount of responsibility.

Provision of initial treatment

The responsibilities of an emergency medical technician are numerous, demanding, and extremely stressful. The EMT's most common responsibilities are related to provision of initial treatment:

- Organization and preparation for emergency calls: Besides having all of the equipment stocked, ambulance maintained and cleaned, and communication devices checked, the emergency medical technician must be psychologically and emotionally prepared to care for distressed patients and family members.
- Immediate and safe response to the emergency scene by knowing the proper location and road systems while maneuvering a heavy and bulky ambulance through traffic.
- Assessment of the safety hazards at the emergency scene, including the safety of the crew, the victims, and the bystanders—as well as understanding the nature of the injuries or illnesses that may be encountered.

- Rapid and efficient evaluation of victims of trauma or illness, using advanced patient assessment skills while recognizing and assigning priority to the most critical injury or illness.
- Delivery of high-quality patient care while utilizing protocols for procedures and interventions established by the emergency medical technician agency, as well as recognizing the need for back-up by an emergency physician.
- Transportation of patients to appropriate institutions if the patients are unstable or needing specialty care (i.e. neurological trauma, cardiovascular intervention). The emergency medical technician makes the decision regarding the best facility for managing the patient's injury or illness.
- Keeping records of all assessment findings and interventions completed on the patient from the field to the receiving facility.

Other responsibilities

Over the years, the scope of the EMTs responsibilities has widened to include educating the public about health issues and participating in injury and disease prevention programs. EMTs are also playing an increasingly important role in medical and **public health** research programs.

Work settings

Emergency medical technicians can work in a variety of settings. Many EMTs work for ambulance agencies. On the other hand, emergency centers, sports facilities, long-term care facilities, and large industries are also employing emergency medical technicians to deliver health care.

Education and training

Prerequisites

Educational requirements for emergency medical technicians differ slightly from state to state. Some EMT programs are designed to accommodate part-time students; others are structured as full-time college-level courses of study. The average length of training for EMTs is 1000 hours, but upgraded standards will probably add a small increase to the number of training hours over the next few years.

Persons considering an EMT-P program must be high school graduates and demonstrate their ability to meet the physical and psychological demands of emergency work. The physical demands are considerable, since EMTs must frequently lift and move patients away

Emergency medical technicians are trained to respond to emergency situations ranging from car accidents to chemical spills. (M. Kowal/Custom Medical Stock Photo. Reproduced by permission.)

from danger zones or into emergency vehicles, without time to call for assistance. Likewise, the sheer number of potential on-the-job hazards, ranging from toxic chemical spills or fire to collapsing buildings or human violence adds to the emotional **stress** of EMT work. In addition to demonstrating their physical stamina and emotional stability, persons entering an EMT-P program must be certified at the EMT-ambulance level. Some programs, however, offer a combination of EMT-ambulance and EMT-P training. Students who have acquired basic EMT training in the armed forces within the past 12 months and have had their work approved by a state agency may be permitted to enroll in an EMT-P program.

Course work

In some states, students enrolled in EMT-P programs are eligible to earn an associate's degree. On the national level, the United States Department of Transportation (U.S. DOT) determines the minimum requirements that must be met for the education of emergency medical technicians. Accredited EMT-P programs include didactic instruction, in-hospital clinical experience, and a supervised field internship in an advanced life-support

unit. The course work should also acquaint students with an understanding of their legal and ethical responsibilities as emergency medical personnel.

The education of a emergency medical technician focuses on three dimensions of human experience and activity:

- The affective domain: assignment of various feelings, morals, and thoughts to information, situations, and scenarios.
- The cognitive domain: recall of information and comprehension of facts, figures, and statistics.
- The psychomotor domain: skill attainment through practice in clinical and controlled laboratory settings.

Advanced skills and knowledge of medical management of patients in the field is a central component of EMT training. Common areas of training are:

- advanced **airway management** techniques, including endotracheal intubation
- intravenous fluid management, including the initiation of intravenous lines and administration of proper fluid replacement

- administration of emergency medications
- cardiac monitoring, interpretation, and intervention
- advanced patient assessment and evaluation
- management of trauma patients
- administration of established advanced cardiac life support, including defibrillation (delivering an electrical **shock**) for abnormal **heart** rhythms
- administration of advanced first aid
- complex immobilization techniques used in acute **fractures**, dislocations, and strains
- proper physical restraining of violent patients, with training focused on safety and de-escalation techniques

Continuing education and specialized training

The education of EMTs does not end with course completion and certification or licensure. The importance of keeping one's skills current is equally important. Every two years, emergency medical technicians must acquire a specific number of continuing education credits in order to maintain certification or licensure in their respective states. Most employers will provide classes for the emergency medical technicians to obtain the necessary continuing education credits.

Specialized certifications are important for the emergency medical technician to complete and update every two years. These certifications include: Advanced Cardiac Life Support (ACLS), Pediatric Advanced Life Support (PALS), Basic Trauma Life Support (BTLS), and Prehospital Trauma Life Support (PHTLS).

Future outlook

The role of emergency medical technicians is expanding because of their ability to independently manage various types of patients. The emergency medical technician has become instrumental in transport of critical care patients from one facility to another via ground transport, helicopter, or larger aircraft. In order for an emergency medical technician to function on an acute care transport vehicle, additional training in critical care medications, **ventilators**, various advanced monitoring systems, and fluid management must be completed.

Emphysema

Definition

Emphysema is a chronic respiratory disease in which overinflation of the alveoli or air sacs causes a decrease in respiratory function and often dyspnea.

Description

Emphysema is the most common cause of death from respiratory disease in the United States, and is the fourth most common cause of death overall. There are 1.8 million Americans with the disease, which ranks fifteenth among chronic conditions that cause limitations of activity. Around 44% of those with emphysema state that their activities of daily living have been affected by the disease.

Normally functioning **lungs** are elastic, efficiently expanding and recoiling as air passes freely through the bronchus to the alveoli, where oxygen is moved into the **blood** and carbon dioxide is filtered out. When a person inhales cigarette smoke, his or her **immune system** responds by releasing substances that are meant to defend the lungs against the smoke. These substances can also attack the cells of the lungs. Normally, the body inhibits such action by releasing other substances. In smokers and those with the inherited emphysema defect, however, no such prevention occurs, and the lung tissue is damaged in such a way that it loses its elasticity. The small passageways leading to the alveoli collapse, trapping air within the alveoli. The alveoli, unable to recoil efficiently and move the air out, overexpand and rupture. The smaller areas of alveoli destruction are known as blebs and the larger ones are called bullae. As the disease progresses coughing and dyspnea occur. In the later stages the lungs cannot supply sufficient oxygen to the blood. Emphysema often occurs with other respiratory diseases, particularly chronic bronchitis. These two diseases are often referred to as one—chronic obstructive pulmonary disease (COPD).

Emphysema is most common among people aged 50 years and older. Those with inherited emphysema may experience the onset as early as their 30s or 40s. Men are more likely than women to develop emphysema, but female cases are increasing as the number of female smokers rises.

Causes and symptoms

Heavy cigarette smoking causes about 80–90% of all emphysema cases. However, a few cases are the result of an inherited deficiency of alpha-1-antitrypsin (AAT). The number of Americans with this deficiency is relatively small, probably no greater than 70,000. Pipe, cigar, and **marijuana** smoking can also damage the lungs. While a person may be less likely to inhale cigar and pipe smoke, these types of smoke can also impair lung function. Marijuana smoke is even more damaging because it is inhaled deeply and held in the lungs longer by the smoker.

The symptoms of emphysema develop gradually over many years. It is a common occurrence for many emphysema patients to have lost 50–70% of their functional lung tissue before they become aware that something is wrong. Dyspnea, a chronic mild cough (which may be productive of large amounts of dark, thick sputum, and often dismissed as “smoker’s cough”), and sometimes weight loss are associated with emphysema. Initially, a patient may notice shortness of breath only when he or she is exercising. However, as the disease progresses, it will occur during less exertion, and ultimately with no exertion at all. Emphysema patients may also develop an enlarged, or “barrel,” chest. Other symptoms may include skipped breaths, insomnia, morning headaches, nasal flaring, increased difficulties breathing while lying down, chronic fatigue, and swelling of the feet, ankles, or legs. Those with chronic emphysema are at risk for other complications resulting from weakened lung function. These include **pneumonia**, pulmonary **hypertension**, cor pulmonale, and chronic **respiratory failure**.

Diagnosis

A history of heavy smoking alone is not enough for a physician to differentiate emphysema from other respiratory diseases. A physician will combine information on symptoms, medical history, **physical examination**, lung function tests, and **chest x ray** results to make a diagnosis of emphysema. One of the first clues may be a hollow sound heard through a **stethoscope** as the patient’s chest is being tapped. The hollow sound is the result of the enlargement or rupture of the lungs’ alveoli.

A variety of pulmonary function tests may be ordered. In the early stages of emphysema, the only result may be dysfunction of the small airways. Patients with emphysema may show an increase in the total amount of air that is in the lungs (total lung capacity), but a decrease in vital capacity. With severe emphysema, vital capacity is substantially below normal. Spirometry, a procedure that measures respiratory gases and resulting pulmonary function, aids in the diagnosis of emphysema.

A chest x ray is often ordered to aid in the diagnosis of emphysema, though patients in the early stages of the disease may have normal findings. Abnormal findings on the chest x ray include excessive inflation of the lungs and an abnormally increased chest diameter. The diaphragm may appear depressed or flattened. In addition, patients with advanced emphysema may show an enlargement of the **heart**. The physician may observe blisters in the lungs and bulging of the accessory muscles of the **respiratory system**. Late in the disease an EKG will show signs of right ventricular failure in the heart

and increased hemoglobin due to lower oxygen in the patient's blood.

Other tests that may be performed include peak flow measurements, arterial **blood gases**, and pulse oximetry.

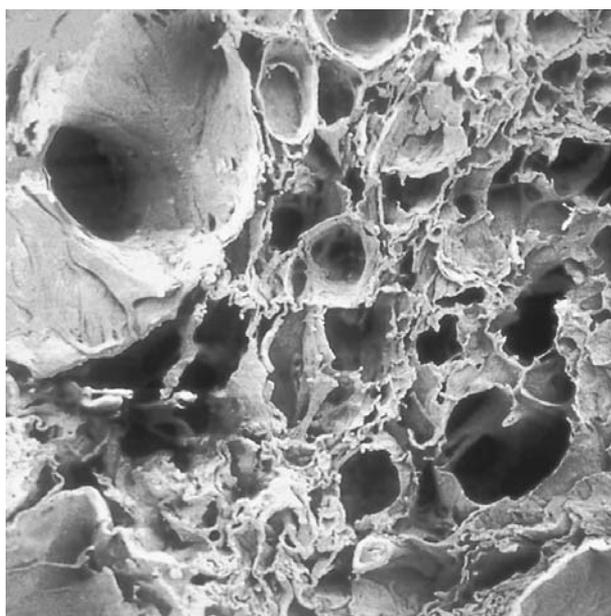

Treatment

Treatment methods for emphysema do not cure or reverse the damage to the lungs. However, they can slow the progression of the disease, relieve symptoms, and help control possibly fatal complications. The first step in treatment for smokers is to quit smoking to prevent any further deterioration of breathing ability. Smoking cessation programs may be effective. Consistent encouragement, along with the help of health care professionals as well as family and friends, can help increase the quit rate.

If the patient and the health team develop and maintain a complete program of respiratory care, disability can be decreased, acute episodes of illness may be prevented, and the number of hospitalizations reduced. However, only smoking cessation has been shown to slow down the progression of the disease; and among all other treatments, only **oxygen therapy** has exhibited an increase in survival rate.

Home oxygen therapy may improve the survival times in those patients with advanced emphysema who also have hypoxemia, or low blood oxygen levels. It may improve the patient's tolerance of **exercise**, as well as improve their performance in certain aspects of **brain** function and muscle coordination. The functioning of the heart may also improve with an increased concentration of oxygen in the blood. Oxygen may also decrease insomnia and headaches. Some patients may receive oxygen only at night, but studies have illustrated that it is most effective when administered for at least 18, but preferably, 24 hours per day. Those patients just beginning the therapy may wish to postpone continuous oxygen administration until it becomes absolutely necessary because of inconvenience and decreased mobility. Portable oxygen tanks prescribed to patients carry a limited supply and must be refilled on a regular basis by a home health care provider. **Medicare** and most insurance companies cover a large proportion of the cost of home oxygen therapy. Patients should be instructed regarding special safety issues involving the transport and presence of oxygen in the home.

A variety of medications may be used in the treatment of emphysema. Usually the patient responds best to a combination of medicines rather than one single drug. Bronchodilators are sometimes used to help alleviate the patient's symptoms by relaxing and opening the airways. There are three primary categories of bronchodilators:

A scanning electron microscopy (SEM) of lung tissue showing the ruptured alveoli (air sacs) that characterize emphysema. (Photograph by Hossler, Custom Medical Stock Photo. Reproduced by permission.)

sympathomimetics (isoproterenol, metaproterenol, terbutaline, albuterol), which can be inhaled, taken by mouth, or injected; parasympathomimetics (atropine); and methylxanthines (theophylline), which may be administered intravenously, orally, or rectally.

Another category of medication often used is **corticosteroids** or steroids (beclomethasone, dexamethasone, triamcinolone, flunisolide). These help to decrease the inflammation of the airway walls. They are occasionally used if bronchodilators are ineffective in preventing airway obstruction. Some patients' lung function improves with corticosteroids, and inhaled steroids may be beneficial to patients with few side effects.

A variety of **antibiotics** are frequently given at the first sign of a respiratory **infection**, such as increased amounts of sputum or a change in the color of the sputum. Expectorants can help loosen respiratory secretions, enabling the patient to more easily expel them from the airways.

Many of the medications prescribed involve the use of a metered dose inhaler (MDI) that may require special instruction to be used correctly. MDIs are a convenient and safe method of delivering medication to the lungs. However, if they are used incorrectly the medication will not get to the right place. Proper technique is essential for the medication to be effective.

For some patients, surgical treatment may be the best option. Lung volume reduction surgery is a surgical pro-

KEY TERMS

Alveoli—Small cells or cavities. In the lungs, these are air sacs in which oxygen enters the blood and carbon dioxide is filtered out.

Arterial blood gases—A test to analyze blood for oxygen, carbon dioxide, and bicarbonate content, as well as blood pH. Used to test the effectiveness of respiration.

Cor pulmonale—A disease characterized by an increase in bulk of the right ventricle of the heart that can lead to heart failure.

Hypoxemia—A condition characterized by deficient oxygen supply in the blood.

Peak flow measurement—Measurement of the maximum rate of airflow attained during a forced vital capacity determination.

Pulmonary—Related to or associated with the lungs.

Pulse oximetry—The noninvasive monitoring or determination of oxygen-hemoglobin saturation of the blood.

cedure in which the most diseased parts of the lung are removed to enable the remaining lung and breathing muscles to work more efficiently. Preliminary studies suggest improved survival rates and better functioning with the surgery. Another surgical procedure used for emphysema patients is lung transplantation. Transplantation may involve one or both lungs. However, it is a risky and expensive procedure and donor organs may not be available.

For those patients with advanced emphysema, keeping the air passages reasonably clear of secretions can prove difficult. Some common methods for mobilizing and removing secretions include:

- **Postural drainage.** This technique helps to remove secretions from the airways. The patient lies in a position that allows gravity to aid in draining different parts of the lung. This is often done after the patient inhales and aerosol medication. The basic position involves the patient lying on the bed with chest and head over the side and forearms resting on the floor.
- **Chest percussion.** This technique involves a caregiver lightly clapping the back and chest of the patient. It may help to loosen thick secretions.
- **Coughing and deep breathing.** These techniques may aid the patient in bringing up secretions.

- **Aerosol treatments.** These treatments may involve solutions of saline, often mixed with a bronchodilator, which are then inhaled as an aerosol. The aerosols thin and loosen secretions. A treatment normally takes 10–15 minutes and is given three or four times a day.

Patients with COPD can be instructed to perform a variety of self-help measures that can help improve their symptoms and ability to participate in activities of daily living. These measures include:

- Avoiding any exposure to dust and fumes.
- Avoiding air pollution, including secondhand cigarette smoke.
- Avoiding other people who have infections like the cold or flu, and getting a pneumonia **vaccination** and a yearly flu shot.
- Drinking plenty of fluids to help loosen respiratory secretions so they can be coughed up more easily.
- Avoiding extreme heat or cold and high altitudes (special precautions can be taken that may enable the emphysema patient to fly on a plane).
- Maintaining adequate nutritional intake; normally, a high-protein diet taken in many small feedings, is recommended.

Many patients are interested in whether any alternative treatments for emphysema are available. Some practitioners recommend supplements of antioxidant nutrients. There have also been some studies indicating a correlation between a low **vitamin A** status and COPD, with suggestions that supplements of vitamin A might be beneficial. Aromatherapists have used essential oils like eucalyptus, lavender, pine, and rosemary, to help relieve nasal congestion and make breathing easier. The herb elecampane may act as an expectorant to help patients clear mucus from the lungs. The patient should discuss these remedies with their health care practitioner prior to trying them, as some may interact with the more traditional treatments already being given.

Prognosis

Emphysema is a serious and chronic disease that cannot be reversed. If detected early effects and progression can be slowed, particularly if the patient ceases smoking immediately. Complications of emphysema include higher risks for pneumonia and acute bronchitis. Overall, the prognosis for patients with emphysema is poor, with a medical survival rate for all COPD patients of four years, and even less for emphysema patients. However, individual cases vary, and many patients can live much longer with supplemental oxygen and other treatment measures.

Health care team roles

Many members of the health care team may treat the patient with emphysema. The patient usually seeks help from a physician first, who will make the diagnosis. In the course of the diagnostic workup, x-ray technicians and respiratory therapists may treat the patient. The nurse plays an important role in assessing the patient, administering medications, in teaching the patient how best to cope with and understand the disease, and—in some cases—provides **home care**. The physical therapist may assist the patient to find ways of increasing their strength and activity tolerance.

Prevention

The best way to prevent emphysema is to avoid smoking. Even patients with inherited emphysema should avoid smoking, as it hastens onset and worsens severity of the disease. If patients quit smoking as soon as evidence of small airway obstruction begins, they can significantly improve their prognosis.

Endocarditis

Definition

Endocarditis is an **infection** of the endocardium, the inner lining of the **heart** muscle and its four valves (tricuspid, pulmonary, mitral, and aortic). Abnormal or dam-

aged endocardium is more likely to become infected when **bacteria** enter the bloodstream. When this happens, during surgical or dental procedures, for example, a condition called bacteremia results. The circulating bacteria can then enter the heart, where damaged tissue or other abnormalities allow them to multiply and cause an infection. Endocarditis is a life-threatening disease that interferes with the heart’s ability to pump **blood**. Untreated, it is always fatal.

Description

Endocarditis most commonly occurs in people whose hearts have damaged valves. This may be the result of acquired valvular disease from rheumatic **fever** or other diseases. Patients with mitral valve prolapse, in which a poorly functioning mitral valve regurgitates blood back into the heart, allowing bacteria to multiply, are also at risk for endocarditis. Prosthetic (artificial) heart valves are more likely to become infected as well.

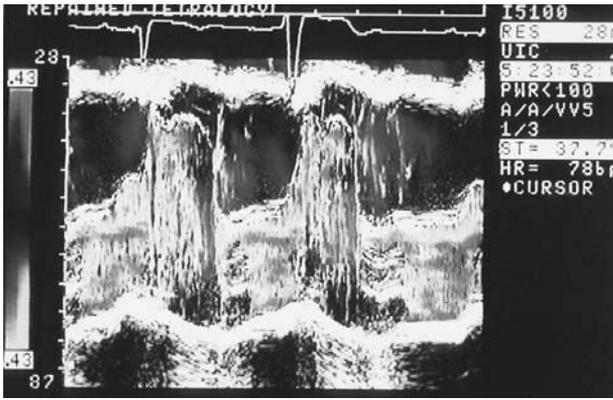

Bacteremia that causes endocarditis can occur in several ways:

- from a localized infection such as a urinary tract infection, **pneumonia**, skin infection, or dental infection
- as a result of certain medical conditions, such as severe periodontal disease, colon **cancer**, or inflammatory bowel disease
- during dental or surgical procedures, such as dental cleaning, tooth extractions, tonsil removal, or endoscopic examinations
- through in-dwelling catheters used for intravenous medications, intravenous feeding, or dialysis
- intravenous drug use using unsterilized, contaminated needles and syringes

The bacteria that cause most endocarditis are gram-positive cocci, such as *Staphylococcus* or *Streptococcus*. Staphylococcal endocarditis occurs most often among intravenous drug users and patients with in-dwelling venous catheters. Gram-negative bacterial endocarditis or fungal endocarditis is much less common; patients are usually intravenous drug users or those with prosthetic heart valves.

Endocarditis patients who appear critically ill are usually suffering from acute bacterial endocarditis, while those with subacute bacterial endocarditis have less severe but persistent symptoms such as weight loss, fatigue, and low-grade fever.

If not discovered and treated, endocarditis can permanently damage the heart valves. If a valve is damaged, it may allow blood to flow backward—a condition known as regurgitation. As a result of a poorly function-

This echocardiogram shows an aortic regurgitation due to endocarditis, an infection of the lining membrane of the cardiac chambers. (Custom Medical Stock Photo. Reproduced by permission.)

ing valve, the heart muscle has to work harder to pump blood and may become weakened, leading to congestive **heart failure**.

Another danger associated with endocarditis is that the overgrowth of bacteria colonizing heart valves may break off and form emboli that can become lodged in arteries. An embolism to an artery supplying the **brain** can cause a stroke; an embolus lodged in the **blood vessels** of the **lungs** may cause pneumonia.

Causes and symptoms

Most cases of infective endocarditis occur in patients between the ages of 15 and 60, with a median age at onset of about 50 years. Men are affected about twice as often as women. Other risk factors for endocarditis are congenital heart problems, heart surgery, past history of endocarditis, and intravenous drug use.

Patients with acute bacterial endocarditis are generally critically ill. Patients with subacute bacterial endocarditis tend to have a low-grade fever, which rarely rises above 102°F (38.9°C), chills, weakness, cough, difficulty breathing, headaches, arthralgias (aching joints), and loss of appetite, although these symptoms vary with individual patients.

Emboli may also cause a variety of symptoms, depending on their location. Emboli throughout the body may cause Osler's nodes, which are small, reddish, painful bumps most commonly found on the inside of fingers and toes. Emboli may also cause petechiae, which are tiny purple or red spots on the skin resulting from hemorrhages under the skin's surface. Tiny hemorrhages resembling splinters may also appear under the fingernails or toenails. If emboli become lodged in the blood

vessels of the lungs, they may cause coughing or shortness of breath. Emboli lodged in the brain may cause a stroke, with such symptoms as numbness, weakness, or **paralysis** on one side of the body or sudden blindness or double **vision**. Emboli may also damage the **kidneys**, causing nephritis. Sometimes the capillaries on the surface of the spleen rupture, causing it to become enlarged and tender. Patients with any of these symptoms require immediate medical attention.

Diagnosis

Clinicians diagnose endocarditis by taking a history and performing a **physical examination**, during which they may observe such signs as fever, an enlarged spleen, signs of kidney disease, or hemorrhaging. The clinician may also detect a heart murmur. A heart murmur may indicate abnormal flow of blood through one of the heart chambers or valves. Laboratory analysis of the patient's blood identifies the bacteria or other microorganisms that may be causing the infection.

The diagnostic workup also involves **echocardiography** to check for abnormalities in the structure of the heart wall or valves. Conventional echocardiography uses ultrasound to view the structures of the heart. This diagnostic procedure is transthoracic; the ultrasound transducer is placed on the chest wall.

One of the hallmarks of endocarditis that may be observed during echocardiography is vegetation, which is the abnormal growth of tissue, composed of blood platelets, bacteria, and a clotting protein called fibrin, that grows around a valve. Another indicator is regurgitation, or the backward flow of blood, through one of the heart valves. A normal echocardiogram does not exclude the possibility of endocarditis, but an abnormal echocardiogram can confirm its presence. If an echocardiogram cannot be performed or its results are inconclusive, a modified technique called **transesophageal echocardiography** is sometimes performed. This technique involves passing an ultrasound device into the esophagus to get a clearer image of the heart.

Treatment

When infective endocarditis is suspected, the patient is admitted to the hospital and antibiotic treatment is started before the results of the **blood culture** are available. The choice of **antibiotics** depends on which infecting microorganism is suspected. Once the results of the blood culture become available, the physician will prescribe specific antibiotics known to be effective against the specific microorganism involved.

Today the treatment of endocarditis is more complicated as a result of antibiotic resistance. Over the past few years, especially as antibiotics have been overprescribed, more and more strains of bacteria have become increasingly resistant to a wider range of antibiotics. For this reason, a few different types of antibiotics—or even a combination of antibiotics—may be necessary to treat the infection successfully. Antibiotics are usually prescribed for about six weeks but may be given for an even longer period of time if the infection is resistant to treatment.

Once the fever and acute symptoms have resolved, most patients are able to continue antibiotic therapy at home. During this time, patients make regular visits to the health care team to ensure that the antibiotic therapy is working, that it is not causing adverse side effects, and that there are no complications such as emboli or congestive heart failure.

Patients must be advised to alert the health care team to any symptoms that could indicate serious complications. For instance, difficulty breathing or **edema** (swelling) in the legs could indicate congestive heart failure. Headache, joint **pain**, blood in the urine, or stroke symptoms could indicate an embolus; and fever and chills could indicate that the treatment is not working and the infection is worsening. Finally, **diarrhea**, rash, itching, or joint pain may suggest an adverse reaction to the antibiotics. Patients experiencing any of these symptoms should be advised to seek immediate medical attention.

In some cases surgical intervention may be needed to treat congestive heart failure, recurring emboli, infection that does not respond to treatment, poorly functioning heart valves, and endocarditis involving prosthetic (artificial) valves. The most common surgical treatment involves debriding (cutting away) damaged tissue and replacing the damaged valve.

Prognosis

Untreated infective endocarditis progresses and is always fatal. However, when diagnosed and properly treated within the first six weeks of infection, the infection can be completely cured in about 90% of the cases. The prognosis depends on a number of factors, such as the patient's age and overall physical condition; the severity of the diseases involved; the exact site of the infection; how vulnerable the microorganisms are to antibiotics; and the nature of the complications.

KEY TERMS

Aortic valve—The valve between the left ventricle of the heart and the aorta.

Congestive heart failure—A condition in which the heart muscle cannot pump blood as efficiently as it should.

Echocardiography—A diagnostic test using reflected sound waves to study the structure and motion of the heart muscle.

Embolus—A bit of foreign material, such as gas, a piece of tissue, or tiny clot, that circulates in the bloodstream until it becomes lodged in a blood vessel.

Endocardium—The inner wall of the heart muscle, which also covers the heart valves.

Mitral valve—The valve between the left atrium and the left ventricle of the heart.

Osler's nodes—Small, raised, reddish, tender areas associated with endocarditis, commonly found inside the fingers or toes.

Petechiae—Tiny purple or red spots on the skin associated with endocarditis, resulting from hemorrhages under the skin's surface.

Pulmonary valve—The valve between the right ventricle of the heart and the pulmonary artery.

Transducer—A device that converts electrical signals into ultrasound waves and ultrasound waves back into electrical impulses.

Transesophageal echocardiography—A diagnostic test using an ultrasound device passed into the esophagus of the patient to create a clear image of the heart muscle.

Tricuspid valve—The valve between the right atrium and the right ventricle of the heart.

Vegetation—An abnormal growth of tissue around a valve that can develop following a bacteremia. Vegetation is composed of blood platelets, the infecting bacteria, a few white blood cells, and fibrin, a protein involved in clotting.

Health care team roles

Endocarditis is generally diagnosed by a primary care physician, emergency medicine physician, or cardiologist. Nurses, ECG technicians, laboratory technologists and other allied health professionals have important roles in the diagnosis of endocarditis as well as institution

of timely treatment. Nurses and other practitioners involved in triage or screening in the emergency department, clinic, office, or other treatment setting must accurately assess patients with indications of endocarditis.

ECG technicians and laboratory technologists are responsible for performing the diagnostic tests, ECG, and blood cultures to confirm the diagnosis and causative microorganism. In the hospital, nurses and allied health professionals are responsible for closely monitoring patients for complications.

Prevention

Some individuals are especially prone to endocarditis. These include patients with past history of endocarditis, those with congenital heart problems or heart damage from rheumatic fever, and patients with prosthetic heart valves. Intravenous drug users are also at increased risk. Patients at high risk for endocarditis need to take a dose of prophylactic antibiotics before undergoing procedures likely to cause bacteria to enter the bloodstream, such as most dental procedures. The American Heart Association recommends two grams of amoxicillin (children: 50 mg/kg) taken by mouth one hour before dental appointments. Patients who are allergic to penicillin can take clindamycin, cephalexin, or azithromycin instead.

Endocrine system

Definition

The endocrine system is a widespread group of glands and organs that acts as the body's control system for producing, storing, and secreting chemical substances called hormones.

Description

The primary glands that compose the endocrine system are the hypothalamus, pituitary, thyroid, parathyroid, adrenal, pineal, ovary, and testes. The **pancreas**, considered both an organ and a gland, is also part of the system. The thymus is sometimes considered an endocrine-system organ. Although not part of the endocrine system, other organs that secrete hormones are the **heart, brain, lungs, kidneys, liver**, skin, and placenta. The word "endocrine" means that in response to specific stimuli, the hormones produced by the glands are released into the bloodstream.

Function

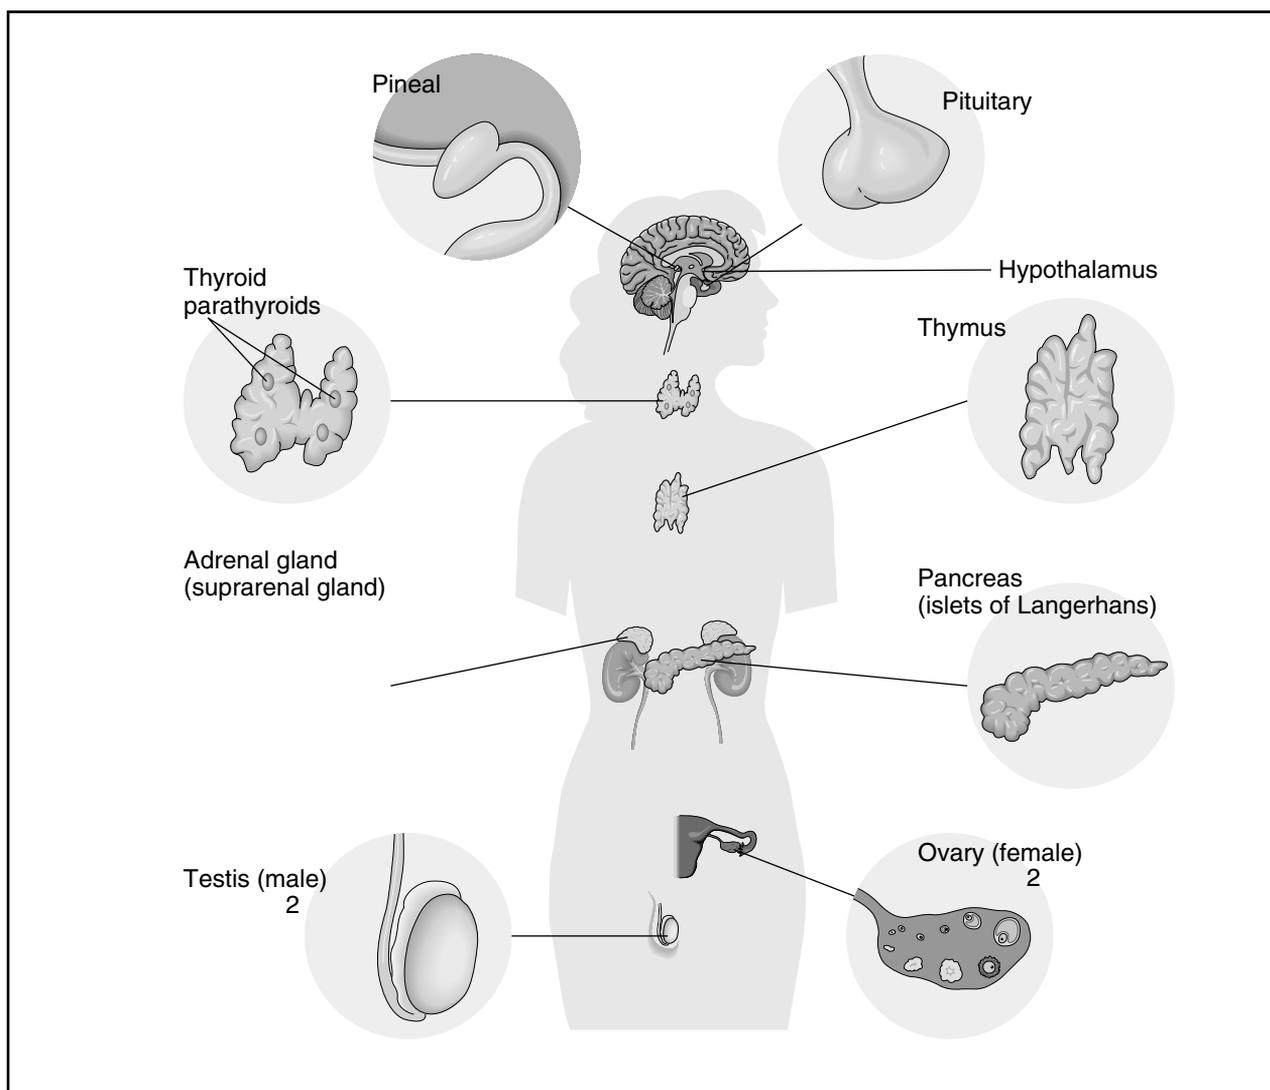

Hormones are compounds produced by the endocrine glands. They generally control the growth, development, and **metabolism** of the body; the electrolyte composition of body fluids; and reproduction. The specific functions of the endocrine glands and pancreas are unique.

Pituitary gland

The pituitary is the master gland of the endocrine system. Located at the base of the brain, the gland, which is about the size of a marble, consists of two parts: anterior and posterior. The anterior pituitary produces hormones that either stimulate other glands (such as adrenal, testis, ovary, and thyroid) to produce target-gland hormones, or directly affect the target organs.

Three of these hormones—adrenocorticotropic hormone (ACTH), gonadotropins, and thyroid-stimulating hormone (TSH)—act on other glands. ACTH stimulates the adrenal cortex to produce corticosteroid hormones and small amounts of male and female sex hormones. Gonadotropins are two hormones that regulate the production of male and female sex hormones and the egg (ova) and sperm (spermatozoa) cells. TSH stimulates the **thyroid gland** to produce and release thyroid hormone.

Another pituitary hormone, growth hormone (GH), has a central role in controlling the growth and development of the body and its components, including organs, tissue, and muscle. It also affects the metabolism of **car-**

The structures of the endocrine system. (Delmar Publishers, Inc. Reproduced by permission.)

bohydrates, protein, and fat. For example, GH increases glucose levels in the **blood** by reducing the amount of glucose used by muscle cells and adipose tissue and by promoting glucose production from certain liver molecules. Other functions of GH include increasing the amount of amino acids that cells take from the blood and stimulating the breakdown of **lipids (fats)** in adipose tissue. The pituitary hormone prolactin acts with other hormones in female breast development and helps regulate breast-milk production (**lactation**).

Two hormones, vasopressin and oxytocin, are stored but not produced in the posterior pituitary. Vasopressin, also called arginine vasopressin (AVP), helps the body to conserve water by increasing reabsorption of water from the kidneys. Oxytocin stimulates contractions in the uterus during **childbirth** and activates milk ejection caused by an infant sucking on the breast.

Adrenal glands

The adrenals are small glands on top of the kidneys. The adrenals have two parts: an outer layer called the cortex, and an inner layer called the medulla. The adrenal cortex produces a variety of hormones called **corticosteroids**, including hydrocortisone (cortisol), which helps increase blood glucose levels. It also reduces the amount of glucose absorbed by muscles and adipose tissue. Another function of cortisol is to protect the body from the adverse effects of **stress**, including emotional and physical trauma.

The adrenal medulla produces adrenaline and norepinephrine, substances that increase the heart rate and **blood pressure** during times of stress. Their action is referred to as the “fight-or-flight” response.

Thyroid gland

The thyroid gland is composed of two sections in front of the windpipe and below the voice box. It produces two hormones, thyroxine (T4) and tri-iodothyronine (T3), which together are called the thyroid hormones. They help regulate growth and development and help in childhood brain development. The thyroid also contains cells that produce the hormone calcitonin, which helps to maintain normal **calcium** levels in the blood.

Parathyroid glands

The parathyroid complex is composed of four small glands, each the size of a pea, and each located on the four corners of the thyroid gland. They secrete parathyroid hormone, which regulates calcium levels in the blood.

Pancreas

The pancreas is located in the upper abdomen, just behind and below the **stomach**. It has two functions: to produce various enzymes that aid in digestion; and to produce insulin and glucagon, hormones that are key to the body's management of glucose (sugar) in the blood.

The primary purpose of insulin is to lower blood-glucose levels in the body. It helps form glycogen, **proteins**, and lipids, which are stored in the body (usually in the liver, muscles, and adipose tissue) to be used for energy. Glucagon increases blood-glucose levels, an action opposite to that of insulin. A strict balance between the glucagon and insulin is required to maintain proper blood-sugar levels.

Hypothalamus

Located deep inside the brain, the hypothalamus maintains direct control of the **pituitary gland**. It acts as the central "control room" of the endocrine system, directing the activities of the other parts of the system. These activities include regulating eating and drinking, sexual behavior, blood pressure, heart rate, body temperature, emotions, and the sleeping/waking cycle. When the brain receives information indicating that hormonal changes are needed somewhere in the body, the hypothalamus secretes chemicals that stimulate or suppress hormone production in the pituitary gland.

Pineal and thymus

The pineal is located in the center of the brain. This gland secretes melatonin, a hormone that helps regulate the sleeping/waking cycle. Disturbances in the production of melatonin causes jet lag, experienced by many long-distance travelers. Melatonin also influences devel-

opment of the male and female sex glands. The thymus processes lymphocytes in infants and is partly responsible for immune-system development.

Ovaries and testes

The ovaries and testes, also called the sex glands, produce cells and hormones essential to reproduction and development of the body, including male and female sex characteristics. The three types of sex hormones are estrogens, progestogens, and androgens (including testosterone).

The main role of estrogens is to coordinate development and function of the female genitalia and breasts. Estrogens are also associated with the start of the menstrual bleeding cycle. Estrogen production in the ovary ceases during **menopause**. Estrogen is also produced in men (by the testes), though at lower levels than occur in women.

Progestogens are produced in the ovaries during part of the menstrual cycle, and in the placenta during **pregnancy**. They cause changes in the lining of the uterus to prepare it for pregnancy, and they act with estrogens to stimulate mammary-gland development in the breasts to prepare for lactation. Progesterone is the main progesterone hormone.

The primary androgen produced in the testes is the steroid testosterone. While mainly associated with male development, testosterone is produced in small amounts in women by the ovaries. During pregnancy, testosterone helps to develop the internal and external male sex organs. In males, testosterone promotes the growth of the sex organs and develops or stimulates male characteristics, such as deepening voice; growth of facial, pubic, and other body hair; and muscle growth and strength. In adult males, testosterone maintains the masculine characteristics and sexual potency and regulates sperm production.

Role in human health

A wide variety and dozens of symptoms can indicate a hormonal imbalance in the body. However, a specific group of symptoms give an initial indication of a problem in the endocrine system. For example, excessive thirst, frequent urination, and unexplained weight loss are classic signs of **diabetes mellitus**, the most common endocrine disorder. Many primary-care physicians still treat endocrine problems, especially diabetes, themselves. However, the primary care doctor often makes a preliminary diagnosis and then refers the patient to an endocrine-system specialist, called an endocrinologist.

Disorders of the endocrine system often, but not always, result from an over- or underproduction of a par-

ticular hormone. Too much or too little of a hormone can be harmful. The endocrine organs use a feedback mechanism to regulate hormone levels. It acts much like a household thermostat, increasing production of a specific hormone when it detects too little in the blood, or decreasing production when it detects too much or the right amount. Tight control of hormone levels is needed for the body to function properly. The endocrine organs secrete hormones directly into the bloodstream, where special proteins usually bind to them, helping to maintain them as they travel through the body.

Common diseases and disorders

There are two basic classes of endocrine disorders: problems associated with hormone-production levels, and problems caused by tissues that are unable to respond to hormones. Hormone-production disorders are broken into two groups: insufficient hormone production, called hypofunction; and too much hormone production, called hyperproduction. Endocrine-system disorders include the following:

- Diabetes mellitus is a disease that includes type 1 and type 2 diabetes. Type 1 is an autoimmune disease caused when the **immune system** destroys certain insulin-producing cells in the pancreas. This causes the pancreas to produce little or no insulin. Type 1 diabetes usually develops in children and young adults, but it can appear at any age. Symptoms include increased thirst and urination, unexplained weight loss, blurred **vision**, and extreme fatigue. There is no cure; insulin, first used in 1921, remains the only treatment. Type 2 diabetes accounts for 90% to 95% of diabetes cases. It usually develops in adults over age 40 and is usually associated with **obesity**. In type 2, the pancreas produces insulin, but the hormone is not used effectively by the body, a condition called insulin resistance. Several years after onset, insulin production decreases below the level needed to maintain glucose homeostasis. The result is the same as for type 1 diabetes: glucose builds up in the blood because the body cannot use it efficiently. Symptoms develop gradually and include increased thirst and urination, weight loss, fatigue, nausea, blurred vision, frequent infections, and **wounds** or sores that heal slowly. Insulin resistance is treated with drugs such as thiazolidinediones (rosiglitazone and pioglitazone) and biguanides (metformin). When insufficient insulin is produced, type 2 diabetes appears. However, research indicates progression of insulin resistance to type 2 diabetes can usually be halted or slowed with the insulin-resistance medications, or by lifestyle changes that result in weight loss.
- Hypothyroidism is caused by the thyroid gland producing too little thyroid hormone. It can lead to severe hypothyroidism, a disorder that usually develops after age 40. Symptoms include intolerance to cold, lethargy, fatigue, weight gain, and mental sluggishness. Congenital hypothyroidism is present at birth and has the same symptoms. If left untreated, it can lead to mental retardation. The standard treatment for both hypothyroid disorders is thyroid hormone-replacement medications such as levothyroxine (Synthroid, Unithroid, Levoxyl, and Levothroid) and triiodothyrene.
- Hyperthyroidism is due to an excess of thyroid hormones and affects women more frequently than men. Symptoms include nervousness, weight loss, intolerance to heat, **diarrhea**, heart palpitations, and insomnia. Some patients experience protruding eyes and trembling. Treatments include medications to inhibit thyroid-hormone production, and removal or destruction of the thyroid gland with radioactive iodine. The most common cause of the excessive thyroid production is Graves' disease, an autoimmune disorder of the thyroid gland.
- Addison's disease is caused by underactivity or immune-system destruction of the adrenal gland. It can be life-threatening if left untreated. Symptoms include weakness, fatigue, nausea, **dehydration**, **fever**, and hyperpigmentation (darkening of the skin without sun exposure.) The standard treatment is with corticosteroid hormones and adequate dietary salt.
- Cushing's syndrome and Cushing's disease are different disorders with similar symptoms: obesity, weakness, easily bruised skin, acne, and **hypertension** (high blood pressure.) Cushing's syndrome is usually caused by excessive production of glucocorticoid hormones in the adrenal gland. However, it can sometimes be caused by benign or cancerous tumors of the adrenal gland. Cushing's disease usually results from the overproduction of the adrenocorticotropic hormone in the pituitary gland, due to a benign tumor. Treatment for both disorders can include surgery, radiation therapy, **chemotherapy**, and blocking production of the glucocorticoid hormones with drugs.
- Less common endocrine disorders include acromegaly, gigantism, and hypogonadism. Acromegaly occurs in adults and gigantism in children. Both are caused by a pituitary tumor that spurs overproduction of growth hormone. Hypogonadism causes delayed sexual maturity in children and **infertility** in adults. It is caused by underproduction of follicle-stimulating hormone (FSH) in the pituitary gland.

KEY TERMS

Adipose tissue—Connective tissue in which fat is stored and that has the cells distended by droplets of fat.

Autoimmune—A term that refers to a condition in which antibodies or T cells attack the molecules, cells, or tissue of the body organ or system producing them.

Electrolyte—A nonmetallic electric conductor in which current is carried by ion movement.

Lactation—The secretion of milk by the mammary gland in the breasts.

Lymphocytes—Weak cells produced in the lymphoid tissue.

Menopause—The period when natural menstruation stops, usually between ages of 45 and 50.

Menstruation—The discharge of blood from the uterus that occurs in approximately monthly intervals in females, starting at puberty.

Endoscope

Definition

An endoscope is characterized by its often long, thin (sometimes flexible) lighted tube containing fiber-optical instrumentation attached to a viewing device through which one may closely observe, via the naked eye or an attached camera, the surface of a canal or hollow organ in the body.

Purpose

The endoscope is often used as a form of less invasive monitoring of the body instead of, or in conjunction with, surgery. A key aspect of the device is that it is not only capable of traversing the body to allow direct observation, but may also be equipped with endoscopic accessories that allow manipulation and diagnostic/therapeutic procedures to be performed much less invasively than more conventional surgical operations.

Endoscopic surgery minimizes **pain**, hospital stays, and recovery time, which is good for patients. Its use is also promoted by health insurance companies and hospital administrators inclined toward reduced costs as well as to offer the best treatment options technology can provide.

Description

The endoscope is a generalization of a broad variety of fiber-optical scopes used to elucidate diverse aspects of the body to medical practitioners for various purposes. Endoscopes come in two main categories: rigid and flexible. The rigid endoscope is designed with a rigid insertion tube and is preferred over flexible endoscopes when feasible because the rigidity allows use of optics that permit greater resolution and the absence of a visible lattice structure. However, it is more difficult to design and construct a rigid endoscope, which entails using lenses rather than fibers to transmit the image externally to the user or to a camera.

The fiber-optical endoscope can in general be viewed as a simple input/output device that utilizes an objective lens system along with a fiber relay and an ocular for magnification. The objective component is inserted directly into the body with a lighting constituent and focuses an image onto the two-dimensional surface of the array of fibers. These fibers, on the order of 10 micrometers, are bundled in groups of hundreds of thousands. Each pixel of a picture can be associated with a fiber in a one-to-one fashion of input light that is transferred from the objective end through the optical fiber relay, and magnified by the ocular to an output image on camera or seen with the naked eye. The elegant aspect is that these fibers may be twisted and flexed without damaging the image, which proves to be an integral element in many types of endoscopy. The optical layout discussed above has been simplified considerably; for spherical, chromatic, and other optical aberrations must be dealt with in order to manufacture a functional endoscope.

Not only must endoscopes be precisely organized optically, but great care must be taken to ensure their biocompatibility, since they come in close contact with extremely sensitive internal body surfaces. Accordingly, biocompatibility is of prime importance to the United States Food and Drug Administration (FDA), which considers endoscopes to be “short-term mucosal contacting, externally communicating devices and testing [for approval of use] should include, but is not limited to, mucosal irritation, sensitization, cytotoxicity, acute systemic toxicity, and short-term implantation.”

Endoscopes may be used to observe and biopsy as well as to perform actual surgeries through tiny incisions in appropriate sites. The latter generally involves use of miniature video cameras and minute surgical instrumentation, often electrosurgical equipment, forceps, or biopsy attachments.

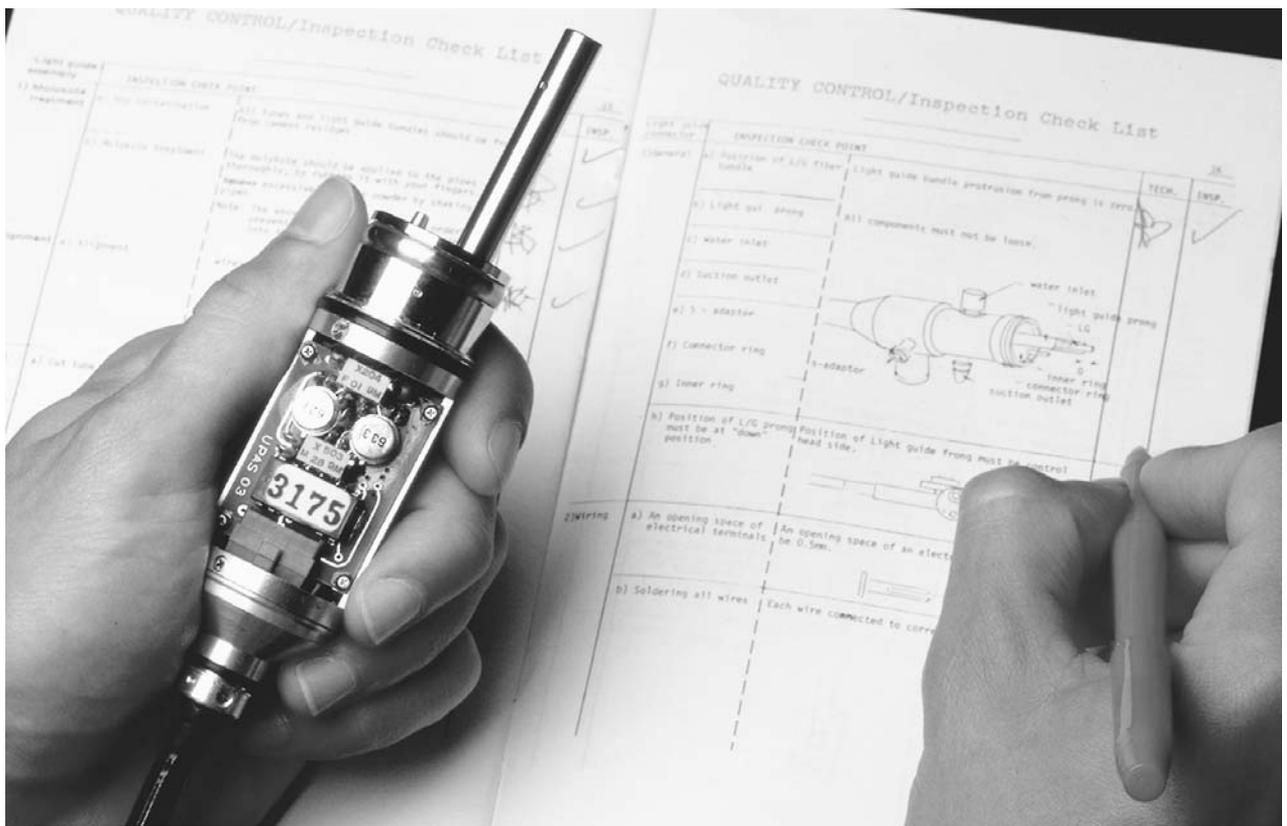

While fiberoptic technology utilizes extremely thin strands of glass or plastic to transmit light through repeated internal reflection along the optical fiber lengths

for image formation and visualization, other forms of endoscopy have surfaced. Electronic endoscopes, which do not require fiber optics (yet possess a field-of-view identical to the fiber-optic endoscope as well as similar controls depressible by finger-tip, i.e. air insufflation, suction, and water injection) are also on the market. These devices boast a mounted computer chip (in reality three chips for red, blue, and green light) on the tip. They are lower-maintenance due to the lack of fiber optics, and images from them can easily be sent to a television monitor for the entire operating room to view. Even more recently (as of July 2001), technology has permitted the development of high-speed 3D endoscopic measurements.

Forms of endoscopy

The abundance of instruments falling under the designation “endoscope” includes the following, with brief descriptions of each:

- **Amnioscope:** Used to examine the fetus through the cervical canal prior to membrane breakage.
- **Angioscope:** Used to examine the interior of **blood vessels**. The scope must thus be very long, slender (generally on the order of 0.5 mm), and flexible to accommodate navigation of minute spaces and dynamic curvature.
- **Arthroscope:** Used to examine intraarticular surfaces of joints. Arthroscopes are rigid and contain stacks of optical lenses while the eyepiece is generally attached to a video camera. Due to the frequency of knee injuries, the arthroscope is most often used to diagnose and help treat knee damage.
- **Bronchoscope:** Aids in exploring the interior of the bronchi, their branches, and tracheal mucosa (the windpipe tissue lining).
- **Choledochoscope:** Used to examine the bile duct (duct carrying bile from the **liver** to the **gallbladder** or from the gallbladder to the **small intestine**) during an open surgical procedure intraoperatively. Both rigid and flexible scopes are employed.
- **Colonoscope:** Used to examine the lower section of the bowel, the **large intestine**, i.e. the colon.
- **Culdoscope:** Used to examine the pelvis and its structures. The scope is normally introduced through a small incision in the posterior vaginal cul-de-sac.
- **Cystoscope:** Used to examine the urinary tract and bladder; it employs similar optics to the arthroscope, yet possesses a longer depth of insertion.
- **Cystourethroscope:** Used to examine the urethra, bladder, and distal ureter.

Endoscope machinery. (Photograph by Christopher Springmann. The Stock Market. Reproduced by permission.)

- **Encephaloscope:** Used to examine **brain** cavities.
- **Endoscopic retrograde cholangiopancreatography:** Used in diagnosis of pancreatic disease through injection of radio-opaque dye into biliary and pancreatic ducts while examining the duodenal area.
- **Enteroscope:** Used to examine the esophagus, small intestine, and **stomach**.
- **Esophagogastroduodenoscope:** Used to examine the esophagus, duodenum, and stomach.
- **Esophagoscope:** Used to examine the channel connecting the pharynx to the stomach.
- **Gastroscope:** Used to examine the stomach lumen.
- **Gonioscope:** Used to examine and help determine the configuration of the angle between the iris and cornea.
- **Hysteroscope:** Used to examine the passage of the uterine cervix and cavity.
- **Laparoscope:** Used to examine the peritoneal cavity through the anterior abdominal wall and is commonly rigid. This scope is the most common type used by the general surgeon.
- **Laryngoscope:** Used to examine the larynx (the sphincter at the entrance of the trachea).
- **Mediastinoscope:** Used to examine the mediastinum (mass of tissues and organs separating the **lungs**, i.e. the **heart**, esophagus, trachea, etc). Often used for visualization of lymph nodes and tumors in the superior mediastinum.
- **Nephroscope:** Used to examine the **kidneys**, i.e. the renal pelvis, calyces, and upper ureter. It is employed during open procedures intraoperatively.
- **Proctoscope:** Used to examine the rectum.
- **Resectoscope:** Used to perform resections of tissue as a part of a diagnostic or therapeutic procedure.
- **Rhinoscope:** Used to examine the nasal cavity.
- **Sigmoidoscope:** Used for direct examination of the sigmoid colon.
- **Thoracoscope:** Used to examine the pleural cavity through an intercostal space (space between adjacent ribs, filled by intercostals muscles).
- **Ureterscope:** Used to examine the ureter.

- Urethroscope: Used to examine the urethra.

Operation

Endoscopic procedures are sometimes performed under **local anesthesia**, especially with regard to upper gastrointestinal endoscopy. However, the majority of patients are sedated entirely. After the appropriate anesthetic has been administered, the physician inserts the endoscope in the anatomically relevant position and views the patient. The anesthesiologist, meanwhile, remains busy watching for **blood pressure** drops and reductions in oxygen saturation; this concern has resulted in a mandate that elderly, cardiovascularly risky, and anemic patients receive extra oxygen during the procedure.

Of paramount importance is the disinfection of used endoscopes. Endoscopic cross-infection is rare, but does occur. According to *Davidson's Principles and Practice of Medicine*, cross-infection has occurred in three ways:

- Transmission of pathogenic organisms from one patient to another, with salmonella the most frequent organism.
- Transmission of **infection**, such as hepatitis B, to staff by needle-stick injury.
- Introduction of opportunistic organisms that colonize the instruments in storage. These may cause serious infection in immunocompromised patients and can cause severe biliary or pancreatic sepsis if introduced during endoscopic retrograde cholangiopancreatography. To eliminate this possibility, many medical practices have become accustomed to disinfecting endoscopes again in the morning before the first patient arrives.

To prevent the above from occurring, health personnel must abide by strict procedures. Endoscopes should be submerged in detergent and water immediately upon removal from a patient. Valves and other removable components (including such endoscopic accessories as biopsy forceps) must be meticulously cleansed with cotton tips and a soft toothbrush, while channels must be washed. Disinfection by immersion in 2% glutaraldehyde (or 10% succine dealdehyde) for at least 20 minutes is strongly recommended since the scrubbing does not wipe out **bacteria** entirely. Also, medical personnel should wear gloves and masks as well as eye protection for positive hepatitis B or HIV patients. The general guideline for endoscopic disinfection is fivefold: cleaning (by mechanical scrubbing); disinfecting (by immersion in glutaraldehyde or some other high-level disinfectant); rinsing (using sterile water); drying (using forced air prior to storage); and storing (without recontaminating equipment, i.e. by hanging it vertically).

Maintenance

Proper care of endoscopes and endoscopic instrumentation should result in:

- enhanced life span of endoscopes and accessory instruments
- reduced repair and replacement costs
- low number of microorganisms, restricting infection possibilities

As indicated above, disinfection is a chief concern in the field of endoscopy. Proper disassembly, cleansing, rinsing, drying, storage, and reassembly of the equipment, all according to the manufacturer's instructions, can help it to remain viable and safe for a long while. Corrosion is a common cause of equipment failure; stainless steel can in fact spot and stain. According to the company Gamma Endoscopy, "when endoscopic instruments do spot or stain common causes are:

- very acid or alkaline pH detergents
- improperly dissolved detergent leaving residual powder
- high mineral content of the water used for cleaning, rinsing, or in the steam autoclave
- residual disinfection solution
- disinfection solutions with an acidic pH
- residual **blood**, organic matter, or irrigation solution (e.g. saline), especially if instruments are not completely disassembled or thoroughly cleaned
- chemical change resulting from prolonged exposure of dissimilar metals to electrolytic solutions (e.g. normal saline, disinfection solutions)
- scratches on instruments that allow corrosive agents to get below the passivation layer, a protective layer on the instrument surface

All moving parts should be lubricated before [reassembly] to prevent 'freezing' of stopcocks and forceps jaws. It is necessary to check the instruction manual to determine which parts to lubricate, and a water-based lubricant may be used when reassembling portions of instruments before sterilization/disinfection. Because sterilization/disinfection mediums may not penetrate tight-locking mechanisms, endoscopic instruments should not be reassembled before sterilization or disinfection."

If all other methods fail, endoscopes may be sent to instrument refurbishment companies that specialize in endoscopic repair.

KEY TERMS

Fiber optics—A technology using glass (or plastic) fibers to transmit data. A fiber optic cable is simply a bundle of these threads, each of which is capable of transmitting light wave data. Fiber optic cables can carry much more data in less space than conventional metal wires (i.e. they have greater bandwidth), are thinner and lighter, and are appropriate for transmission of digital data. It is possible to construct flexible fiber bundles that are spatially aligned for use in endoscopic procedures.

Health care team roles

Physicians perform endoscopic procedures while nurses and other medical personnel aid them. Health personnel prepare the equipment prior to examination and play a critical role in disinfecting it after the procedure has culminated. Endoscopes and accessories should be examined by health care staff for structural integrity, proper function, and cleanliness before use; during the exam; immediately following disinfection procedures; and prior to disinfection/sterilization. It is also recommended that endoscopes and accessories be thoroughly tested before initial use and used in accordance with the manufacturer's manual.

Training

Training varies from procedure to procedure among the widely varying types of endoscopy; however, disinfection training is essentially similar, except that there are major differences in cleansing between rigid, flexible (the most difficult), and electronic endoscopes.

Endotracheal tube management

Definition

Endotracheal tube management consists of ensuring a patent (open and unblocked) airway, suctioning pulmonary and oral secretions, and providing frequent oral and/or nasal care.

Purpose

The endotracheal tube is the most common artificial airway used for short-term **airway management** or mechanical ventilation. The tube may be inserted either orally or nasally. The patient with a endotracheal tube must be closely monitored to ensure that the tube remains patent, that skin breakdown does not occur from the tube, and that **infection** is prevented.

Precautions

If the patient is restless or agitated, any activities that involve loosening the straps that hold the endotracheal tube in place should be rescheduled for a time when the patient is calm or after a sedative has been given. Otherwise, the tube may be inadvertently removed and the airway lost.

Description

A primary portion of endotracheal tube management is suctioning down the tube every two hours or as needed. This is a sterile procedure. The color and amount of any sputum return should be noted since the endotracheal tube provides a direct connection to the **lungs**, making these patients highly susceptible to infection. The oral cavity should also be suctioned as these patients often have difficulty swallowing saliva.

The patient must also be monitored for skin breakdown in either the oral or nasal cavity (depending on where the tube is inserted). Thorough oral care should be provided every eight hours and as needed. If the patient

has a bite block to prevent them from biting the tube, it must be removed and cleaned or replaced every eight hours. The tube should be repositioned so that it is not continuously exerting pressure in the same area. If the tube is taped to the patient's face, the tape must be removed and replaced on the opposite side of the face at least once per day and as needed.

The endotracheal tube has a cuff that is inflated with air to hold the tube in place in the trachea. The amount of air in the cuff should be checked every eight hours to ensure that the cuff is not exerting too much pressure on the trachea walls. This is often done by the respiratory therapist, but may also be done by the nurse.

Preparation

Any needed supplies for endotracheal tube care should be at the bedside prior to beginning the procedure. This includes a sterile suction kit, a bottle of sterile 0.9% sodium chloride, sterile gloves, a clean bite block if necessary, and tape already torn into appropriately-sized pieces. It is recommended that another health care professional firmly hold the endotracheal tube in place during any activity that requires loosening the straps that hold the tube. The patient should also be preoxygenated with 100% oxygen prior to suctioning.

Aftercare

All waste should be properly disposed of, either in the garbage or a biohazard container. The respiratory status of the patient should be reassessed. The insertion point (in centimeters) of the endotracheal tube should be confirmed to be the same as prior to the procedure, unless the purpose of the procedure was to change the depth of the tube.

Complications

The greatest risk of manipulating the endotracheal tube is that it may be inadvertently removed, causing the patient to experience respiratory distress.

Results

The anticipated outcomes of endotracheal tube management include a continuously patent airway, control of oral and pulmonary secretions, and prevention of infection.

Health care team roles

The nurse and respiratory therapist are equally responsible for endotracheal tube management. Both per-

KEY TERMS

Bite block—Plastic device inserted into the patient's mouth to prevent him/her from biting on the endotracheal tube.

Endotracheal tube—Flexible tube inserted into the trachea via either the oral or nasal cavity for the purpose of providing an airway and supplemental oxygen, as well as providing access for suctioning.

form sterile suctioning and both are responsible for assessing respiratory status. However, it is usually the nurse who repositions the tube and provides oral care.

Endurance testing

Definition

Endurance testing involves determining the amount of time a person can maintain an activity or perform a task or activity of daily living before becoming fatigued and needing to stop. The level of activity used to test endurance can be minimal to maximal.

Purpose

Endurance testing is often used to assess a person's cardiovascular fitness to determine if cardiovascular disease is present and to evaluate the patient before embarking on a physical fitness program. The goal of **exercise** testing is to produce a sufficient level of exercise **stress** without too much strain on an individual. Exercise tests measure **heart** rate, **blood pressure**, respiratory rate, and breathlessness. The patient also reports on a rating of perceived exertion (RPE), which is a 15-point scale that

grades exertion from extremely light to extremely hard. Clinicians make note of any discomfort or **pain**.

Maximal exercise testing can be used to determine the greatest amount of activity a person can endure and how rigorous the activity can be. Submaximal testing determines the best level for a person to safely engage in during a physical activity program.

Other types of endurance testing are important in determining how independent an individual can be in performing work activities. Such testing is particularly important in work hardening programs. A person who is injured on the job may be referred to a rehabilitation therapist for work hardening treatment. The therapist ascertains whether the individual can perform job tasks, and if not, designs a relevant rehabilitation program. It is often a challenge to accurately duplicate work environments.

Precautions

A person with poor balance or coordination should not undergo endurance testing that involves movements that could cause dizziness or fainting. Persons with cardiac disease, **hypertension**, or diabetes could experience distress during endurance testing and must be closely monitored.

Description

Clients are generally referred to a therapist by a physician treating them for a disease or disability. The physician often includes specific instructions. Endurance testing can be conducted in a variety of ways. A device such as a dynamometer is used to measure strength, and physical endurance can subsequently be charted. A therapist can determine endurance by instructing a client to perform a particular task for a specific length of time or perform the task for a specific number of repetitions. A therapist also can instruct a client to perform a task until becoming fatigued.

Exercise testing protocols

TREADMILL TEST. The treadmill is one of most commonly used endurance tests. Although the Bruce Treadmill Test protocol has been the most widely used, its results have been considered to sometimes overestimate a person's exercise capacity. Although it is best suited for younger and active patients, the Bruce protocol was designed to diagnose cardiovascular disease. During treadmill tests, individuals walk on various inclines at various speeds for increasing lengths of time.

BICYCLE ERGOMETRY. Bicycle tests are a common alternative to treadmill testing. A bicycle ergometer

measures the individual's workload and increases workload in increments for eight to 12 minutes. For patients with lower limb limitations who cannot be tested on a treadmill or bicycle, the upper limb ergometer, a modified bicycle with hand-powered pedals, is used. For wheelchair-bound individuals, some clinicians have fabricated wheelchair ergometers. Such testing is not widely used because of lack of equipment.

TWELVE-MINUTE RUN TEST. This test consists of various run-walk tests. It is typically used to evaluate cardiopulmonary fitness for functional individuals. The patient is asked to cover the longest distance possible in 12 minutes, preferably by running, but by walking if needed.

TWENTY-METER SHUTTLE TEST. This test assesses maximal aerobic capacity and was designed for children, adults, and athletes. The subject runs between two lines spaced 20 meters apart. The examiner increases the pace at which the subject is required to run back and forth. The highest speed reached is the maximal aerobic speed.

ONE-MILE TRACK WALK TEST. This test was designed for many age groups and fitness levels. The examiner records the time an individual can walk one mile.

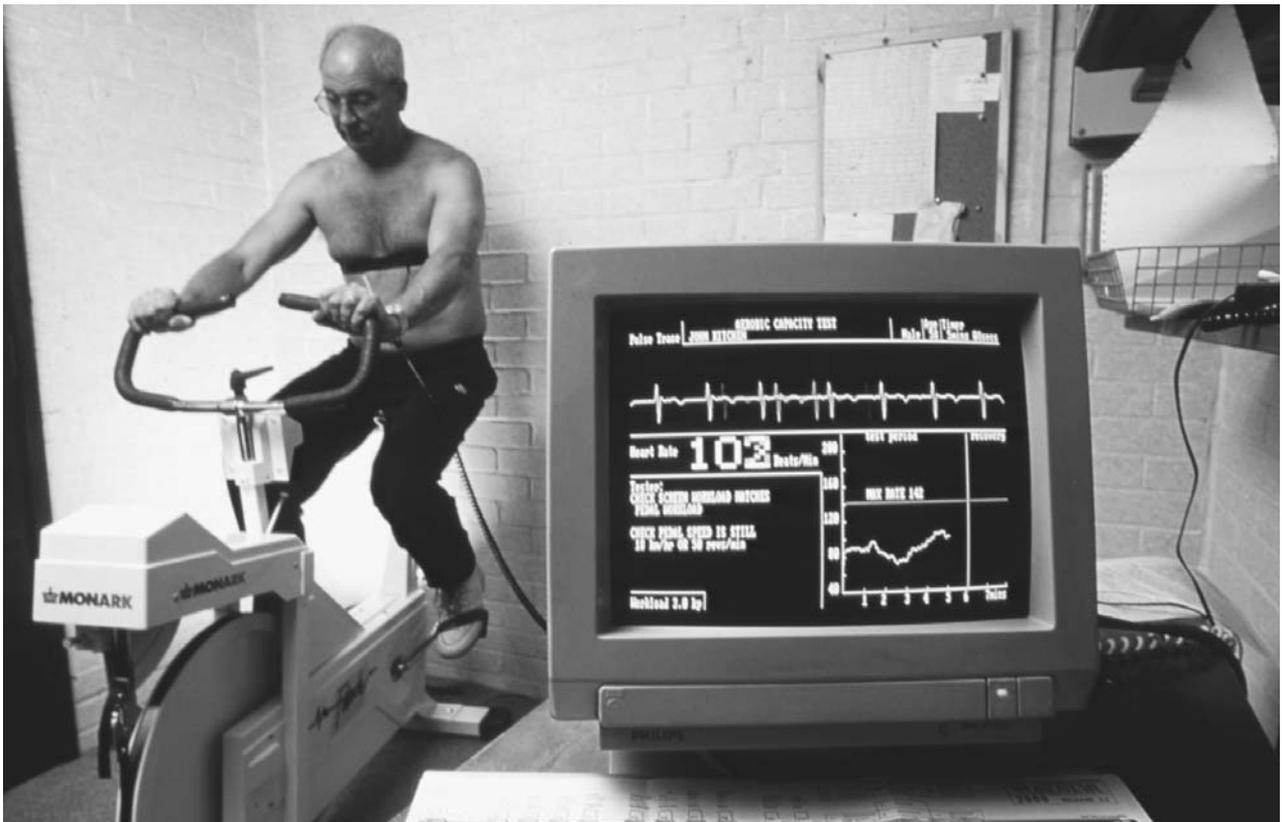

SELF-PACED WALKING TEST. This test was developed for the elderly and for those with low fitness levels. It involves walking at three speeds down a hallway while speed, time, stride frequency, and heart rate are measured. This protocol evaluates a person's walking efficiency and cardiopulmonary capacity. It does not actually test endurance but can provide guidelines for activities of daily living.

Many people are affected by low endurance or loss of stamina for a variety of reasons. After age 50, muscle strength and endurance begin to decline. People with physical disabilities also typically have endurance problems.

A typical treatment plan to build endurance includes such aerobic exercise as walking, jogging, swimming, and bicycling. Aerobic exercise improves cardiovascular health, which also increases endurance. Specific activity goals should be set for the client.

In work-hardening programs, therapists use several assessment devices to determine a person's capacity to return to work. The Baltimore Therapeutic Equipment (BTE) work simulator allows users to replicate most upper-limb motions and tasks involved in many job activities. For example, a client may be asked to repetitively lift a box weighing 40 pounds (18 kg) at any pace until becoming tired.

How well the simulator measures endurance has only been analyzed recently. Clients were found to have

A computer monitors this man's cardiorespiratory system performance as he exerts himself on an exercise bike.
(Photograph by James King-Holmes. Science Source/Photo Researchers. Reproduced by permission.)

an easier time completing tasks in the simulated environment than in the workplace. One occupational therapist who performs work-hardening programs for workers injured on off-shore oil rigs found that employees were able to perform the strenuous work in the air-conditioned clinical setting but did not last long after getting back to the humid conditions of the workplace. To improve the program, the therapist built a facility and duplicated the humid conditions, then tested clients for a full work day.

Preparation

A thorough medical history is taken and all surgeries documented prior to administering an exercise test. Practitioners should inquire about current medications and any physical or cognitive limitations the individual may have. This alerts medical professionals to any underlying problems or possible complications. Other issues that should be considered when determining exercise testing protocol are the person's age, weight, nutritional status, mobility, assistive device use, and work environment.

To conduct an aerobic test, clinicians should ensure that the risk of injury is minimized. The client should be instructed how to properly perform exercises to avoid injury. Practitioners should keep in mind that an exercise test can be too stressful depending on the person's condition. Any medical professional involved in administering exercise testing should be certified in **cardiopulmonary resuscitation (CPR)**.

Proper monitoring depends on individual circumstances. Heart rate is typically measured before, during, and after any testing procedure. The 12-lead electrocardiogram (EKG) is monitored before the test and periodically throughout the test. Following the test, the EKG and **blood** pressure are measured again, and every one to two minutes subsequently until levels return to baseline.

Aftercare

Following completion of a treatment program for building strength and endurance, a client should be educated on a continuing treatment program to be done at home. Strength and endurance will wane if activity is not maintained.

Complications

Occupational and physical therapists in return-to-work programs must take into consideration that work simulation techniques don't entirely duplicate working conditions.

The type of activity performed may also affect endurance. A person may show less endurance when performing an activity that he or she finds unpleasant or perceives as useless. The most effective intervention and treatment programs are associated with clients performing tasks they enjoy or that reflect the individual's self-worth.

Health care team roles

Collaboration among all caregivers plays a big part in any kind of rehabilitation intervention. Referring physicians should communicate with the therapist about the client and what treatment is recommended. Social workers or mental health professionals involved with the client should also be apprised of interventions, because emotional problems could affect test outcomes.

Enema administration

Definition

The term enema is used to refer to the process of instilling fluid through the anal sphincter into the rectum and lower intestine for a therapeutic purpose. An enema administration is performed using a flexible plastic rectal tube with several large holes in the tip. This is connected to the tubing from a solution bag or container. An enema can also be performed using a prepackaged solution that comes in a soft plastic bottle with a pre-lubricated rectal tip attached. **Enema** solutions are prepared using plain tap water or saline, soapsuds solutions, oil solutions, or various medication solutions.

Purpose

The most common purpose for administering an enema is to stimulate peristalsis (involuntary contraction) and to evacuate stool from the rectum. A tap water or soapsuds enema dilates the bowel, stimulates peristalsis, and lubricates the stool to encourage a bowel movement. These types of enemas are instilled and held for five to 10 minutes, as tolerated. They are used to treat constipation, to cleanse the bowel before a bowel exam, and to cleanse the bowel before bowel surgery. Another type of enema, the oil retention enema, is prepared in a smaller volume and is retained in the bowel for 30-60 minutes. The purpose of the oil retention enema is to soften the hardened stool and allow normal elimination. Enemas are also used to deliver medication directly onto the rectal mucous membranes to be absorbed into the bloodstream. Steroid enema solutions can be administered to alleviate bowel inflammation in patients with ulcerative colitis.

Antibiotic enema solutions can be administered to treat localized bacterial infections. Medicated hypertonic enema solutions can be used to pull excessive potassium or ammonia from the bloodstream through the rectal wall. These substances are then eliminated with the stool.

Precautions

Enemas should not be used as a first-line treatment for constipation. Frequent use of enemas can lead to fluid overload, bowel irritation, and loss of muscle tone of the bowel and anal sphincter. Never deliver more than three consecutive enemas to treat a patient. A patient with **diarrhea** may not be able to hold an enema. Enema administration must be used with caution in cardiac patients who have arrhythmias or have had a recent **myocardial infarction**. Insertion of the enema tube and solution can stimulate the vagus nerve which may trigger an arrhythmia such as bradycardia. Enemas should not be given to patients with undiagnosed abdominal **pain** because the peristalsis of the bowel can cause an inflamed appendix to rupture. Enemas should be used cautiously in patients who have had recent surgery on the rectum, bowel, or prostate gland. If the patient has rectal bleeding or prolapse of rectal tissue from the rectal opening, cancel the enema and consult with the physician before proceeding. Do not force the enema catheter into the rectum against resistance. This can cause trauma to the rectal tissue. Use only mild castile soap for soapsuds enemas because other soap preparations are too harsh and irritate the rectal tissue.

Description

To administer an enema solution, the clinician should have the patient lie down on the left side, knees bent. Lift the upper buttock so that the rectal opening can be visualized. Place the lubricated tip of the enema catheter at the anal opening, and gently advance the catheter through the anal sphincter into the rectum toward the umbilicus (navel), 3–4 in (7.5–10 cm) for an adult. Insert the tubing 2 in (5 cm) for a child less than six years and 1 in (2.5 cm) for an infant. After alerting the patient, open the enema tubing to allow the solution to flow or squeeze premixed enema solutions slowly into the rectum. If the patient complains of cramping, slow or stop the enema flow and have the patient breathe slowly through the mouth to encourage relaxation. When giving fluid through an enema bag, start with the bag suspended from an IV pole at the patient's hip level. As the tubing is opened, slowly raise the IV pole to promote fluid flow until the bag is 12 inches (30.5 cm) above the hip for an adult. Continue to hold the rectal tube in place throughout the procedure or it will be expelled from the rectum.

If the fluid will not flow in, gently rotate the tubing within the rectum to clear the holes of the tubing from the wall of the bowel or the impacted stool that may be occluding the flow. If ordered to give a high enema, slowly raise the bag no more than 18 inches (46 cm) above the adult patient's hip (12 inches (30.5 cm) above a child's hip and six inches (15 cm) above an infant's hip). This will increase the water pressure to deliver the fluid higher into the bowel. When all of the solution has been administered, clamp the tubing, remove the enema catheter, and release the buttock.

Preparation

Before administering an enema, ensure the patient's privacy by closing the room door. The patient should be encouraged to empty both bladder and bowels before the procedure. Have the patient undress completely from the waist down. Position the patient on the bed on his or her left side with the top knee bent and pulled slightly upward toward the chin. Place a waterproof pad under the patient's hips to protect the bedding and drape a sheet over the patient covering the entire body except the buttocks. Place a bedpan and toilet paper within quick access. Explain the procedure to the patient. Emphasize the importance of breathing slowly through the mouth to encourage relaxation of the rectal sphincter and to avoid oppositional pressure. Let the patient know that while he or she may feel the urge to defecate, most enemas need time to work and he or she should try to hold the fluid for at least five to 10 minutes after instillation (30–60 minutes for retention enemas and longer for some medicated enema solutions). Check the medication label if it is a medicated solution to avoid medication errors. Be sure it is the right medicine, the right dose (strength), the right time, the right person, and the right method. Verify the expiration date on the label. Do not use outdated medicine.

Wash hands thoroughly and put on gloves. To prepare for premixed disposable enema instillations, follow the directions on the package. Most premixed disposable enemas come with the tip already lubricated. Shake the solution bottle. Remove the cap from the tip and expel excess air from the apparatus before use. To prepare solutions to be administered using an enema bag, heat the solution to 105°F. Adult solutions are generally 750–1000cc of solution for a non-retention enema and 150–200cc of fluid for a retention enema. Children's solutions are 250–500cc of solution for a non-retention enema and 75–150cc of solution for a retention enema. Infants' solutions are 150–250cc of solution for a non-retention enema. If preparing a medicated solution, follow the physician's orders. Select a rectal tube appropri-

KEY TERMS

Anal sphincter—A ring-shaped muscle located at the bottom of the anal canal that maintains constriction to keep the anal canal closed to the outside of the body. The anal sphincter relaxes and opens during defecation.

Defecation—The process of eliminating stool from the body.

Hypertonic—A solution that has a higher osmotic pressure than a comparative solution.

ate to the patient's size (#14–30 French rectal tube for an adult, #12–18 for a child, #12 for an infant) and connect it to the tubing from the bag. Fill the enema bag with the solution and open the tubing. Run the solution through the tubing to the tip of the rectal tube to clear air from the line. Clamp the tubing and adjust the bag on an IV pole so that it will hang at the patient's hipline. Put water-soluble lubricant on a clean 4x4 gauze pad and roll the tip of the rectal tube in the lubricant. Coat all of the rectal tube that will be inserted into the rectum to avoid traumatizing the rectal tissue [3–4 inches (7.3–10 cm) for an adult, 2–3 inches (5–7.5 cm) for a child, 1–1 1/2 inches (2.5–4 cm) for an infant].

Aftercare

After administering an enema, remain near the patient in case he or she needs assistance with the bedpan or to get to the bathroom. Medicated enemas that are expelled immediately may need to be repeated, using fresh solution. Follow the directions or consult with the physician. To assist the patient with retaining an enema after instillation, apply gentle pressure to the rectal opening using a 4x4 gauze pad or squeeze the buttocks together. Tuck a 4x4 gauze pad between the buttocks to collect seepage. This maneuver may help the patient feel more secure. Cover the patient after the procedure and instruct him or her to lie still for five to 10 minutes or longer if a medicated solution or retention enema is administered. This will allow time for the solution to take effect. Wash items that might be reused, such as non-disposable enema bags and tubing, in warm soapy water. Rinse and allow them to air dry. Place disposable items, gauze pads, and gloves in a trash bag, then seal and discard it. Assist the patient to the bathroom or with the bedpan after he or she has held the enema solution for the correct amount of time. Hands should be washed after performing the procedure. Note the results of the enema.

Complications

Complications of enema administration are not common but can include irritation, swelling, redness, bleeding, or prolapse of the rectal tissue. If any of these symptoms are apparent, or if the patient complains of pain or burning during enema instillation, stop the procedure and notify the physician.

Results

Most enemas, because of their liquid state, are absorbed quickly and work rapidly. Retention enemas will take 30–60 minutes to achieve full therapeutic effect. Cleansing enemas usually work within 10–15 minutes to cleanse the bowel and relieve constipation. They may, however, need to be repeated one or two times to thoroughly cleanse the bowel in preparation for a bowel exam or bowel surgery. Medicated enemas, such as antibiotic or anti-inflammatory solutions, may need to be repeated daily over a period of a week or more for full therapeutic effect.

Health care team roles

Enemas are administered by a licensed nurse (R.N. or L.P.N.) in the health care setting. Unlicensed staff, however, may be trained to administer non-medicated enemas under the direction of a **registered nurse** in some settings. An alert and cooperative patient may also be allowed to self-administer non-medicated enemas in some health care settings under the direction of a nurse. The nurse should, however, assess the patient and the effectiveness of the enema. The patient, or members of the patient's family, can be taught to administer an enema in the home setting.

Enemas

Definition

An enema is a procedure wherein liquid is infused into the rectum via a tube either for treatment or to diagnose a condition.

Purpose

Enemas may be given for the following purposes:

- To remove feces when an individual is constipated or impacted.
- To infuse oil into the rectum to help soften feces when the person is constipated or impacted.
- To remove feces and cleanse the rectum in preparation for an examination.
- To remove feces prior to a surgical procedure to prevent contamination of the surgical area.
- To administer drugs such as corticosteroids dissolved in water to stop inflammation and bleeding caused by ulcerative colitis.
- To introduce barium sulfate, a metallic chemical substance that outlines the intestines for diagnostic purposes.
- To act as a carminative, or remove flatus, or gas, from the intestines.
- To irrigate the colon or **large intestine**, thus stimulating peristalsis (sometimes called a colonic irrigation).

Precautions

The rectal tube used for infusion of the enema solution should be smooth and flexible to decrease the possibility of damage to the mucous membrane that lines the rectum. Tap water is commonly used for adults but should not be used for infants because of the danger of electrolyte imbalance. (Electrolytes are substances that conduct electric current in the body fluids. Proper bal-

ance is essential for sustaining life.) The colon absorbs water, and repeated tap water enemas can cause cardiovascular overload and electrolyte imbalance. Similarly, repeated saline enemas can cause increased absorption of fluid and electrolytes into the bloodstream, resulting in overload. Individuals receiving frequent enemas should be observed for overload symptoms that include dizziness, sweating, or vomiting.

Soap suds and saline used for cleansing enemas can cause irritation of the lining of the bowel, with repeated use or a solution that is too strong. Only white soap should be used; the bar should not have been previously used, to prevent infusing undesirable organisms into the individual receiving the enema. Common household detergents are considered too strong for the rectum and bowel. The commercially prepared castile soap is preferred, and should be used in concentration no greater than 5 cc soap to 1,000 cc of water. Enemas should not be administered to individuals who have recently had colon or rectal surgery, a **heart** attack, or who complain of undiagnosed abdominal **pain** (which can be a ruptured appendix), or suffer from an irregular heartbeat.

Description

Traditionally, soap suds enemas (SSEs) have been used, as the soap caused some irritation of the bowel wall. This irritation, paired with distention caused by the volume of fluid instilled, causes bowel contractions and stimulation that usually will lead to expelling feces from the rectum. When the enema is administered, the individual is usually on the left side-lying position, which places the sigmoid colon (lower portion of bowel) below the rectum and facilitates infusion of fluid. The length of time it takes to administer an enema depends on the amount of fluid to be infused. The amount of fluid administered will vary depending on the age and size of the person receiving the enema; however, general guidelines would be:

- Infant: 250 cc (approximately one cup) or less.
- Toddler and preschooler: 500 ml (two cups) or less.
- School-aged child: 500 to 1,000 cc (between a pint and a quart).
- Adult: 750 to 1,000 cc (three-quarters to a full quart).
- Colonic irrigations or carminative enemas are normally administered only to adults and usually less than 200 cc (three-quarters of a cup) of fluid is used. This is instilled and allowed to flow back out five to six times.

KEY TERMS

Carminative—An agent that will remove gases from the gastrointestinal tract.

Electrolyte—A substance that conducts electric current within the body and is essential for sustaining life.

Intestine—Also called the bowels. Divided into large and small intestine, they extend from the stomach to the anus, where waste products exit the body. The small intestine is about 20 ft (6 m) long and the large intestine, about 5 ft (1.5 m) long.

Rectum—The portion of bowel just before the anus. The prefix *recto* is used with a variety of words in relation to conditions that affect the rectum.

Some health care workers differentiate between high and low enemas. A high enema, given to cleanse as much of the large bowel as possible, is usually administered at higher pressure and with larger volume (1,000 cc), and the individual changes position several times in order for the fluid to flow up into the bowel. A low enema, intended to cleanse only the lower bowel, is administered at lower pressure, using about 500 cc of fluid.

Oil retention enemas serve to lubricate the rectum and lower bowel, and soften the stool. For adults, about 150 to 200 cc (approximately two-thirds, to three-quarters of a cup) of oil is instilled, while in small children, 75 to 150 cc (one-third to two-thirds of a cup) of oil is considered adequate. Salad oil or liquid petrolatum are commonly used at a temperature of 91°F (32.8°C). There are also commercially prepared oil retention enemas. The oil is usually retained for one to three hours before it is expelled.

The rectal tube used for infusion of the solution, usually made of rubber or plastic, has two or more openings at the end through which the solution can flow into the bowel. The distance to which the tube must be inserted is dependent upon the age and size of the patient. For adults, insertion is usually 3–4 in (7.5–10 cm); for children, approximately 2–3 in (5–7.5 cm); and for infants, only 1–1.5 in (2.5–3.75 cm). The rectal tube is lubricated before insertion with a water-soluble lubricant to ease insertion and decrease irritation to the rectal tissues.

The higher the container of solution is placed, the greater the force with which the fluid flows into the patient. Routinely, the container should be no higher than

12 in (30 cm) above the level of the bed; for a high cleansing enema, the container may be 12–18 in (30–45 cm) above the bed level, because the fluid is to be instilled higher into the bowel.

Preparation

The solution used in the procedure is measured, mixed, and warmed before administration of the enema.

Aftercare

If necessary, a stool specimen will be collected for diagnostic evaluation. If the enema was given to alleviate constipation, good nutritional education is necessary to prevent the recurrence of constipation in the future. The recommendation is normally with a high fiber diet (between five and six servings per day of whole grain foods) and adequate fluid intake (between seven and eight glasses of water per day). A study reported in the *Canadian Nurse* sought to evaluate whether the use of **laxatives**, enemas, and suppositories could be reduced by using more bran in the diet. It was found that the subjects given bran with their breakfasts each day reduced use of laxatives, enemas, and suppositories by nearly 50%. Regular **exercise** and going to the bathroom when necessary will also help. If constipation is a chronic problem, medical help should be consulted to determine if there is an underlying disorder.

Complications

Habitual use of enemas as a means to combat constipation can make the problem even more severe when their use is discontinued. Enemas should be used only as a last resort for treatment of constipation and with a doctor's recommendation. The use of enemas can cause an irregular heartbeat in some patients.

Results

Optimum results are thorough and appropriate cleansing of the lower bowel when necessary, and the introduction of proper diet and exercise to prevent chronic constipation.

Health care team roles

Healthcare providers will typically become involved in the treatment of constipation or fecal impaction as a side effect of other, debilitating illnesses.

- Primary care physicians (PCPs) will commonly order enemas for the relief of constipation, or for patients at risk for fecal impaction, to prevent more serious com-

plications such as intestinal obstruction, or as a means of cleansing the bowel prior to tests or surgery.

- Registered nurses (RNs) or licensed practical nurses (LPNs) will often be responsible for either administering the enema or assuring that the patient knows how to administer it to themselves. Nurses will monitor the results of the enema to see if it has been effective in cleansing the lower bowel. Nursing staff involved in the administration of enemas need to be aware that this is an intrusive procedure that can be upsetting to patients. Professionalism and understanding are essential. Nurses should educate the patient about the procedure and should also be involved in teaching patients about the importance of diet and exercise in the prevention of chronic constipation.

Enterostomy

Definition

An enterostomy is a procedure in which the surgeon makes a passage into the patient's **small intestine** through an incision in the abdomen, leaving an opening to allow for drainage or to insert a feeding tube. The opening is called a *stoma* from the Greek word meaning mouth. Enterostomies may be either temporary or permanent. They are classified according to the part of the intestine that is used to create the stoma. If the ileum, which is the lowest of the three sections of the small intestine, is used to make the stoma, the operation is called an ileostomy. If the jejunum, which is the middle section of the small intestine, is used, the operation is

called a jejunostomy. Some people use the word "ostomy" as a word that covers all types of enterostomies.

Purpose

Enterostomies are performed to create a new opening for the passage of fecal matter when normal intestinal functioning is interrupted or when diseases of the intestines cannot be treated by medications or less radical surgery. Some situations that may require enterostomies include:

- Healing of inflamed bowel segments. Enterostomies performed for this reason are usually temporary.
- Emergency treatment of gunshot or other penetrating **wounds** of the abdomen. An enterostomy may be required to prevent the contents of the intestine from causing a serious inflammation of the inside of the abdominal cavity (peritonitis). These enterostomies are also usually temporary.
- Placement of a tube for enteral feeding. Enteral feeding is a method for conveying nutritional solutions directly into the **stomach** or jejunum through a tube. Tube enterostomies may be long-term, but are not permanent.
- Removal of diseased sections of the intestines. Ileostomies performed for this reason are permanent. The most common disorders requiring permanent ileostomy are **Crohn's disease**, familial polyposis, and ulcerative colitis. Familial polyposis and ulcerative colitis are serious health risks because they can develop into **cancer**.
- Treatment of advanced cancer or other causes of intestinal obstruction.

Precautions

Enterostomies are usually performed only as emergency treatments for traumatic injuries in the abdomen or as final measures for serious disorders of the intestines. Most patients do not refuse the procedure once the need for it is explained. A small minority, however, refuse enterostomies because of strong psychological reactions to personal disfigurement and the need to relearn bowel habits.

Description

Ileostomy

Ileostomies represent about 25% of enterostomies. They are performed after the surgeon removes a diseased colon and sometimes the rectum as well. The most com-

mon ileostomy is called a Brooke ileostomy after the English surgeon who developed it. In a Brooke ileostomy, the surgeon makes the stoma in the lower right section of the abdomen. The ileum is pulled through an opening (incision) in the muscle layer. The surgeon then turns the cut end of the intestine inside out and sews it to the edges of the hole. He or she then positions an appliance for collecting the fecal material. The appliance consists of a plastic bag that fits over the stoma and lies flat against the abdomen. The patient is taught to drain the bag from time to time during the day. The bag needs to be emptied frequently because the digested food contains large amounts of water. Shortly after the operation, the ileostomy produces one to two quarts of fluid per day. However, after a month or two of adjustment, the volume decreases to one or two pints per day. Nearly 30% of patients receiving the Brooke ileostomy for inflammatory bowel disease develop at least a limited **infection**. Another 20%–25% require at least a minor surgical revision.

KOCK POUCH (CONTINENT ILEOSTOMY). The Kock pouch is a variation of the basic ileostomy and is named for its Swedish inventor. In the Kock technique the surgeon forms a pouch inside the abdominal cavity behind the stoma to collect fecal material. The stoma is shaped into a valve to prevent fluid from leaking onto the patient's abdomen. The patient then empties the pouch several times daily by inserting a tube (catheter) through the valve. The Kock technique is sometimes called a continent ileostomy because the fluid is contained inside the abdomen. It is successful in 70%–90% of cases. Patients with chronic ulcerative colitis usually have all of the diseased tissue removed during the Kock method. The primary benefit of the Kock approach compared with the Brooke method is that discharge is captured without an external appliance. Unfortunately, the complication rate following the Kock technique is much higher than with the Brooke method. Patients receiving both techniques have problems with perineal wound healing in about one-third of cases.

Jejunostomy

A jejunostomy is similar to an ileostomy except that the stoma is placed in the second section of the small intestine rather than the third. Jejunostomies are performed less frequently than ileostomies and are almost always temporary procedures.

Tube enterostomies

Tube enterostomies are procedures in which the surgeon makes a stoma into either the stomach itself or the jejunum in order to insert a tube for liquid nutrients. Tube

enterostomies are performed in patients who need tube feeding for longer than six weeks, or who have had recent mouth or nose surgery. Jejunostomies require a continuous infusion of nutrients whereas tube feeding through the stomach can be given in large single feedings (boluses). As long as the patient's intestinal tract can function, tube feedings are considered preferable to intravenous feeding because it is safer and helps keep the patient's digestive tract functioning.

Preparation

Preoperative preparation includes both **patient education** and physical preparation.

Patient education

If the patient requires a permanent ileostomy, the doctor will explain what will happen during the procedure and why it is necessary. Most patients are willing to accept an ostomy as an alternative to the chronic **pain** and **diarrhea** of ulcerative colitis or the risk of cancer from other intestinal disorders. The patient also can meet with an enterostomal therapist (ET) or a member of the United Ostomy Association, which is a support group for people with ostomies.

Medical preparation

The patient is prepared for surgery with an evaluation of his or her nutritional status, possible need for **blood** transfusions, and **antibiotics** if necessary. If the patient does not have an intestinal obstruction or severe inflammation, he or she may be given a large quantity of a polyethylene glycol (PEG) solution to cleanse the intestines before surgery.

Aftercare

Aftercare of an enterostomy is both psychological and medical.

Patient education

Ileostomy patients must learn to watch their fluid and salt intake. They are at greater risk of becoming dehydrated in hot weather, from **exercise**, or from diarrhea. In some cases they may need extra bananas or orange juice in the diet to keep up the level of potassium in the blood. Poorly digested foods, such as lightly cooked vegetables, certain types of fruit, nuts, and corn can lead to stromal obstruction if the food is not thoroughly chewed.

Patient education includes social concerns as well as physical self care. Many ileostomy patients are worried

about the effects of the operation on their close relationships and employment. If the patient has not seen an ET before the operation, the aftercare period is a good time to find out about self-help and support groups. The ET can also evaluate the patient's emotional reactions to the ostomy.

In some instances the appliance is poorly fitted. This can lead to problems with the skin near the stoma. Certain foods, such as onions and beans, can produce bad odors in the ileostomy bag. The odor primarily develops from **bacteria** working on these digested foods. Frequent bag emptying and the addition of chlorine or sodium benzoate tablets to the bag can significantly reduce odor.

Medical aftercare

If the enterostomy is temporary, aftercare consists of the usual monitoring of surgical wounds for infection or bleeding. If it is a permanent ileostomy, aftercare includes teaching the patient to use the appliance or empty the Kock pouch, to keep the stoma clean, and to readjust bathroom habits. Recovery takes a significant amount of time because major surgery is a shock to the system and the intestines take several days to resume normal functioning. The patient's fluid intake and output will be checked frequently to minimize the risk of **dehydration**.

Complications

Enterostomies are not considered high-risk operations by themselves. Possible complications include:

- Skin irritation caused by leakage of digestive fluids onto the skin around the stoma is the most common complication.
- Diarrhea, both severe and chronic, needs to be brought to the attention of the physician.
- Gallstones or stones in the urinary tract may develop.
- Inflammation of the ileum can occur.
- Odors from an ileostomy can often be prevented by a change in diet.
- Intestinal obstruction may develop.
- Prolapse can occur in which a section of the bowel pushes out of the body.
- Leakage from the ileostomy pouch can occur if the stoma is not at least 2 inches above the level of the skin.
- Variceal bleeding—bleeding from **blood vessels** around the stoma—can occur in patients with portal **hypertension** and other conditions.

KEY TERMS

Crohn's disease—A disease of the intestines that causes inflammation leading to scarring, thickening of the walls of the intestine, and eventual obstruction.

Duodenum—The first of the three segments of the small intestine. The duodenum connects the stomach and the jejunum.

Enteral nutrition—A technique for feeding patients with liquid formulas conveyed directly into the stomach or jejunum through tubes.

Enterostomal therapist (ET)—A specialized counselor, usually a registered nurse, who provides ostomy patients with education and counseling before the operation. After surgery the ET helps the patient learn to take care of the stoma and appliance, and offers long-term emotional support.

Familial polyposis—A disease that runs in families in which lumps of tissue (polyps) form inside the colon. Familial polyposis may develop into cancer.

Ileum—The third segment of the small intestine, connecting the jejunum and the large intestine.

Jejunum—The second of the three segments of the small intestine, connecting the duodenum and the ileum.

Kock pouch—A type of ileostomy in which the surgeon forms an artificial rectum from a section of the ileum. A Kock pouch is sometimes called a continent ileostomy because it is drained with a tube.

Ostomy—A common term for all types of enterostomies.

Stoma—The surgically constructed mouth or passage between the intestine and the outside of the patient's body.

Tube enterostomy—An enterostomy performed to allow the insertion of a feeding tube into the jejunum or stomach.

Ulcerative colitis—A disease of the colon characterized by inflammation of the mucous lining, ulcerated areas of tissue, and bloody diarrhea.

- Ileal **abscess** and fistula can occur, in which the ileum becomes punctured by sutures, recurrent disease, or the effects of a poorly-fitted appliance.

Results

Normal results include recovery from the surgery with few or no complications. About 95% of people with ostomies recover completely, are able to return to work, and consider themselves to be in good health. Many ileostomy patients enjoy being able to eat a full range of foods rather than living on a restricted diet. Some patients, however, need to be referred to psychotherapists to deal with depression or other emotional problems after the operation.

Health care team roles

A variety of allied health personnel will be involved in the care of individuals who require an enterostomy. A surgeon will perform the actual procedure. A nurse will likely be involved in aftercare instructions, and an important member of the allied health care team is the ET. The ET is generally a **registered nurse** who has received specialized training in the area of enterostomy and is typically certified in the field. The ET generally performs the following activities:

- presurgical counseling and education of the patient and family
- care of the stoma immediately following the operation
- training of the patient in the proper use of the appliance and overall long-term self-care
- proper fitting of the appliance
- educating the patient on the daily management of the stoma
- advising the patient on how to cope with skin complications and odor problems
- identifying stomal problems associated with the surgery
- supporting the patient emotionally, physically, and morally
- providing information about the national organization for those who have received an ostomy—the United Ostomy Association

Nutritional therapists may also consult the patient about various nutritional factors and how they might affect the patient who has undergone an enterostomy. In particular, this information will include how various foods lead to diarrhea, or bad odors in the bag. **Wound care** nursing specialists also may be called in when wound healing is not progressing at an appropriate rate.

Enzyme immunoassay *see* **Immunoassay tests**

Epidural anesthetic *see* **Anesthesia, local**

Epidural therapy

Definition

An epidural is a local (regional) anesthetic delivered through a small tube into a vacant space outside the **spinal cord**, the epidural space.

Purpose

The anesthetic agents that are infused through the small catheter block spinal nerve roots in the epidural space and the sympathetic nerve fibers adjacent to them. Epidural anesthesia can block most of the **pain** of labor and birth for vaginal and surgical deliveries. Epidural analgesia is also used after cesarean sections to help control post-operative pain.

Precautions

The primary problem associated with receiving epidural anesthesia is low **blood pressure**, otherwise known as hypotension, because of the blocking of sympathetic fibers in the epidural space. The decreased peripheral resistance that results in the circulatory system causes dilation of peripheral **blood vessels**. Fluid collects in the peripheral vasculature (vessels), simulating a condition that the body interprets as low fluid volume. A simple measure that prevents most hypotension is the

infusion of 500-1000 cc of fluid intravenously into the patient prior to the procedure. Ringer's lactate, as opposed to a solution containing dextrose, is preferable because the elevated maternal glucose that accompanies the rapid infusion of solutions containing dextrose can result in hyperglycemia in the newborn with rebound hypoglycemia.

It is important not to place a woman flat on her back after receiving an epidural because the supine position can bring on hypotension. If a woman's **blood** pressure does drop, then the proper treatment is to turn her on her side, administer oxygen, increase the flow of intravenous fluids and possibly administer a medication such as ephedrine if the hypotension is severe. Very rarely, convulsions can result from severe reactions. Seizure activity would be treated with short-acting barbiturates or diazepam (Valium).

Description

Epidural anesthesia, because it virtually blocks all pain of labor and birth, is particularly helpful to women with such underlying medical problems as pregnancy-induced **hypertension**, **heart** disease, and pulmonary disease. Epidural anesthesia for labor is usually initiated at the woman's request, providing the labor is progressing well, or if the mother feels severe pain during early labor.

Preparation

To prepare for the administration of epidural anesthesia, the woman should have the procedure explained fully and sign consent forms if required. An intravenous line is inserted if not already in place. She is positioned on her side or in a sitting position and connected to a blood pressure monitoring device. The nurse/assistant has the following equipment available: oxygen, epidural insertion equipment, fetal monitor, and additional intravenous fluid.

The health care provider cleans the area with an antiseptic solution, injects a local anesthetic to create a small wheal at the L 3-4 area (between the third and fourth lumbar vertebrae) and inserts a needle into the epidural space. Once it is ascertained that the needle is in the correct place, a polyethylene catheter is threaded through the needle. The needle is removed and a test dose of the anesthetic agent is administered. The catheter is taped in place along the patient's back with the end over her shoulder for easy retrieval when further doses are required.

If the patient responds well to the test dose a complete dose is administered. Pain relief should be to the

Epidural anesthesia may be administered to a woman in labor to ease the pain of labor and birth. (*M. English, MD/Custom Medical Stock Photo. Reproduced by permission.*)

level of the umbilicus. The epidural anesthesia lasts approximately 40 minutes to two hours, or longer as required. If necessary, additional doses of anesthetic, or top-up, are injected through the catheter or a continuous infusion on a special pump.

Epidural anesthesia can be given in labor in a “segmented” manner. In this instance, the laboring woman receives a small dose of anesthesia so that the perineal muscles do not fully relax. The baby's head is more apt to undergo internal rotation when the perineal muscles are not lax thus facilitating delivery. At the time of delivery, an additional dose can be administered for perineal relief.

Women who have cesarean deliveries may have additional medication injected into the epidural to control intra-operative pain. Medications used generally are narcotics such as fentanyl or morphine (Duramorph). Side effects include severe itching, nausea, and vomiting. Treatment of these side effects with the appropriate med-

KEY TERMS

Analgesia—A medication that decreases the awareness of pain.

Anesthesia—Loss of sensation through the administration of substances that block the transmission of nerve impulses signaling the feeling of pain and pressure.

Regional anesthesia—Blocking of specific nerve pathways through the injection of an anesthetic agent into a specific area of the body.

ication can be helpful. Despite these problems, epidural analgesia is an effective method to relieve pain after cesarean delivery, allowing the woman to move well, thereby facilitating rapid recovery.

Aftercare

It is important to carefully monitor **vital signs** after the administration of epidural anesthesia. Hypotension can result in fetal death and can also have grave consequences for the mother. The nurse should monitor the patient constantly and use a continuous blood pressure machine to obtain regular blood pressure readings for 20-30 minutes after each administration of anesthesia. The systolic blood pressure should not fall below 100 mm Hg or be 20 mm Hg less than a baseline systolic blood pressure for a hypertensive patient.

It is important to remind the woman to empty her bladder at least every two hours. With epidural anesthesia there is loss of sensation of the need to void. Sometimes, if the bladder fills excessively it could actually block the descent of the baby's head. A catheter can be inserted into the bladder to drain the urine. The nurse needs to closely monitor intake and output and assess the bladder for signs of distension.

Complications

Side effects and complications are rare but sometimes the patient will experience a "spinal headache" due to leakage of cerebrospinal fluid (CSF).

When a woman receives epidural anesthesia for labor pains, at times the labor can be prolonged because of excessive relaxation of the muscles. Also, the baby's head may not rotate—especially if it is in the occiput-posterior position (the back of the head is facing toward the woman's back). The woman may not have the sensation that results in the desire to push during contractions

when she is fully dilated. These complications may result in an increased incidence of births with the use of vacuum extraction, forceps, or even cesarean deliveries. Administering a Pitocin (oxytocin) drip intravenously can counter this problem. Pitocin is a medication that causes the uterus to contract. Allowing the epidural to wear off in the second stage of labor, when the woman is pushing, may avoid this problem, but the return of the labor pains may be overwhelming to the woman.

Occasionally, slow absorption of the medication from the epidural space into the circulation can result in toxic reactions evident by decreased level of consciousness, slurred speech, loss of coordination, drowsiness, nervousness, and **anxiety**. The health care provider should look out for these signs, and also report any elevation in temperature, before a top-up dose is administered.

Results

Epidural anesthesia is a safe and effective method of giving pain relief to women during labor and delivery and also can be used for cesarean births. It is believed that very little of the anesthetic is absorbed throughout the body (systemically), therefore epidural anesthesia is ideal because it does not pass medication on to the baby.

Health care team roles

Epidurals are administered by anesthesiologists and certified nurse anesthetists.

Undergoing the insertion of an epidural can be a frightening experience for the patient because of the injection technique. It is important to offer ample encouragement and support during the entire process.

Esophageal function tests

Definition

The esophagus is the muscular tube through which food passes on its way from the mouth to the **stomach**. The main function of the esophagus is to propel food into the stomach. In order to ensure material does not go the wrong way (reflux), sphincters at either end of the esophagus close when material is not passing through them in the correct direction. Esophageal function tests are used to determine if these processes are normal or abnormal.

Purpose

The esophagus has two sets of constricting muscles (or sphincters) at the top and bottom. Each of these muscular areas must contract in an exact sequence for swallowing to proceed normally. The upper esophageal sphincter normally stops the backflow of stomach contents into the pharynx and larynx. The lower esophageal sphincter guards against stomach acid moving up into the esophagus. The lower sphincter should be tightly closed, except to allow food and fluids to enter the stomach.

The three major symptoms occurring with abnormal esophageal function are difficulty with swallowing (**dysphagia**), heartburn, and chest **pain**. Doctors perform a variety of tests to evaluate these symptoms. Endoscopy, which is not a test of esophageal function, is often used to determine if the lining of the esophagus has any ulcers, tumors, or areas of narrowing (strictures). Many times, however, endoscopy only shows the doctor if there is an injury to the esophageal lining, and the procedure gives no information regarding the cause of the problem. Therefore, in addition to endoscopy, several studies are available that measure esophageal function. There are three basic types of tests used to assess esophageal function:

- Manometry is used to study the way the muscles of the esophagus contract, and is most useful for the investigation of difficulty with swallowing.
- Esophageal pH monitoring measures changes in esophageal acidity, and is valuable for evaluating

patients with heartburn or gastroesophageal reflux disease (GERD).

- X-ray studies investigate dysphagias, either by using a fluoroscope to follow the progress of barium during the process of swallowing, or by using radioactive scanning techniques.

Precautions

Since sedatives may alter test values, they are not administered prior to esophageal function testing. Eating prior to the test will also alter the results. Pregnant patients undergoing x-ray exams should carefully review the risks and benefits of any proposed tests with their doctors. Additionally, patients with bowel obstruction should not participate in any test using barium. Also, esophageal function tests are contraindicated in those patients who are unable to cooperate with the test.

Description

Manometry

This study is designed to measure the pressure changes produced by contraction of the muscular portions of the esophagus. An abnormality in the function of any one of the segments of the esophagus can cause difficulty in swallowing (dysphagia). This exam is most useful in evaluating patients whose endoscopy yields normal results.

During manometry, the patient swallows a thin tube carrying a device that senses changes in pressures in the esophagus. Readings are taken at rest and during the process of swallowing. Medications are sometimes given during the study to aid in the diagnosis. The results are then transmitted to recording equipment. Manometry is most useful in identifying diseases that produce disturbances of motility or contractions of the esophagus. In 2001, a solution containing five drops of peppermint oil in 10 mL of water was found to improve the manometric features of diffuse esophageal spasm (DES). The peppermint oil solution eliminated simultaneous esophageal contractions in all patients in the study.

ESOPHAGEAL PH MONITORING. This procedure measures the esophagus' exposure to acid reflux from the stomach. The test is ideal for evaluating recurring heartburn or gastroesophageal reflux disease (GERD). Excessive acid reflux may produce ulcers, or strictures resulting from healed ulcers, in addition to the symptom of heartburn.

Normally, acid refluxes into the esophagus in small amounts for short periods of time. The lower esophageal

sphincter usually prevents excessive reflux (in patients without disease). Spontaneous contractions that increase esophageal emptying and production of saliva also act to prevent damage to the esophagus.

Researchers have shown that in the esophagus, the presence of acid is damaging only if it persists for prolonged periods. Therefore, esophageal pH monitoring has been designed to monitor the level of acidity over 24 hours, usually in the home. In this way, patients are able to maintain their daily routine, document their symptoms, and correlate symptoms with specific activities. During this period, a thin tube with a pH monitor remains in the esophagus to record changes. After the study, a computer is used to compare changes in acidity with symptoms reported by the patient.

Additional tests, the Bernstein test (also known as the acid perfusion test) and the acid clearing test, may be performed. In the Bernstein test, hydrochloric acid (HCl) is directed into the esophagus. If the patient experiences pain with the administration of the HCl, the test is positive for reflux esophagitis. If there is no discomfort, another cause must be found to explain the patient's symptoms. In the acid clearing test, HCl is also directed into the esophagus. However, in this test, the patient's ability to quickly swallow the HCl is examined. If the patient needs more than 10 swallows, it indicates the patient has problems with esophageal motility.

pH monitoring is usually performed before surgery to confirm the diagnosis and to judge the effects of drug therapy. In 2001, studies showed that integrated esophageal and gastric acidity provided better quantitative measures of GERD pathophysiology than conventional pH parameters. This finding has implications for the evaluation of therapeutic interventions.

X-RAY TESTS. X-ray tests fall into two categories: (1) those performed using barium and a **fluoroscope**; and (2) those performed with radioactive materials. Studies performed with fluoroscopy are especially useful in identifying structural abnormalities of the esophagus. Oftentimes a sandwich or marshmallow coated with barium is used to identify the site of an obstruction. However, fluoroscopy can diagnose or provide important information about a number of disorders involving esophageal function, including craniopharyngeal achalasia (a swallowing disorder of the throat), decreased or reverse peristalsis, and hiatal hernia.

During fluoroscopy, the radiologist can observe the passage of material through the esophagus in real time, and video recordings may also be made. This is particularly useful when the swallowing symptoms appear to occur mostly in the upper region of the esophagus. The most common cause of difficulty swallowing is a previ-

ous stroke, although other diseases of the neuromuscular system (like myasthenia gravis) can produce similar symptoms.

Scans using low-dose radioactive materials are useful because they may demonstrate that food passes more slowly than normal through the esophagus, and how slowly the bolus may be passing. These studies involve swallowing food coated with radioactive material, followed by a nuclear medicine scan. Scans are often used when other methods have failed to make a diagnosis, or if it is necessary to determine the degree of the abnormality.

Preparation

Patients should not eat or drink anything after midnight before the exam. Many medications affect the esophagus; doses may need to be adjusted or even discontinued prior to testing. Patients must inform their physician of any and all medications they take, including over-the-counter medications, and any known **allergies**.

Aftercare

For most of these studies, no special care is needed after the procedure. Patients can often engage in normal daily activities following almost all of these tests. One exception is that patients who undergo a x-ray exam with the use of barium may experience constipation. A cathartic may be given to those patients.

Complications

Exposure of a fetus to x-rays, especially in the first three months, can be extremely harmful to the fetus. Barium swallows may also cause impaction (hardening) of fecal matter. Additionally, although the tubes passed through the esophagus during some of the esophageal function tests are small, and most patients adjust to them quite well, some patients may gag and aspirate (breathe in) some gastric juices.

Results

Normal findings include:

- lower esophageal sphincter pressure ranging from 10–20 mm Hg
- normal peristaltic waves
- normal size, shape, position, patency and filling of the esophagus
- negative acid reflux
- acid clearing in less than 10 swallows

- negative Bernstein test

Manometry is used to diagnose abnormalities related to contraction or relaxation of the various muscular regions of the esophagus. These studies cannot distinguish whether injury to either the muscle or nerves of the esophagus is producing the abnormal results—only the final effect on esophageal muscle is identified. Results should be interpreted in light of the patient’s entire medical history.

For example, there are many diseases that cause poor relaxation of the lower esophageal sphincter. When no cause is found, the condition is called achalasia. Achalasia is a frequent finding in individuals with Down’s syndrome.

Abnormal results of pH tests can confirm symptoms of heartburn or indicate a cause of chest pain (or rarely, swallowing difficulties). Doctors may want to initiate or change medications based on these results, or even repeat the test using different doses of medication. As noted above, these studies are indicated before surgical treatment of GERD.

X-ray tests can serve to document an abnormality, and they are far from perfect. If they are negative, then other studies are often needed.

Health care team roles

The health care team may consist of the physician, the nurse, and others. A radiologist will be required if the procedure involves scans, x-rays, or nuclear medicine studies. Unlicensed assistive personnel (UAPs), such as GI assistants, GI technicians or medical technicians may have direct patient care responsibility. They are supervised by a **registered nurse (RN)**. UAPs can assist the physician and RN during diagnostic and therapeutic procedures. The RN is responsible for the assessment of patient care needs and for determining the capability of assistive personnel to whom a task is delegated. An advanced practice nurse (APN) specializing in gastroenterology may perform a comprehensive history and physical assessment. Depending on the practice, the APN may also order and/or perform diagnostic studies. Otherwise, these tasks are performed by the physician.

Training

An APN is a nurse who has completed an advanced degree in nursing (master’s or doctorate). An APN may be a nurse practitioner or a **clinical nurse specialist**. UAPs may receive on-the-job training in their duties.

KEY TERMS

Achalasia—Failure to relax. Often applied to sphincter muscles, the normal function of which is persistent contractions with periods of relaxation.

Bolus—“A lump.” May describe a mass of food ready to be swallowed, or a preparation of medicine via the oral or intravenous (IV) route.

Cathartic—An active agent which produces bowel movements.

Craniopharyngeal achalasia—A swallowing disorder of the throat.

Diffuse esophageal spasm (DES)—An uncommon condition that results in simultaneous contractions of the esophagus.

Esophagus—The muscular canal between the throat and the stomach.

Heartburn—Acid liquid raised from the stomach, causing a burning sensation in the esophagus.

Hiatal hernia—A condition in which part of the stomach pushes up through the same hole in the diaphragm that the esophagus passes through.

Peristalsis—The contraction of muscles which passes food from the mouth to the stomach and out the anus.

Patient education

If barium is used in the testing, the patient should understand that all of the barium needs to be excreted. At first, the patient’s stools will be white, but once the barium has been completely excreted, the stools will return to normal.

Advise the patient that a **sore throat** is common after tests requiring tube placement. Explain to the patient that sedatives are not given prior to testing involving tube placement, due to the interference with the test results and test administration.

Ergonomic assessment

Definition

Ergonomic assessment is a physical therapist's or other specialist's evaluation of a workplace and its furnishings, tools, and tasks in relation to the physical abilities of the worker. It is also known as work activities evaluation and treatment.

Purpose

The professional evaluation is used to identify and report any risk factors that the worker may encounter while employed. By identifying those risks for injury and physical **stress**, the evaluator provides recommendations

for modified design and practice. The ergonomic assessment and its implementation can help make the work environment safer and more physically efficient. It will also help reduce injuries and related expenses while improving the well-being, productivity, and morale of employees. A job analysis (a written description of tasks according to their physical functions and requirements) may be provided, to match the capabilities of the worker to the job's physical requirements. Ergonomic assessment reports and subsequent modifications help the employer to meet insurance company, Occupational Safety and Health Administration (OSHA), or other organizational standards. The physical therapist may be called in to treat an injured worker or make general preventative recommendations. The therapist helps the worker return to work more quickly and safely by advising revisions in the work tasks and environment. The employer receives advice in how to accommodate the abilities of a disabled or recently injured employee in compliance with the **Americans with Disabilities Act** (ADA) requirements.

Precautions

Ergonomic assessments are used to prevent further or recurring injuries. If a worker returns to work while still in recovery or returns to the same dangerous environment, the injury is liable to happen again, perhaps with a worse outcome.

Description

Ergonomic assessment is provided to an employer or employee to identify risk factors in the workplace; provide recommendations of ways to reduce them; and to prevent or treat injuries and accommodate disabilities. The evaluation helps employees perform their jobs in a safe, healthy, and efficient manner, spending less time off due to work-related disorders. The term ergonomics is derived from the Greek roots *erg*, meaning work and *nomos*, meaning natural laws. OSHA defines ergonomics as "the science of fitting the jobs to the people who work in them," stating that "work-related musculoskeletal disorders (MSDs) result when there is a mismatch between the physical capacity of workers and the physical demands of their jobs." Some job-related MSDs include **carpal tunnel syndrome**, tendinitis, and back injuries.

Many industries and work environments expose workers to hazardous conditions and constant physical stress resulting in accident, injury, and such chronic conditions as work-related musculoskeletal disorders (WMSDs), cumulative trauma disorders (CTDs), and repetitive motion injuries (RMIs). Some high-risk groups

are assembly line workers, manufacturing employees, health care workers, and office workers. Jobs requiring continual heavy lifting or constant repetition of the same motion can be especially stressful. Office work—especially that involving constant computer use—can lead to various physical problems. These include eye strain from artificial lighting and computer screens; back problems related to incorrect posture and chairs or work stations; and hand, wrist, or arm injuries due to excessive or incorrect keyboard use.

Once these risks are identified, the recommendations may be in the form of a work risk analysis report that includes a biomechanical description of the job, a description of observed risks, and steps to correct them.

Ergonomic assessment and intervention includes the “Five E’s” of correction and injury prevention:

- **Ergonomic-engineering:** Redesigning the job or workspace to reduce stress. For example, the height or angle of a counter, chair or keyboard may be adjusted.
- **Exposure reduction:** Reducing the amount of time workers are exposed to unavoidable stress by rotating tasks; increasing the variety of tasks performed and how they are performed; and changing physical positions and movements.
- **Exercise:** Stretching the muscles relieves stress and helps to prevent injury. This proves especially important when certain physically stressful tasks must be repeatedly performed.
- **Enforcement of preventative procedures or policies:** Teaching such procedures as proper lifting techniques, are necessary if they are to benefit the employees.
- **Education:** Knowing the proper procedures and the physical reasons for use.

Preparation

A physical therapist may either be employed by a company to treat workers on-site or act as a consultant with various companies. If the treatment is in response to an employee injury, the employer’s insurance company generally pays for the physical therapist’s services. If the therapist is providing general injury prevention consultation the employer usually pays for the service, which is cost-effective because it reduces injury-related expenses. Physical therapists are by the nature of their training well educated in anatomy, posture, body mechanics, and ergonomics, but the physical therapist who provides ergonomic assessment and treatment in the workplace may also have additional training or education in ergonomics and occupational health. Physical therapists are generally used more outside the United States, but

KEY TERMS

ADA—Americans with Disabilities Act.

Biomechanics—The study of biological and muscular activity.

CTD—Cumulative trauma disorder.

Ergonomics—Arranging and studying things people use to derive efficient and safe conditions that produce the best results.

OSHA—Occupational Health and Safety Administration.

RMI—Repetitive motion injury.

WMSD—Work-related musculoskeletal disorders.

would prove beneficial given their expertise in the human body and its activities.

Aftercare

After the ergonomic assessment for each employee’s job assignment and work station has been conducted and the employees have been instructed in proper work place ergonomics and safety, beneficial results depend on application. The employer needs to actually apply recommendations for changes in the work station or job description. Employees also have to continue to put the new techniques they have learned into practice.

Complications

While complications resulting from the ergonomic assessment itself are not likely, there may possibly be complications resulting from an injured employee’s early return to work, even with a modified job description. If the resumed or modified activity causes irritation or risk of reinjury, the employee may need to cease the resumed activities and return to the physical therapist or physician for further treatment. Care should be taken to screen employees for any conditions contraindicating exercise before preventative stretches or other new physical activities are recommended.

Results

The desired outcomes of ergonomic assessment and intervention are quicker return to work by injured employees, a safer and more efficient work environment, prevention of future injuries, and increased understanding of safe work and postural practices. By reducing

injuries, Workers' Compensation claims, and employee absenteeism, adjustments made to the work environment and related activities can lead to reductions in cost to the employer.

Health care team roles

A company doctor, Workers' Compensation doctor, or other physician may refer the patient to a physical therapist for treatment and workplace ergonomic evaluation. The employer also has the option of directly requesting the physical therapist's services. Educational specialists and others with special training in ergonomics and occupational health may be involved in addition to or in place of the physical therapist. Often the physical therapist will be the sole consultant for the employer and employees.

Esophageal radiography see **Upper GI exam**

Esophagogastroduodenoscopy

Definition

An esophagogastroduodenoscopy (EGD), or upper endoscopy, is a procedure in which a camera mounted on

a small flexible tube is used to view the esophagus, **stomach**, and duodenum (part of the **small intestine**). Small instruments may also be passed through the tube to treat disorders or biopsy lesions.

Purpose

An EGD is performed to evaluate (or treat) symptoms relating to the upper gastrointestinal tract, such as:

- upper abdominal or chest **pain**
- nausea or vomiting
- gastroesophageal reflux disease (GERD)
- difficulty swallowing (dysphagia)
- anemia
- bleeding from the upper intestinal tract

In addition, an EGD may be used to confirm abnormalities indicated by other exams, such as an upper GI series or a CT scan, or may be used to treat certain conditions, such as an area of narrowing (stricture) or bleeding in the upper gastrointestinal tract.

Upper endoscopy is more accurate than x rays for detecting inflammation, ulcers, or tumors. It is used to diagnose early **cancer** and can frequently determine whether a growth is benign or malignant. Biopsies (small tissue samples) of inflamed or "suspicious" areas can be obtained and examined by a pathologist. Cell scrapings can also be taken by the introduction of a small brush; this helps in the diagnosis of cancer or infections. Small instruments can be passed through the **endoscope** and can stretch narrowed areas or remove swallowed objects (such as coins, pins or other **foreign bodies**). In addition, bleeding from ulcers or vessels can also be treated by endoscopic techniques.

Precautions

An EGD is contraindicated in patients with:

- severe upper gastrointestinal (UGI) bleeding
- history of **bleeding disorders** such as platelet dysfunction or hemophilia
- esophageal diverticula
- suspected perforation
- recent UGI surgery

An EGD is also contraindicated for those patients who are unable to cooperate fully with the procedure.

Description

First, patients either gargle a local anesthetic or have one sprayed into their mouth (onto the throat) to numb the gag reflex. Patients are also usually sedated for the procedure by injection of medications into a vein. The endoscopist then has the patient swallow the scope, which is passed through the upper gastrointestinal tract. The lens or camera at the end of the instrument allows the endoscopist to examine each portion of the upper gastrointestinal tract; photos can be taken for reference. Air is pumped in through the instrument to allow proper observation. Biopsies and other procedures can also be performed.

Preparation

The upper intestinal tract must be empty for the procedure, so patients *must not* eat or drink anything for at least six to 12 hours before the exam.

Aftercare

Someone should be available to take the person home after the procedure and stay with them for a while; patients will not be able to drive themselves due to sedation. Pain or any other unusual symptoms should be reported immediately.

It is important to recognize early signs of any possible complication. The doctor should be notified if the patient has:

- fever
- trouble swallowing (dysphagia)
- difficulty breathing (dyspnea)
- increasing throat, chest, or abdominal pain

Complications

The overall complication rate of EGD is less than 2%, and many of these complications are minor (such as inflammation of the vein through which medication is given). However, serious complications can and do occur. Almost half of them are related to the **heart** or **lungs**. Bleeding or perforations are also reported, especially when tumors or narrowed areas are treated or biopsied. Infections have also been transmitted (rarely); careful attention to cleaning procedures should prevent this complication.

Results

Normal results show the esophagus, stomach and duodenum without any strictures, ulcers or erosions,

KEY TERMS

Duodenum—The first portion of the small intestine.

Endoscope—A surgical tool used to view areas that can't be directly observed (like the esophagus or the colon).

Esophagus—The muscular canal between the throat and the stomach.

Pathologist—A doctor who specializes in the anatomic (structural) and chemical changes that occur with diseases. These doctors function in the laboratory, examining biopsy specimens, and regulating studies performed by the hospital laboratories (blood tests, urine tests, etc). Pathologists also perform autopsies.

diverticula, masses, or bleeding. Other abnormal results include esophageal infections, fissures and tears. An increasingly common finding is medication-induced esophageal injury, caused by tablets and capsules that have lodged in the esophagus.

Health care team roles

The health care team may consist of the physician, the nurse, and others. Unlicensed assistive personnel (UAPs), such as GI assistants, GI technicians or medical technicians may have direct patient care responsibility. They are supervised by a **registered nurse (RN)**. UAPs can assist the physician and RN during diagnostic and therapeutic procedures. The RN is responsible for the assessment of patient care needs and for determining the capability of assistive personnel to whom a task is delegated. An advanced practice nurse (APN) specializing in gastroenterology may perform a comprehensive history and physical assessment. Depending on the practice, the APN may also order and/or perform diagnostic studies. Otherwise, these tasks are performed by the physician.

Training

An APN is a nurse who has completed an advanced degree in nursing (master's or doctorate). An APN may be a nurse practitioner or a **clinical nurse specialist**. UAPs may receive on-the-job training in their duties.

Patient education

Instruct the patient not to eat or drink anything until the gag reflex has returned. Normally, the gag reflex will

return in two to four hours after the procedure. To test if the gag reflex has returned, place a spoon on the back of the tongue for a few seconds with light pressure. If the patient does not gag, wait 15 minutes and attempt the maneuver again. Do not use small or sharp objects. Advise the patient that hoarseness and a mild **sore throat** are normal after the procedure. Encourage cool fluids and gargling to relieve the soreness. Because of the introduction of air during the procedure, it is normal to have some bloating, belching and flatulence after an EGD. To prevent pill-induced esophageal injury, advise patients to drink at least 4 ounces of liquid with any pill, and at least 8 ounces of liquid with pills that can cause injury. Patients should remain sitting upright for 30 minutes after taking pills that are likely to cause injury.

Ethical codes and oaths

Definition

Ethical codes and oaths are statements of the moral principles and values that govern the conduct of a group, profession, or individual. In the health professions, ethical codes embody the ideals of compassion for the suffering and respect for the dignity of all human beings, as well as the highest standards of clinical research and practice.

Ethics as a discipline is the study of moral values and moral reasoning. There are two major approaches to ethics, normative and non-normative. Non-normative ethics describes and studies moral beliefs without making value judgments about right and wrong. Normative ethics tries to define and distinguish between right and wrong.

Description

Ethical codes and oaths are formal statements that serve to remind practitioners of their obligations to their patients and to the larger society. In the United States and Canada, the ethical codes that have been drafted by the various health professions are also regarded as the foundation of the legal obligations of health care professionals—including disciplinary standards. For example, a patient who files a complaint with the ethics committee of a physician's medical society or hospital can take the complaint to the state licensing board as well. Ethics committees in the health professions have the power to suspend or expel members who have violated the ethical code that governs the profession.

The ethical standard set by the professional organization may be simple and forthright like the Hippocratic Oath for physicians, or more thorough and specific as is the code of conduct for nurses. Modern medical codes and oaths are patterned after the Hippocratic Oath and contain the same basic concepts: to work for the good of one's patients; to cause them no harm; to honor the profession of medicine and protect it from corruption; to give no drugs or perform no operation that would cause harm to the patient; and to keep medical information confidential. Whether the code is an ancient or a contemporary version, it gives the health care professional a high standard of conduct for which to strive.

Viewpoints

Historical background

The earliest statement of ethical standards for physicians is the so-called Hippocratic Oath, attributed to the “father of medicine” in the fifth century B.C. In the West, both Judaism and Christianity gave extensive consideration to the importance of the physician’s moral character as well as his clinical duties to patients. In Judaism, **medical ethics** is rooted in the study of specific case histories interpreted in the light of Jewish law. In medieval Christianity, ethical reflection took the form of an emphasis on duty, moral obligation, and right action. In both faiths, the relationship between the medical professional and the patient was regarded as a covenant or sacred bond of trust rather than an economic transaction or a business contract.

Since the eighteenth century, several developments have led to increased concern about the ethical standards of the health professions. These changes include:

- A philosophical emphasis on individual freedom and personal rights rather than on obligations to family or society.
- Advances in scientific knowledge and technology that raise new questions about the nature of human personhood, life, and death.
- Recognition of the vulnerability of the health professions to abuse by government authority. Specific examples include medical experiments on concentration camp inmates in Nazi Germany and the abuse of psychiatry in Stalinist Russia.
- The increased role of economic considerations in health care decisions on the individual as well as the communal level.
- The loss of a universal moral framework accepted by all or most people. Although there are a number of religious and philosophical perspectives on ethical questions that many people accept, none of these perspectives is accepted by everyone.

Present models for making ethical decisions in medicine

Models are outlines or patterns that can be used in ethical decision-making to help the care provider organize his or her thoughts and bring in all relevant considerations. One widely used model for decision-making in medicine holds that any ethical decision must consider four factors:

- Medical indications. These include the diagnosis and treatment of the patient’s condition.

- Patient preferences. This factor assumes that health professionals should respect the patient’s wishes, and wherever possible provide care that does not violate them.
- Quality of life. This factor is to be evaluated from the patient’s point of view, not the medical professional’s perspective.
- The wider context. This factor includes all the other features that may be involved in a specific decision, such as the family’s feelings, legal considerations, socioeconomic issues, religious practices, and others.

Another model that is sometimes used in clinical practice proposes three rules to be followed in ethical decision-making:

- Impartiality. This rule requires the health professional to place him- or herself in the patient’s position and ask whether they would be willing to have the action performed if they were the patient.
- Universality. This rule asks whether the health professional would be willing to apply the same solution to the patient’s situation in all similar cases.
- Justifiability. This rule asks the health professional to consider whether he or she could defend the decision to other people or discuss it in public.

Other considerations

Although there are many medical codes and guidelines within individual medical associations, some observers have proposed a universal code of ethics binding on all health care professions. It has been suggested that a universal code of ethics would unify the medical community and restore society’s trust in its professional care givers.

Another dimension of ethical decision-making in medicine that has received greater attention in recent years is the role of empathy and compassion. The ethical codes that govern health professionals do not specify these characteristics in health care providers, but both care givers and patients increasingly recognize that ethical integrity can be cold and lifeless without emotional rapport. Human beings have feelings as well as capacities for intellectual reflection and analysis. Empathy and compassion help to build trust between care giver and patient, improve communication, and often contribute to healing.

Professional implications

One implication for health professionals is the importance of studying ethical issues during one’s professional education. Many medical, dental, and nursing

KEY TERMS

Empathy—The ability to identify with the feelings or thoughts of another person.

Ethics—A system or set of moral principles; also, the study of values relating to human conduct.

Hippocratic Oath—The ethical oath attributed to Hippocrates that is used as a standard for care by physicians worldwide.

Non-normative ethics—An approach to ethics that emphasizes analysis of moral decisions without making judgments of right or wrong.

Normative ethics—An approach to ethics that attempts to define right and wrong and distinguish between them.

Rapport—A relation between two people that is harmonious and sympathetic.

schools now include courses in their curricula that deal with such topics as moral decision-making, definitions of life and death, the ethical complexities of professional-patient relationships, and the moral safeguards of medical research.

A second implication is recognizing the necessity of interdisciplinary conversation and cooperation. Health professionals can benefit from the insights of scholars in the social sciences, philosophy, theology, law, and history. At the same time, health professionals have much to offer to scholars in other fields gained from their clinical experience.

Euthanasia

Definition

Euthanasia is the act of putting a person (or animal) to death painlessly, or allowing a person (or animal) to die by withholding medical treatment in cases of incurable (and usually painful) disease. The word "euthanasia" comes from two Greek words that mean "good death." Euthanasia is sometimes called "mercy killing."

Description

Terms and categories

It is important to distinguish euthanasia from "assisted suicide," which is sometimes used loosely as a synonym for euthanasia. Assisted suicide, which is often called "self-deliverance" in Britain, refers to a person's bringing about his or her own death with the help of another person. Because the other person is often a physician, the act is often called "doctor-assisted suicide." Assisted suicide is illegal everywhere in the United States except the state of Oregon, while euthanasia is illegal in all fifty states. Euthanasia strictly speaking means that the physician or other person is the one who per-

forms the last act that causes death. For example, if a physician injects a patient with a lethal **overdose** of a pain-killing medication, he or she is performing euthanasia. If the physician leaves the patient with a loaded syringe and the patient injects himself or herself with it, the act is an assisted suicide.

Euthanasia is usually categorized as either active or passive, and as either voluntary or involuntary. The first set of categories refers to the means of ending life, and the second set of categories refers to the agent of the decision. Active euthanasia involves putting a patient to death for merciful reasons; passive euthanasia involves withholding medical care, or not doing something to prevent death. In voluntary euthanasia, the patient is the one who wishes to die and has usually requested either active or passive euthanasia. In involuntary euthanasia, someone else makes the decision to terminate the patient's life, usually because the patient is in a **coma** or otherwise unable to make an informed request to die.

Another important term to understand is the so-called doctrine of double effect. This is a legal term that has been underscored by the United States Supreme Court in one of its decisions. The doctrine of double effect states that a medical treatment intended to relieve **pain** but that incidentally hastens the patient's death is still appropriate and legally acceptable. In other words, a doctor who gives a dying patient high doses of morphine to prevent pain, knowing that such high doses may shorten the patient's life by a few days, is protected by the doctrine of double effect.

Historical overview

Although euthanasia has been practiced in various human societies for centuries, it has become a major social issue only in the twentieth century. Some ancient societies allowed infants born with serious birth defects to die, and some allowed the elderly to starve themselves to death as a form of voluntary euthanasia. In addition, it was not unusual for soldiers on the battlefield to give a death blow, or coup de grâce, to a mortally wounded comrade to prevent him from being captured by the enemy as well as to end his suffering. The French phrase literally means "stroke of mercy."

In the nineteenth century, euthanasia became a topic of ethical discussion partly because the discovery of reliable anesthetics and analgesic (pain-killing) medications meant that painless death was now easier to bring about. Prior to this period, the methods of suicide that were available to people were either violent, painful, or uncertain—and sometimes all three. For example, when the heroine of one mid-nineteenth-century French novel commits suicide by taking arsenic, the author describes

her agonizing death in clinical detail. But after the discovery of chloroform, ether, **nitrous oxide**, and similar anesthetics, people began to consider using them to relieve the suffering of the dying as well as the pain involved in surgical operations.

In the twentieth century, a number of social and technological changes made euthanasia a morally acceptable choice to growing numbers of people. The Euthanasia Society of America (which changed its name to the Society for the Right to Die in 1975) was founded as early as 1938. One important change was the increasing size of the elderly population, a development that resulted from the lengthening of the life span brought about by advances in medical science. A second was the invention of respirators, intravenous feeding, dialysis machines, and other means of prolonging a patient's life even in cases of terminal illness. Discomfort at the thought of ending one's life at the mercy of machinery is frequently mentioned in public opinion polls as a justification for euthanasia or assisted suicide. Another important transition was a change in social attitudes in favor of individual freedom and autonomy, rather than emphasizing a person's membership in a family or community. Many people today feel strongly that they are the best judges of their own well-being, and that they should have the "right to die" if necessary.

Viewpoints

Medical professionals

As of 2001, most North American professional societies in the health care professions have stated their opposition to active euthanasia. The American Medical Association (AMA) sponsored the establishment of an Institute for Ethics in the late 1990s, intended to educate American doctors about pain relief, palliative care at the end of life, and alleviation of patients' fears. The AMA has expressed its concern about the expansion of doctor-assisted suicide in the Netherlands—which became legal in April 2001—to include euthanasia without the patient's knowledge or consent. The American Nurses Association (ANA) signed on to the *amicus curiae* (friend of the court) brief submitted by the AMA to the United States Supreme Court in 1997 opposing doctor-assisted suicide. The ANA also stated that the health care professions should emphasize respectful, compassionate, and ethically responsible care at the end of life, including palliative care, so that patients do not seek assisted suicide as an alternative.

KEY TERMS

Active euthanasia—Putting a person to death as an act of mercy, as when a physician gives a patient a lethal dose of a medication.

Assisted suicide—A form of self-inflicted death in which a person voluntarily brings about his or her own death with the help of another, usually a physician, relative, or friend.

Doctrine of double effect—A legal principle that protects physicians treating patients to relieve pain even though the palliative treatment may shorten the patient's life.

Mercy killing—Another term for euthanasia.

Palliative care—A form of health care intended to relieve pain without attempting to cure the disease or condition.

Passive euthanasia—The withholding of medical care, or not taking some other action to prevent death; allowing a person to die.

Self-deliverance—Another term for assisted suicide.

Voluntary euthanasia—A form of euthanasia in which a person asks to die, either by active or by passive euthanasia.

Religious groups

In the United States and Canada, most mainstream Christian and Jewish groups remain opposed to active and involuntary euthanasia, though some permit carefully regulated forms of passive euthanasia. Christian and Jewish bodies emphasize not only God's ultimate power over death and life, and the value of human beings as creatures made in God's image, but also the relationships that bind humans to one another and to God. From this perspective, these religious traditions stand in contrast to the individualism of much of secular culture.

Contemporary Buddhist thought is divided on the issue of euthanasia. Some Buddhist ethicists believe that euthanasia and assisted suicide are both consistent with Buddhist principles, but others disagree. One reason for the disagreement is the fact that Buddhism encountered Western medicine and its ethical dilemmas only relatively recently.

Professional implications

The goals of medicine and health care

Euthanasia and assisted suicide compel medical professionals to reexamine their understanding of the purposes and goals of medical treatment. Those who maintain that preserving life and doing no harm are central to the ethical practice of medicine will have a different view of euthanasia from those who regard the relief of suffering as central.

Professional-patient relationships

The brief that the AMA submitted to the Supreme Court in 1997 included physician-patient relationships among its reasons for rejecting doctor-assisted suicide. Many American and Canadian physicians believe that acceptance of doctor-assisted suicide would undermine the credibility of the health care professions, and destroy trust between doctors and patients. In addition, others have pointed to the potential abuse of a physician's power to end a patient's life.

Interprofessional consultation and cooperation

Euthanasia and assisted suicide are questions that involve public policy, the legal system, and religious institutions as well as the health care professions. The complexity of the social and political considerations, together with the moral concerns, requires better communication among these different groups. One promising development has been the introduction of graduate-level ethics courses that bring together students from law, medical, nursing, and theological schools. Another has been the establishment of research centers and "think tanks" devoted to end-of-life issues.

Purpose

EP studies, also known as evoked responses, measure the very faint electrical response of the **brain**, brainstem, or peripheral nerves to a mild stimulus, displaying it as a wave on a paper strip or computer monitor. Because the response is of such low amplitude, the responses to many stimuli must be averaged to distinguish the potentials from the background brain activity. The general purpose of this group of tests is to diagnose nerve disorders and to distinguish nonorganic loss of sensation from nerve damage. The tests can locate the site of the lesion and serve to evaluate the condition of a patient's nervous response after treatment or during surgery.

Auditory EP studies are often used to assess the cause of a **hearing loss** or balance problems, especially in children. They are the most common way **hearing loss** is evaluated in **premature infants**. Most auditory EPs record activity from the brainstem, and are therefore called brainstem auditory evoked potentials. This test is also particularly useful in screening for acoustic neuroma (a benign tumor of the nerves of the auditory canal).

Visual EP studies are used to assess eyesight in infants and children, as well as to diagnose disorders of the optic nerve and muscles. They can also distinguish hysterical blindness, a psychiatric disorder, from blindness caused by nerve damage.

Somatosensory EP studies are commonly used in the diagnosis of **multiple sclerosis** and transverse myelitis, although **magnetic resonance imaging** (MRI) has made this test less useful for these purposes. After trauma, somatosensory EP can determine whether loss of sensation in an arm or leg is due to injury in the brain or **spinal cord**.

Auditory, visual, or somatosensory testing can detect tumors and other abnormalities affecting the brain and spinal cord, assess brain stem function in **coma**, and assist in the determination of brain death. Perhaps the most prominent future role of this group of tests is the monitoring of brain activity and signals from the nerves during surgery on the brain, spine, or carotid region, and during **general anesthesia**.

Precautions

There are several benign conditions that can affect the results of evoked potential studies. Visual EP tests should not be performed on persons having severe nearsightedness. Auditory EP studies are contradicted for persons having excessive earwax or severe inflammation of the middle ear. All three types of tests can be adversely affected by muscle spasms in the head or neck of the patient.

Evoked potential studies

Definition

Sensory evoked potential (EP) studies are the measurement of the electrical response of nervous tissue to auditory, visual, and somatosensory stimulation.

KEY TERMS

Amplitude—The distance from the baseline to the peak of the sensory response; represents the approximate number of healthy nerves available.

Latency—The amount of time between stimulus and sensory nerve response.

Waveform—The shape of the electrical response of the brain, brainstem, or peripheral nerve as recorded by the active electrode.

Description

The test is often performed by an electrodiagnostic technologist, a nurse, or another allied health professional. It begins with the location and marking of specific spots on the patient's head for placement of electrodes. These spots are cleaned, and an adhesive conducting paste is applied. Cup electrodes are attached. For somatosensory EP, spots on the arm or leg are also marked and cleaned; electrodes may be taped in place. The patient sits or reclines in a chair throughout the tests.

For a visual EP, electrodes are attached to the scalp over the brain region responsible for **vision**. The patient focuses on a TV screen that displays a checkerboard pattern. The eye not being tested is covered with a patch. For children or others whose attention may wander, goggles are used which show the pattern to one eye at a time. Each eye is usually put through two series of tests where hundreds of sample recordings are collected for averaging. The entire procedure takes approximately one hour.

For auditory EP, electrodes are placed on the top of the head and on the earlobe of the ear being tested. Headphones are used to deliver a series of clicks to one ear at a time. A masking or static sound is played into the other ear. Each ear is usually put through two trials, and the entire procedure takes approximately one hour.

For somatosensory EP, electrodes for recording are placed on the scalp and along the spinal cord, while electrodes for delivering a mild electrical shocks are placed on either the arm or the leg. The shock is not painful, but may cause some twitching and tingling. Multiple trials are done for each nerve tested, and the entire procedure can take up to three hours, if both arm and leg nerves are evaluated.

Preparation

The patient's hair should be clean, with no gels, sprays, or other preparations applied. Jewelry should be removed.

Aftercare

After the tests, the electrodes are removed with acetone and the scalp is cleaned. The patient can resume normal activities.

Complications

There are no complications that result from this group of tests.

Results

Results are recorded as waveforms, either on paper or a digital display. For somatosensory or visual EPs, the traces are displayed so a negative potential at the active electrode produces an upward deflection in the wave. Brainstem auditory EPs, in contrast, are recorded such that a positive potential at the active electrode produces an upward deflection. By using these conventions, the waves of interest are always recorded as upward deflections. In general, EP tests produce both latency (speed of conduction) and amplitude (electrical strength of response) results, with the latency measurements more often clinically significant. Results are often compared to age-specific normal values that are established at each laboratory, with a value of 2.5 to 3.0 standard deviations from the mean interpreted as abnormal. Comparisons between data collected from the left and right sides of an individual patient are also informative.

Health care team roles

Evoked potential studies are often performed by specially trained electrodiagnostic technologists. Training for such a position can be on the job but often involves study at a one- to two-year college or vocational program. A typical program would include:

- human anatomy and physiology
- neurology and neuroanatomy
- neurophysiology
- medical terminology
- computer technology and instrumentation

Certification of electrodiagnostic technologists specializing in evoked potentials and the related area of **electroencephalography** is available through the

American Board of Registration of Electroencephalographic and Evoked Potential Technologists.

A physician such as neurologist, neurosurgeon, or internist does the final review and diagnosis based on the results of EP studies. The doctor can be present for the testing or may review saved tracings. Other health care professionals, such as nurses, aid in **patient education** concerning this procedure.

Exercise

Definition

Exercise is physical activity that is planned, structured, and repetitive for the purpose of conditioning any part of the body or to improve performance in a specific task. Exercise is utilized to improve health, main-

tain fitness, and is important as a means of physical rehabilitation.

Purpose

Exercise is used in preventing or treating coronary **heart** disease, **osteoporosis**, weakness, diabetes, **obesity**, and depression. Range of motion is one aspect of exercise important for increasing or maintaining joint function. Strengthening exercises provide appropriate resistance to the muscles and increase endurance and strength. **Cardiac rehabilitation** exercises are developed and individualized to improve the **cardiovascular system** for prevention of and rehabilitation from cardiac disorders and diseases. A well-structured exercise program can improve general health by increasing strength, endurance, balance, and confidence. Furthermore, an exercise program may delay or minimize the effects of disease and aging. The benefits of exercise not only extend into the areas of physical health, but also enhance emotional well-being.

Precautions

Before beginning any exercise program, evaluation by a physician is recommended to rule out any potential health risks. Once health and fitness are determined and any or all physical restrictions identified, the exercise program should be under the supervision of a health care professional, especially when used as a form of rehabilitation. If symptoms of dizziness, nausea, excessive shortness of breath, or chest **pain** are present during any exercise program, the individual should stop the activity and inform the physician before resuming activity. Exercise equipment must be checked often for wear and durability.

Description

There are two types of rehabilitation to restore or improve function: cardiac and physical rehabilitation.

Cardiac rehabilitation

Exercise is very helpful in prevention of and rehabilitation from cardiac disorders and disease. With an individually designed exercise program set at a safe level, **heart failure** patients can improve their fitness levels substantially. Endurance or aerobic routines, such as running, brisk walking, cycling, or swimming, increase the strength and efficiency of the muscles of the heart. The increase in endurance should also translate into a generally more active lifestyle.

Exercise can be used to restore muscle strength after an illness or injury. A computer monitors this man's performance and provides a visual display of his progress. (Photograph by Geoff Tompkinson. Science Source/Photo Researchers. Reproduced by permission.)

Physical rehabilitation

Physical rehabilitation deals with improving function in specific individuals who have functional impairments secondary to disease, injury, or disuse. This is accomplished by **therapeutic exercise** that focuses on strengthening, coordination, balance, and endurance training. Both types of rehabilitation can incorporate range of motion exercises and strengthening exercises.

RANGE OF MOTION EXERCISE. Range of motion exercise refers to activity aimed at improving movement of a specific joint. This motion is influenced by several structures: configuration of bone surfaces within the joint; joint capsule; ligaments; and muscles and tendons acting on the joint. There are three types of range of motion exercises: passive, active, and active assistive. Passive range of motion is movement applied to the joint solely by another

person or persons or by a passive motion machine. When passive range of motion is applied, the joint of the individual receiving exercise is completely relaxed while the outside force takes the body part, such as a leg or arm, throughout the available range. Injury, surgery, or immobilization of a joint may affect the normal joint range of motion. Active range of motion is movement of the joint provided entirely by the individual performing the exercise. In this case, there is no outside force aiding in the movement. Active assistive range of motion is described as the joint receiving partial assistance from an outside force. This range of motion may result from the majority of motion applied by the exerciser or by the person or persons assisting the individual. It may also be a half-and-half effort on the joint from each source.

STRENGTHENING EXERCISE. Strengthening exercise increases muscle strength and mass, bone strength, and

the body's **metabolism**. It can help attain and maintain proper weight and improve body image and self-esteem. A certain level of muscle strength is needed to do daily activities, such as walking, running, and climbing stairs. Strengthening exercises increase muscle strength by putting more strain on a muscle than it is normally accustomed to receiving. This increased load stimulates the production of **proteins** inside each muscle cell that allow the muscle as a whole to contract with greater force. There is evidence indicating that strength training may be better than aerobic exercise alone for improving self-esteem and body image. Weight training allows immediate feedback through observation of progress in muscle growth and improved muscle tone.

Strengthening exercises can be further categorized in terms of the mode of resistive training, such as isometric, isotonic, or isokinetic.

ISOMETRIC EXERCISE. During isometric exercises muscles contract; however, there is no motion in the affected joints. The muscle fibers maintain a constant length throughout the entire contraction. The exercises are usually performed against an immovable surface or object, such as pressing the hand against the wall. The muscles of the arm are contracting but the wall is not moving as a result of the physical effort. Isometric training is effective for developing total strength of a particular muscle or group of muscles. It is often used for rehabilitation, since the exact area of muscle weakness can be isolated and strengthening can be administered at the proper joint angle. This kind of training can provide a relatively quick and convenient method for overloading and strengthening muscles without any special equipment and with little chance of injury.

ISOTONIC EXERCISE. Isotonic exercise differs from isometric exercise in that there is movement of the joint during the **muscle contraction**. It is exercise with a fixed resistance and variable speed. A classic example of an isotonic exercise is weight training with dumbbells and barbells. As the weight is lifted throughout the range of motion, the muscle shortens and lengthens. Calisthenics are also an example of isotonic exercise. These would include chin-ups, push-ups, and sit-ups, all of which use body weight as the resistance force.

ISOKINETIC EXERCISE. Isokinetic exercise utilizes machines that control the speed of movement within the range of motion. Isokinetic exercise attempts to combine the best features of both isometrics and weight training. It is resistive exercise utilizing a fixed speed and variable resistance. It provides muscular overload at a constant preset speed while the muscle mobilizes its force through the full range of motion. For example, an isokinetic stationary bicycle set at 90 revolutions per minute means

that no matter how hard and fast the exerciser works, the isokinetic properties of the bicycle will allow the exerciser to pedal only as fast as 90 revolutions per minute. Machines known by such brand names as Cybex and Biodex provide isokinetic resistance; they are generally used by physical therapists and are not readily available to the general population.

Preparation

A **physical examination** by a physician is important to determine if strenuous exercise is appropriate or detrimental for the individual. Prior to the exercise program, proper stretching is important to prevent the possibility of soft tissue injury resulting from tight muscles, tendons, ligaments, and other joint-related structures.

Aftercare

Proper cool-down after exercise is important in reducing the occurrence of painful muscle spasms. It has been documented that proper cool-down may also decrease frequency and intensity of muscle stiffness the day following any exercise program.

Complications

Improper warm-up can lead to muscle strains. Furthermore, overexertion with insufficient rest time between exercise sessions may lead to musculoskeletal injury. Stress **fractures** are also a possibility if activities are strenuous over long periods of time. Although exercise is safe for the majority of children and adults, there is still a need for further research to evaluate potential risks of strength training in children. There is a possibility of exercise "burnout," or over-training, if the exercise program is not varied and adequate rest periods are not taken between exercise sessions.

Health care team roles

Significant health benefits are obtained by including a moderate amount of physical exercise in the form of an exercise prescription. Physical activity plays a positive role in preventing disease and improving overall health status. People of all ages, both male and female, benefit from regular physical activity. Regular exercise also provides significant psychological benefits and improves quality of life.

Patient education

Nurses and other allied health professionals can educate their patients by using videotapes, manuals, and Web-based literature. However, it would be recommended that instructional workshops or classes be set up in an

KEY TERMS

Aerobic—Exercise training that is geared to provide a sufficient cardiovascular overload to stimulate increases in cardiac output.

Calisthenics—Exercise involving free movement without the aid of equipment.

Endurance—The time limit of a person's ability to maintain either a specific force or power involving muscular contractions.

Osteoporosis—A disorder characterized by loss of calcium in the bone, leading to thinning of the bones. It occurs most frequently in postmenopausal women.

Exercise electrocardiogram see **Stress test**

Exercise stress test see **Stress test**

Exercise thallium test see **Thallium heart scan**

Eye examination

Definition

An eye examination is a series of tests performed by an ophthalmologist or an optometrist to determine if there are any pre-existing or potential problems with a patient's **vision**.

Purpose

Eye examinations measure a person's ocular health and visual status, in order to detect abnormalities in the components of the visual system, and to determine how well the person can see. Eye exams may also reveal the presence of non-eye diseases such as high **blood pressure** or diabetes.

Infants should be examined to detect any physical abnormalities. If a problem is noted the infant can be further examined, generally by a pediatric ophthalmologist. A child without symptoms should have an eye exam before age three. Early exams are important because some conditions may result in permanent problems with vision. For example, amblyopia, more commonly known as a lazy eye, should be corrected before permanent damage occurs, usually between the ages of six and nine. If a child continues to be symptom-free, the second exam should take place before first grade. After first grade, the American Optometric Association recommends an eye exam every two years until age 19. From ages 19–40, an examination every two to three years is recommended, and from ages 41–60, an exam every two years is recommended. After that, healthy persons without risk factors are recommended to have annual examinations. Doctors should advise patients at risk for eye disease that they

may need more frequent checkups. Persons with visual problems should seek medical attention right away.

Precautions

The examiner, who may be an O.D., D.O., M.D., ophthalmic nurse, ophthalmic assistant, or ophthalmic technician, should log any medications the patient is taking and any existing health conditions. Some medications can affect vision or interfere with the eyedrops used during the exam. Certain types of eyedrops should not be prescribed if the patient has **asthma**, **heart** problems, or other conditions.

The patient may need transportation if the eyes are dilated. Physicians may advise patients to wear dark glasses to decrease the glare from strong light until the effects of the medication are sufficiently diminished.

Description

An eye examination is performed by an optometrist (who has an O.D. degree) or an ophthalmologist. Ophthalmologists either have an M.D. or a D.O. (doctor of osteopathy) degree. An eye examination, given by an ophthalmologist or optometrist with assistance from ophthalmic nurses, assistants and technicians, costs about \$100 and may or may not be covered by insurance. It begins with a patient history and continues with a series of primary tests. Additional specialized tests are administered as needed. The primary tests can be divided into two groups: those that evaluate the physical state of the eyes and surrounding areas; and those that measure the ability to see. Some variation exists, but most eye examiners and their assistants take a patient history and perform a standard set of primary tests.

Patient history and initial observations

The ophthalmic nurse, assistant, or technician will take eye and medical histories that include the patient's chief complaint, any past eye disorders, current medications, any family history of eye disorders, and any systemic disorders the patient may have. Sample questions may include "How is your vision?" or "Do you have any allergies?" Examiners also should ask about the patient's lifestyle. This information may modify prescriptions. For example, a construction worker needs protective eyewear. Patients should be encouraged to bring all of their currently used corrective lenses to the exam (contacts and glasses). This allows the ophthalmic staff to determine the prescription using a lensometer, and allows the examiner to determine the efficacy of the current prescription.

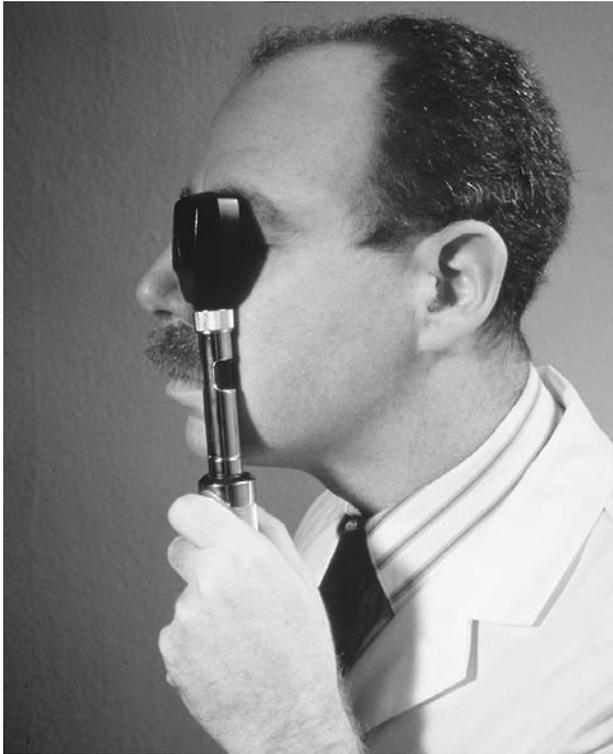

A doctor examines a patient's eyes using an ophthalmoscope. (Photograph by Andy Levin. Science Source/Photo Researchers. Reproduced by permission.)

Visual acuity tests

Visual acuity measures how clearly the patient can see. The examiner measures each eye separately, with and without the current prescription. Examiners use a Snellen eye chart with lines of different-sized letters. Each line has a number at the side denoting the distance from which a person with normal vision can read that line. Other charts are available for children or anyone unfamiliar with the Roman alphabet. Charts should be placed at the recommended distance (usually 20 feet, or 6 m) from the patient. At that distance, persons with normal vision can read the line marked 20/20, and are said to have 20/20 vision. Patients who cannot read that line are assigned a ratio based on the smallest line they can read. The first number (numerator) of the ratio is the distance between the chart and the patient, and the second number (denominator) is the distance where a person with normal vision would be able to read that line. The ratio 20/40 means the patient sees at 20 feet what people with normal vision can see at 40 feet.

When a patient is unable to read any of the lines, the patient is moved closer until the line with the largest letters is readable. A ratio of 5/200 means the person being tested can see at five feet (1.8 m) what a normal person can see at 200 feet (60 m).

If a patient can't read the chart at all, the examiner may hold up fingers and ask the patient to count them at various distances. The examiner records the result as "counting fingers" at the distance of recognition. If the patient cannot count the fingers at any distance, the examiner determines if the patient can see hand movements. If so, the result is recorded as "hand movements." If not, the examiner determines if the patient can detect light from a penlight. Detection of light and its direction is recorded as "light projection." If the patient can detect

Eye examiner using an ophthalmoscope. (Phototake, NYC. Reproduced by permission.)

the light but not its direction, the result is recorded as “light perception.” If the patient cannot detect the light at all, the result is recorded as “no light perception.”

Eye movement examination

The examiner asks the patient to follow an object (often the examiner’s finger) left, right, up, down, and in all four diagonal directions in order to ensure that the eyes are capable of the full range of motion and that the motions are smooth. Next is a peripheral visual field test. The examiner asks the patient to stare at an object, then quickly covers one eye and notes any movement in the eye that remains uncovered. This procedure is repeated with the other eye. This, and another similar test, helps detect an eye turn or problem with fixation. The examiner may also have the patient look at a pen and follow it as it is moved close to the eyes to check convergence.

Iris and pupil examination

The doctor or assistant checks the pupil’s response to light and accommodation (whether it dilates and constricts appropriately). The iris is viewed for symmetry and overall physical appearance. The iris is checked more thoroughly during the slit lamp examination.

Refraction examination

If a patient has visual acuity less than 20/20, the examiner will determine the refractive error and prescribe corrective lenses. To determine refractive error, the examiner utilizes a phoropter. A phoropter is an instrument equipped with many lenses. The examiner uses them to test many combinations of corrections in order to learn which correction allows the patient to see the eye chart most clearly. The phoropter also contains prisms, and sometimes the examiner will intentionally make the patient see double. This maneuver may help in determining a slight eye turn, as well as comparing the acuity of the right and left eye. The exam assesses far (distance) vision and near (reading) vision.

Examiners can also determine a lens prescription by utilizing an automated refracting device. The device measures the necessary refraction by shining a light into the eye and scanning the reflected light. Another way to obtain a prescription is using a hand-held retinoscope. As in the automated method just mentioned, the doctor shines a light in the patient’s eyes and can determine an objective prescription. This is helpful in young children or infants.

Physicians or assistants may instill eyedrops in the patient’s eyes before refraction. The drops relax accommodation so that the refraction is more accurate. This is helpful in children and people who are farsighted.

Ophthalmoscopic examination

These observations are best accomplished after dilating the pupils and require an ophthalmoscope. The ophthalmoscope most frequently used is called a direct ophthalmoscope. It is a hand-held illuminated 15X multi-lens magnifier that allows the examiner to view the back of the inside area of the eye (the fundus). The retina, **blood vessels**, optic nerve, and other structures are examined.

Slit lamp examination

The slit lamp (biomicroscope) is a **microscope** with an adjustable light source. This instrument magnifies and illuminates the external structures of the eyes. The lid and lid margin, cornea, iris, pupil, conjunctiva, sclera, and lens are examined. The slit lamp is also used in contact lens evaluations. With the use of a condensing lens, the biomicroscope provides an excellent view of the internal structures of the eye.

Visual field measurement

A perimeter, an instrument for measuring visual fields, is a hollow hemisphere equipped with a light

source that projects dots of light over the inside surface of the hemisphere. The patient's head is positioned so that the eye being tested is at the center of the sphere and 33 cm. (about 13 in.) from all points on the hemisphere's inside surface. The patient stares straight ahead at an image on the center of the surface of the perimeter, and signals whenever they detect a light with their peripheral, or side, vision. The perimeter records whether flashes are seen or missed and maps the patient's field of vision.

Intraocular pressure (IOP) measurement

Small probes called tonometers are used to measure IOP. Contact tonometers contact the eyeball directly. A colored anesthetic eyedrop is usually instilled immediately before this test. Other tonometers (noncontact tonometers) measure pressure by expelling a puff of air toward the eyeball from a very short distance. The noncontact tonometers are often not as accurate as the contact tonometers.

Additional tests

In addition to the primary tests already described, the examiner should observe the general health of the eye and structures around it. Depending upon the results of all the primary tests, other tests may also be necessary. These can include, but are not limited to, binocular indirect ophthalmoscopy, gonioscopy, color vision tests, and contrast sensitivity. The patient may have to return for additional visits.

Aftercare

Seeing clearly does not necessarily mean the eyes are healthy. Patients should be advised that regular checkups can detect abnormalities. Patients also should be examined if they notice a change in vision, eyestrain, blur, flashes of light, a sudden onset of floaters, distortion, double vision, redness, **pain** or discharge.

External observations

INITIAL OBSERVATIONS AND SLIT LAMP EXAM. Some general observations the doctor may be looking for include: head tilt; drooping eyelids; eye turns; red eyes; eye movement; the iris size, shape, and color; clarity of the cornea, anterior chamber, and lens. The anterior chamber lies behind the cornea and in front of the iris. If it appears cloudy or if cells can be seen in it during the slit lamp exam, an inflammation may be present. A narrow anterior chamber may place the patient at risk for **glaucoma**. Any abnormality indicates a need for medical care.

Internal observations

OPHTHALMOSCOPIC EXAM. The observations include, but are not limited to, the retina, **blood** vessels, optic nerve, macula, and fovea. The macula is a 3–5 mm area of the central retina and is responsible for central vision. The fovea is a small area located within the macula and is responsible for sharp vision. When a person looks at something, they are directing the fovea at the object. Changes in the macular area can be observed with the ophthalmoscope. Retinal tears or detachments can also be seen. An abnormality may indicate a need for medical care.

Visual ability

VISUAL ACUITY. The refraction will determine the refractive status for each eye. Different materials for glasses or **contact lenses** may be suggested.

VISUAL FIELDS. A normal visual field extends about 60° upward, about 75° downward, about 65° toward the nose, and about 100° toward the ear. There is one blind spot close to the center, which corresponds to the area of the optic nerve, which has no light-sensing cells. Defects in the visual field signify damage to the retina, optic nerve, or the neurological visual pathway. An abnormality may indicate a need for medical care.

Results

An eye examination can help maintain or restore clear, comfortable vision. It also aids in disease prevention. After an examination, patients should be more aware of their ocular health and general health.

Health care team roles

Nursing and allied health professionals play an important role in the eye examination and follow-up. Ophthalmic assistants and technicians facilitate the examination by logging the pertinent patient history.

Depending on skill level, ophthalmic assistants may perform measurement of visual acuity under both low and high illumination; assessment of ocular motility and binocularity; and assessment of visual fields and measurement of IOPs with tonometers.

Advanced and intermediate level ophthalmic technicians perform refractions and determine the patient's depth perception. These professionals may also perform corneal topography (mapping).

Some of these professionals seek certification through the American Board of Opticianry/National Contact Lens Examiners and other organizations. These organizations offer seminars and testing that inform pro-

KEY TERMS

Amblyopia—Decreased visual acuity, usually in one eye, in the absence of any structural abnormality in the eye.

Conjunctiva—The mucous membrane that covers the white part of the eyes (sclera) and lines the eyelids.

Cornea—Clear outer covering of the front of the eye.

Floaters—Translucent specks that float across the visual field, due to small objects floating in the vitreous humor.

Fundus—In the eye, fundus refers to the back area that can be seen with the ophthalmoscope.

Glaucoma—Glaucoma results in optic nerve damage and a decreased visual field and blindness if not treated. It is usually associated with increased IOP, but that is not always the case. The three factors associated with glaucoma are increased IOP, a change in the optic nerve head, and changes in the visual field.

Gonioscope—An instrument used to inspect the eye (e.g., the anterior chamber). It consists of a magnifier and a lens equipped with mirrors; it's placed on the patient's cornea.

Iris—The colored ring just behind the cornea and in front of the lens that controls the amount of light sent to the retina.

Macula—The central part of the retina where the rods and cones are densest.

Ophthalmoscope—An instrument designed to view structures in the back of the eye.

Optic nerve—The nerve that carries visual messages from the retina to the brain.

Pupil—The circular opening that looks like a black hole in the middle of the iris.

Retina—The inner, light-sensitive layer of the eye containing rods and cones; it transforms the image it receives into electrical messages which are then sent to the brain via the optic nerve.

Sclera—The tough, fibrous, white outer protective covering that surrounds the eye.

Slit lamp—A microscope that projects a linear slit beam of light onto the eye; it allows viewing of the conjunctiva, cornea, iris, aqueous humor, lens, and eyelid.

Tonometer—An instrument that measures intraocular pressure (IOP).

professionals of technological advances in refraction and eyeglass manufacturing.

Eye glasses

Definition

Eye glasses are devices that correct refractive errors in **vision**. Eye-glass lenses are mounted in frames that position the lenses in front of the eyes.

Purpose

Eye glasses are used to correct or improve the vision of patients with nearsightedness (**myopia**), farsightedness (**hyperopia**), **presbyopia**, and **astigmatism**. They are also utilized to correct refractive errors after cataract surgery.

Precautions

Ophthalmic assistants, technicians, and nurses take a careful patient history to determine patient sensitivities to certain frame materials. Patients allergic to certain plastics should avoid frames or lenses manufactured from that type of plastic. Patients allergic to nickel should not wear Flexon frames. Ophthalmic personnel also address

the patient's lifestyle. People at risk for accidents due to professions, sports, or hobbies are advised to choose plastic lenses, preferably polycarbonate. Also, people at risk of receiving electric shocks should avoid metal frames.

Description

Eyes are examined by optometrists (O.D.s) or ophthalmologists (M.D.s), with assistance from ophthalmic assistants, technicians, or nurses. If necessary, prescriptions are given to patients for glasses. An optician generally makes the glasses. Eye glasses can be created in an in-office laboratory or an off-site manufacturing lab.

Patients whose eyes have refractive errors do not see clearly without glasses. This is due to the fact that the light emitted by the objects they see does not come into focus on their retinas. For farsighted (hyperopic) patients, images come into focus behind the retina; for nearsighted (myopic) patients, images come into focus in front of the retina.

Lenses

Lenses work by changing the direction of light so that images come into focus on the retina. The greater the index of refraction of the lens material and the greater the difference in the curvature between the two surfaces of the lens, the greater the change in direction of light that passes through it, and the greater the correction.

Lenses can be unifocal, with one correction for all distances, or they can correct for more than one distance (multifocal). One type of multifocal lens, the bifocal, has an area of the lens (usually at the bottom) that corrects for near objects (about 14 in [35.5 cm] from the eyes); the remainder of the lens corrects for distant objects (about 20 ft [6 m] from the eyes). Another type of multifocal lens, a trifocal, has an area in-between that allows correct viewing of intermediate objects (usually about 28 in [71 cm]), such as computer screens or automobile dashboards.

The greater the index of refraction, the thinner the lens can be. Lenses are made from either glass or plastic (hard resin). Plastic is lightweight and more impact-resistant than glass. Glass is scratch-resistant and provides the best visual acuity. In recent years, however, glass that is thinner and more impact-resistant has been developed.

A plastic called CR-39, introduced in the 1960s, is the plastic of choice of most opticians. Today, eyeglass wearers can also choose between polycarbonate, which is the most impact-resistant material available for eyewear, and polyurethane, which has exceptional optical qualities

and an index of refraction of up to 1.66, much higher than the conventional plastics. Polycarbonate is the most easily scratched of the plastics used for lenses, so an anti-scratch coating is always applied to the lenses. In addition, an improvement in the polycarbonate manufacturing process now produces clear lenses—previously all polycarbonate lenses had a bluish cast.

Patients with high prescriptions should consider high index materials. Aspheric lenses also are useful for high prescriptions. They are flatter and lighter than conventional lenses. These lenses make it possible for patients with higher prescriptions and thick lenses to wear metal and titanium frames, when formerly they could wear only plastic frames.

There are many lenses and lens-coating options for individual needs, including coatings that block harmful ultraviolet (UV) light or UV and blue light. Such coatings are not needed on polycarbonate lenses, which already have UV protection.

There are anti-scratch coatings that increase the surface hardness of lenses and anti-reflective (AR) coatings that eliminate almost all glare. AR coatings may be particularly helpful to people who use computers or drive at night. Polarized lenses that block reflected light also allow better vision in sunny weather. Photosensitive (photochromic) lenses that darken in bright light are handy for people who do not want to carry an extra pair of sunglasses. Photochromic lenses are available in glass, plastic, and polycarbonate.

Frames

Frames can be made from metal or plastic, and they can be rimless. There is an almost unlimited variety of shapes, colors, and sizes. The type and degree of refractive correction in the lens determine to some extent the type of frame most suitable. Some lenses are too thick to fit into metal rims, and some large-correction prescriptions are best suited to frames with small-area lenses, since a smaller lens area minimizes the thickness of a lens with a large correction for myopia.

Rimless frames are the least noticeable type, and they are lightweight because they have only an upper rim to which the nosepiece and temples are attached. The lenses are held in place in the frames by nylon string that encircles the bottom of the lenses and attaches to the upper rim.

Metal frames are less noticeable than plastic and are lightweight. They are available in solid gold, gold-filled, anodized aluminum, nickel, silver, stainless steel, titanium, and titanium alloy. Until the late 1980s, when titanium-nickel alloy and titanium frames were introduced,

metal frames were, in general, more fragile than plastic frames. The titanium frames, however, are very strong and lightweight. An alloy of titanium and nickel, called Flexon, is strong and lightweight and returns to its original shape after being twisted or dented. It is not perfect for everyone, though, because some patients are sensitive to nickel.

Plastic frames are durable, can accommodate just about any lens prescription, and are available in a wide range of prices. They are also offered in a variety of plastics (including acrylic, epoxy, cellulose acetate, cellulose propionate, polyamide, and nylon) and in different colors, shapes, and levels of resistance to breakage. Epoxy frames are resilient and return to their original shape after being deformed, so they do not need to be adjusted as frequently as other types. Nylon frames are almost unbreakable. They revert to their original shape after extreme trauma and distortion; because of this property, though, they cannot be readjusted after they are manufactured.

Preparation

Before eye glasses are prescribed, an optometrist or an ophthalmologist examines the patient's eyes. The exam begins with the physician or ophthalmic assistant taking a detailed medical history from the patient. Then the physician, or in some cases a highly trained ophthalmic assistant, begins the ocular examination by measuring visual acuity and refracting.

During the exam, the physician or ophthalmic assistant also determines ocular motility and alignment, near-point of convergence, near fusional vergence amplitudes, relative accommodation measurements, and accommodative amplitude and facility. Corrective lens prescriptions, if necessary, are then given to patients.

To be correctly fitted for eye glasses, the distance between the patient's eyes (PD) is measured, so that the optical centers of the lenses correlate with the pupillary axis. Bifocal heights also are measured with the chosen frame in place and adjusted on the patient. If not positioned correctly, the patient may experience eyestrain or will not have the optimal visual results.

After the eye glasses are ready for the patient, the dispensing optician, physician, or ophthalmic assistant ascertains the proper fit to ensure the best vision and comfort.

Patients may sometimes need up to two weeks to adjust to a new prescription. However, if problems persist the glasses should be rechecked.

Presbyopic patients may choose over-the-counter reading glasses instead of professionally prescribed eye

glasses. These patients should be advised that the distance between the lenses in these glasses is for a "standard" person. If a patient is sensitive or has more closely set eyes, for example, blurred vision and headaches may result from the use of these glasses. In addition, the prescriptions are equal for both eyes, these glasses do not correct for astigmatism, and they are made with cheaper lens and frame materials. As a result, these over-the-counter reading glasses may not be a patient's best option.

Aftercare

Patients are advised to return to the physician's office if they experience headaches or blurred vision. If these symptoms do not occur, they are instructed to return to the office for a regular **eye examination** in one or two years.

Complications

Matching an individual with the correct frames and lenses usually avoids complications. Ensuring that the lenses are positioned properly will greatly reduce the likelihood of headaches and blurred vision. A thorough patient history minimizes the chance that the patient will select a frame that causes sensitivities or lenses that could harm his or her eyes.

Results

It is normally expected that people will achieve 20/20 vision while wearing corrective lenses.

Health care team roles

Nursing and allied health professionals assist with eyeglass examination and fitting, and with **patient education**. With advances in refracting technology, technicians now have duties that previously were performed only by optometrists or ophthalmologists.

Ophthalmic assistants and technicians facilitate the fitting process by recording the pertinent patient history and measuring the eye for the proper lens fit. Advanced- and intermediate-level ophthalmic technicians perform refractions and determine the patient's depth perception. These professionals also may perform corneal topography (mapping). Some of these professionals seek certification through the American Board of **Opticianry** and the National Contact Lens Examiners or other organizations. These organizations offer seminars and testing that help professionals keep current with technological advances in refracting and eyeglass manufacturing.

Patient education

Patients are told that it may take up to two weeks to adjust to new eye glasses. They also are advised to return to the physician's office if they experience blurry vision and headaches.

AR-coating and other specialized lens coatings need special care to maintain the coat and prevent scratching. Patients are told to carefully clean their lenses with special cloths and cleaners obtained from the physician or optician, never to use paper towels or harsh soap.

Training

Optometrists and ophthalmologists receive training in **optometry** or during a medical residency for these procedures. In some practices, ophthalmic personnel complete part of the eye exam. Ophthalmic assistants, technicians, and nurses can complete specialized training from certified programs to learn how to refract and complete other parts of the eye exam. Opticians receive training in creating lenses.

KEY TERMS

Astigmatism—A vision condition that occurs when the cornea is slightly irregular in shape. This irregularity prevents light from focusing properly on the retina.

Cornea—The clear outer covering of the front of the eye.

Index of refraction—A constant number for any material that is an indicator of the degree of the bending of the light caused by that material.

Lens—A device that bends light waves.

Polycarbonate—A very strong type of plastic often used in safety glasses, sport glasses, and children's eye glasses. Polycarbonate lenses have approximately 50 times the impact resistance of glass lenses.

Presbyopia—A condition affecting people over the age of 40 where the system of accommodation that allows focusing of near objects fails to work because of age-related hardening of the lens of the eye.

Retina—The inner, light-sensitive layer of the eye containing rods and cones; it transforms the image it receives into electrical messages sent to the brain via the optic nerve.

Ultraviolet (UV) light—Part of the electromagnetic spectrum with a wavelength just below that of visible light. It is damaging to living material, especially eyes and DNA.

Eyedrop instillation

Definition

Eyedrop instillation is the dispensation of a sterile ophthalmic medication into a patient's eye.

Purpose

Eyedrops may be instilled to treat a number of eye disorders or to anesthetize an eye before treatment. An ophthalmic assistant, technician, nurse or physician instills eyedrops during a routine **eye examination** or during treatment for ocular disease. Anesthetic eyedrops are instilled before surgery on the eye. Sometimes ophthalmic professionals instill dyes to help diagnose ocular disease, either by traditional methods, or by intravenous administration, or by the use of strips.

Eyedrops or ophthalmic solutions are used to treat **glaucoma**, uveitis, allergic reactions and infections. Dilatory eyedrops may be instilled during an examination to achieve a better view of the retina.

Precautions

Health care professionals need to ensure that the proper drug is being instilled and that it has not passed its expiration date. Some ophthalmic solutions may be contraindicated or can cause allergic reactions. Eyedrop containers should be clearly labeled and checked before instillation.

The eyedrops should also be monitored for discoloration or sedimentation, which indicate that the ophthalmic solution is decomposing. In that case, a new dose of medicine should be obtained and the affected bottle discarded.

Moreover, the ophthalmic staff member dispensing the drops should double-check the patient's identification and chart to ensure the correct dose is being instilled into the correct eye. The dispensing ophthalmic professional should never touch the tip of the eyedropper to the patient's eye. Touching will contaminate the remaining medication. In case of direct eye contact, the medication should be thrown away.

Description

Sterilization is an important part of eyedrop instillation. Before eyedrops are instilled, the ophthalmic assistant, technician, nurse, optometrist, or ophthalmologist should wash his or her hands thoroughly. The ophthalmic staff member then should gather all necessary supplies. For some eyedrops, the dispenser may want to warm the

drops to body temperature by holding the bottle in his or her hand for about two minutes.

Next, the dispenser should position the patient correctly. The patient should sit back in the examination chair with their head slightly hyperextended. Once the patient is correctly positioned, the dispenser should clean the eyelids from the inner canthus outward with a sterile saline solution to remove any eye secretions or previously instilled medications. The dispenser should wash their hands after these preparations are completed.

Immediately before instillation, the dispenser should depress the patient's lower lid with the finger of one hand and lightly pinch the patient's lower lid to make a pouch for the medication. The upper lid should also be held open to prevent blinking during instillation. The dispenser should tell the patient to look up. Using the other hand, the dispenser should instill the drop into the everted lower lid. The drops should not be instilled on the cornea. This precaution is necessary to avoid startling the patient, or causing unnecessary **pain**.

After the appropriate amount of medication is instilled, the ophthalmic professional should release the lid and remove any excess fluid. The patient should be told to gently close their eyes so as to not release any medication. If another medication is to be instilled, a delay of at least 30 seconds is required between instillations.

Preparation

Patients should have the procedure explained to them before instillation to ensure best results. If patients are treated for certain eye ailments such as conjunctivitis, they should be warned in advance not to wear **contact lenses** or eye makeup.

Before instillation, the ophthalmic staff should double-check the dosage and type of medication. They should also wash their hands thoroughly.

Aftercare

Patients who will be dispensing their own eyedrops after the initial treatment need careful instructions on proper instillation. Allied health professionals should guide patients step by step through the procedure to ensure maximum benefit from the medication.

If patients are treated for infections or conjunctivitis, they should be advised to wash their hands regularly; avoid touching their eyes; avoid wearing eye makeup or contact lenses; and to discard any eye drops or eye makeup used before treatment for the **infection** began. Follow-up appointments for further treatment may also be necessary.

Glaucoma patients using eyedrop medications should be monitored to determine if the drops are effective. Many times a combination of drops is necessary to treat glaucoma.

Complications

Eyedrops cause irritation in some patients that might result in eye redness or burning. Stronger medications can cause more extreme allergic symptoms, such as dizziness and disorientation. Some cycloplegic drops can cause such severe reactions as delirium, a rapid pulse, and difficulty swallowing. Patients should be monitored after instillation, and health care professionals should record any side effects.

Results

Properly instilled eyedrops should effectively treat a number of eye disorders. Dilatory drops facilitate eye refraction and retinal examination.

Health care team roles

Nursing and allied health professionals are usually responsible for eyedrop instillation. Ophthalmic assistants, technicians and nurses ensure that the proper dosage is administered to the correct patient, the medication is fresh, the medication and eyedropper are sterile and in good condition, and the patient is told step-by-step how the procedure is performed. The allied health professional may also need to repatch an affected eye, monitor patients for side effects, chart medications for each patient, and dispose of (used) equipment.

KEY TERMS

Canthus—Either of the angles formed by the meeting of an eye’s upper and lower eyelids.

Conjunctivitis—Inflammation of the thin membrane covering the eye. It is caused by bacteria, virus, allergies, etc.

Cornea—The clear outer covering of the front of the eye.

Cycloplegic drops—Drops used to dilate the pupil and paralyze the eye’s powers of accommodation.

Drops—A term for a liquid medicine taken in specific doses and usually applied by a dropper.

Glaucoma—An eye disease in which increased pressure within the eyeball can result in damage to the optic disk and a loss of vision.

Ophthalmic solutions—Sterile solutions for instillation in the eye.

Uveitis—Inflammation of the uvea. The uvea is a continuous layer of tissue that consists of the iris, the ciliary body, and the choroid. The uvea lies between the retina and sclera.

Fad diets

Definition

According to the United States Surgeon General's Report on **Nutrition** and Health, fad diets include "the promotion for profit of special foods, products, processes, or appliances with false or misleading health or therapeutic claims."

Purpose

Fad diets are generally used by consumers to shed a great amount of weight in a short period of time. They are usually based on the erroneous belief that a particular food or food component can cause rapid weight loss or cure a disease. Another tenet of fad diets is that certain foods are harmful and therefore should be avoided completely.

Precautions

Fad diets usually result in a short-term weight loss—but most people gain the weight back after discontinuing the diet. The American Dietetic Association (ADA) has established a few guidelines to help evaluate the reliability of fad diets. They suggest that consumers avoid diets that claim weight loss can be achieved in a very short period of time; that imply that weight can be

lost without any physical activity; or that rely on undocumented studies.

The most reliable way to lose weight safely and maintain weight loss is by eating a variety of foods and exercising consistently. Dieters who follow the guidelines set by the ADA, which include eating a variety of foods, balancing food intake with **exercise**, choosing a variety of fruits and vegetables, limiting saturated fat and cholesterol, and keeping total fat intake to a moderate level will have a healthy lifestyle—which when adhered to will ultimately aid in weight management. Many fad diets, for example, counsel dieters to eliminate certain foods or to eat one specific food for a long period of time. This approach does not promote healthy eating habits, nor does it augur well for permanent weight loss.

Description

Fad diets have been promoted and used for many years. Some of the most popular fad diets today include high-protein diets, liquid diets, the grapefruit diet, food-combining diets, the cabbage diet, and a variety of diet pills.

High-protein diets

High-protein diets began in the 1970s, based on the theory that too many **carbohydrates** in the diet interfere with the body's ability to burn fat. This diet encourages the consumption of large quantities of protein-rich foods such as meat, fish, shellfish, eggs, poultry, and cheese. Some popular high-protein diets include the Atkins diet, the Zone, and the protein-power diet.

Liquid diets

Liquid diets actually began in the early 1930s, but gained more popularity in the 1970s when commercial meal-replacement health shakes began to hit the market. SlimFast and Nestlé Sweet Success are two brands of health shakes that are usually consumed as a replacement

KEY TERMS

Ketones—Acidic by-products of fat breakdown that alter the acid-base balance of the blood.

Nitrogen—A component of protein that is highly toxic when too much protein is consumed and the kidneys are unable to process and excrete it.

Saturated fat—Type of fat that is usually solid at room temperature.

for two meals and a snack during the day. Health shakes normally provide about 200 calories each, with the last meal of the day consisting of low-fat, nutrient-dense foods that offer another 600 calories.

The grapefruit diet

Grapefruit is essentially a fat-free, low-calorie, low-sodium food that is high in **vitamin C**, beta-carotene, and fiber. The grapefruit diet began in the 1930s, when the Hollywood diet made its debut. This regimen consisted of a few vegetables, a small amount of protein, and a grapefruit (which was thought to possess a fat-burning enzyme) at every meal. It is usually followed for a period of three weeks. The diet provides only 800 calories per day, which makes the possibility of weight loss very likely.

Food-combining diets

Food-combining diets are based on the mistaken idea that carbohydrates and **proteins** should not be consumed at the same time, and that fruit should not be eaten with proteins or carbohydrates. There are a variety of food-combining diets, but most recommend eating large portions of fruit for the first several days, which is thought to burn up calories before the body metabolizes them. A few carbohydrates and very little protein are then added during the last part of the diet.

The cabbage soup diet

The cabbage soup diet is a more recent fad that results in a significant amount of weight loss from shedding water. It consists of eating cabbage soup, which contains cabbage, onions, green peppers, tomatoes, celery, and water, for one week. Each day as much soup is eaten as desired, along with one specified food, which can also be eaten in unlimited amounts. The cabbage does not burn fat, but it does promote a sense of fullness.

Diet pills

Diet pills and prescription drugs have become one of the most marketable tools against **obesity**, but their safety and effectiveness is questionable. Both diet pills and prescription drugs can reduce appetite and promote fullness by changing **brain** chemicals. Prescription drugs should be an option only for people who are significantly overweight.

Complications

High-protein diet

This type of diet does slow the rate of carbohydrate absorption, which helps control blood sugar levels and promotes a feeling of fullness. However, high-protein diets also tend to be high in saturated fat and cholesterol, which can contribute to **heart** disease. When high-protein diets are followed for a very long time, they cause the body to burn excessive amounts of fat for fuel. This releases chemicals called ketones into the bloodstream, causing dizziness, headaches, nausea, and bad breath. Too much protein also places extra work on the **kidneys**, forcing them to work harder to excrete the nitrogen present in protein. They also create extra work for the **liver**, which must break the protein compounds into individual amino acids.

Liquid diets

While liquid diets are often convenient and easy to prepare, the transition back to solid foods can lead to weight gain.

Grapefruit diet

While this diet is very low in calories and almost guaranteed to result in some weight loss, limiting dieters to such a small amount of food is very restrictive and eliminates such vital nutrients as **calcium**, **iron**, **folic acid**, and other **vitamins**.

Food-combining diet

Since fruits are so low in calories, it is possible to lose a significant amount of weight in a short period of time. Due to the protein restriction, however, muscle and organ tissues may be broken down for energy.

Cabbage-soup diet

This diet can cause bloating, gas, nausea, and lightheadedness after a few days. It is not recommended by health professionals; but since soup is usually a low-calorie food, eating this soup in conjunction with a healthy diet consisting of a variety of foods can facilitate a healthy weight loss.

Diet pills

These compounds may help start weight loss, but their benefit usually plateaus after a year, after which their effect declines. In addition, they can strain the heart by increasing **blood pressure** and heart rate.

Results

While each of these diets may result in a temporary weight loss, most are unhealthful and deprive the body of needed nutrients. Most dieters regain the weight after they stop following the diet.

Health care team roles

The American Dietetic Association, the United States Surgeon General, the National Academy of Sciences, and the American Heart Association all employ qualified professionals who can educate consumers on the advantages and disadvantages of fad diets. While certain components of fad diets may aid in weight management when used in conjunction with a healthy lifestyle, it is not recommended that they be used alone. People must understand that behavior modification is the most effective way to lose weight and keep it off. Through physical exercise, eating a variety of nutritious foods, and consciously changing eating habits, weight loss can be achieved and maintained.

Falls

Definition

Falls are a common source of injury, particularly in the elderly population. They are more likely to occur if impairments in balance, strength, perception, joint range of motion, postural function or coordination are present. Serious injury from falls, such as **fractures**, occur commonly in people with **osteoporosis**, a common degenerative disease involving loss of bone mass. Hip fracture is one of the most serious potential consequences of a fall, with a mortality rate as high as 20%.

Description

Falling is a serious health problem in the United States, especially for the elderly. According to the National Center for Injury Prevention and Control, one in every three adults 65 years of age and older falls each year, with an increasing incidence as a person ages. Falls can result in serious injury, not only posing a burden on the individual who falls, but also on family members and the health care system.

Causes and symptoms

Falls can often be attributed to environmental hazards. Icy sidewalks and uneven terrain are common dangers. In the home, climbing on unstable step stools, sliding in wet showers, or slipping on throw rugs are frequent causes of falls.

Medical factors can also make falls more likely to occur. Orthostatic hypotension, sensory loss, stroke, **dementia**, medications, and neuromuscular disease increase the risk of falling. Deficits in strength, joint range of motion, coordination, sensory perception, and **vision** may further impair balance. Osteoporosis, common in the elderly population, makes a fall more likely to result in serious injury.

Diagnosis

Individuals who are at risk of falling because of a medical condition or medications need to be routinely

Falls among people 65 years of age and older

Falls are the leading cause of accidental deaths in persons over 65 years of age.

Falls are the seventh leading cause of death among people older than 65 years.

In the United States 75% of deaths from falls occur in the 12% of the population that is older than 65 years.

From 75 years of age the rate of death from falls rises for both genders and all racial groups.

Thirty-three percent of healthy community-dwelling elders (older than 65 years) fall annually.

Sixty-seven percent of nursing home residents fall annually.

Between 33% and 67% of older patients in hospital-like environments fall annually.

Complications from falls or prolonged floor contact after falls include fear of falling, dehydration, pressure sores, hypothermia, pneumonia, and rhabdomyolysis.

Whites who fall have twice the hip fracture rate as persons from other racial groups.

Five percent of falls among older people will result in fractures.

The most common fractures as a result of falls among the elderly are humeral, wrist, pelvis, and hip, with the presence of osteoporosis making fractures more likely.

Ten to twenty percent of falls among older people will result in soft-tissue injuries, with 50% of these requiring medical care.

Falls contribute to 40% of admissions to nursing homes.

Seventy percent of emergency room visits by people older than 75 years are due to falls.

SOURCE: National Center for Health Statistics, 1980, 1984.

tested for instability during functional activities. The following characteristics should also be assessed:

- balance
- strength
- sensation
- vision
- joint range of motion
- **hearing**
- postural awareness
- gait

Balance

Balance testing can be done in a rehabilitation facility to assess people's ability to transfer weight and control their center of gravity. Numerous tests such as the Berg balance assessment, functional reach test, get-up-and-go test, and Tinetti tests are useful in a balance evaluation.

Strength

Strength testing should be done to identify weakness, strength asymmetry between sides, and muscle strength imbalance within the same limb.

Sensation

Sensation testing of the lower extremities assesses light touch, pressure, and limb awareness.

Vision

Vision should be assessed by a licensed professional. If corrective lenses are indicated, they should be used during further testing, such as balance and gait assessment.

Joint range of motion

Joint motion assessment evaluates the loss of range of motion and its relationship to impairments in transfers and gait.

Hearing

If **hearing loss** is suspected, it should be tested and corrected, if possible, before rehabilitation is addressed.

Postural awareness

In a rehabilitation center, individuals can be put through a battery of tests that assess perception of the center of gravity with relation to the environment. Specific tests include postural sway tests and perturbation tests.

Gait

Walking can be evaluated by direct observation to assess for gait abnormalities. If a severe gait disturbance is present, further gait analysis using motion analysis, force platforms, and **electromyography** should be done.

Treatment

Individuals who have fallen may have such injuries as fractures, dislocations, bruising, cuts to the skin, and muscle tears that may require casting, surgery, or hospitalization, depending on the severity. Initiation of life-long medications for osteoporosis to reduce the rate of further bone loss may be indicated. Most people, including the frailest elderly, can usually benefit from an **exercise** program that includes strengthening and balance components. Assistance in regaining confidence may also be needed.

Someone who has fallen, once medically stable, needs to be evaluated for:

- balance
- strength
- sensation
- vision
- joint range of motion

- hearing
- postural awareness
- gait

If deficits are noted and the reason for the fall is clear, a treatment plan can be developed that may include:

- balance training
- strength training
- aerobic exercise
- sensory integration
- correction of vision
- change in medication
- flexibility exercises
- hearing aids
- postural exercises
- patient education
- family and caregiver education
- analysis of environmental barriers
- gait retraining

Treatment may include the fabrication of an orthotic for lower limb dysfunction; prescription of an assistive device such as a cane or rolling walker; and education to the patient or caregiver regarding safety in the home.

Prognosis

How quickly and completely a patient recovers after a fall depends on the extent of the injury, the patient's medical condition prior to the fall, and the rehabilitation program. A positive attitude and adequate social support can be critical factors to a patient's recovery. Regaining mobility is critical, especially for the elderly patient who rapidly loses strength and function when immobile. A severe injury such as hip fracture has high morbidity and mortality, partially due to the long bed rest required after the injury.

Health care team roles

Nurses and other allied health professionals need to coordinate rehabilitation activities in an effort to integrate all facets of rehabilitation with functional activities. The rehabilitation team must take an active role in patient, caregiver, and family education, specifically related to restoring mobility and preventing falls in the home.

KEY TERMS

Coordination—The ability to do activities with precision and proficiency.

Electromyography—An evaluation tool that can detect electrical activity of muscles during an activity.

Force platform—A large plate, usually mounted in the floor, that records forces when an individual stands or walks on it.

Motion analysis—Use of an instrumented system to record whole-body and joint movement for later analysis.

Perturbation tests—Tests in which the patient stands on a platform, and a small, rapid movement of the platform is used to disturb balance. Forces and sway are recorded as the individual loses balance and then recovers.

Sensory perception—The ability to perceive touch, pressure, pain, and joint position in the limbs and trunk.

Transfers—The movement from one position to another, such as sit-to-stand, supine-to-sit, wheelchair-to-toilet, etc.

Prevention

Individuals, especially the elderly, should take the following steps to minimize their risk of falling:

- Take someone's arm when icy or slippery surfaces cannot be avoided.
- Remove loose rugs from floors.
- Use only steady stepstools with hand supports when additional height is needed.
- Install hand rails on stairs.
- Wear good walking shoes.
- Assess the home for small objects and cords that can be tripped on as well as unstable pieces of furniture.
- Install grab bars next to toilets and in showers.
- Evaluate home lighting. Use night lights in bathrooms and between the bedroom and bathroom.
- Have vision and hearing checked regularly.
- Report dizziness, fainting, unusual sensations, or sudden loss of function to a physician at once.

- Engage in daily exercise that incorporates aerobics, weight training, and balance and coordination exercises.

Fats, dietary

Definition

Dietary fats are one of the three forms of energy-giving nutrients, providing a rich source of energy.

Purpose

Fats or **lipids** carry unique properties; they are packed with calories (9 kcal per gram, more than double the amount in protein and carbohydrate), and because they are insoluble in water, they help with the absorption and transport of the fat-soluble **vitamins** A, D E, and K. Dietary fat not required immediately for energy is stored in layers of fatty tissue under the skin and around internal organs, where it can be called upon for energy. Fats contain about 95% triglycerides, which are lipids consisting of three fatty acid chains.

Besides providing energy and essential fatty acids necessary for **brain** development and proper growth, dietary fats get considerable attention because of their association with coronary **heart** disease (CHD) and stroke, leading causes of death in the United States. Atherosclerosis, the underlying cause in both, involves changes in the innermost layer of the large arteries. Atherosclerosis often begins in childhood, and while many factors play roles, lesions called plaque form from fat deposits and such other materials as **calcium** and fibrin.

According to a U.S. Department of Agriculture (USDA) food consumption study, fat intake peaked to 70 lb (31.75 kg) per person between 1970 and 1993. Since then, levels have dropped slightly, to around 66 lb (29.9 kg); but one concern is the rising percentage provided by added fats and oils from fried food and snack foods. Current recommendations state that total fat intake should comprise less than 30% of total calories, and saturated fat less than 10%. For a 1500-calorie diet, this standard means less than 1.76 oz (50 g) total fat and 0.59 oz (17 g) saturated fat; for 2500-calorie diets, it is 2.92 oz (83 g) and 0.98 oz (28 g), respectively. People can refer to food labels, which list these amounts.

Precautions

Research shows that two types of dietary fats in particular, saturated fats and trans fats, raise **blood** cholesterol, which increases CHD risk.

Description

The major fats in foods are saturated, polyunsaturated, monounsaturated and trans fatty acids, which are discussed below.

- Saturated fatty acids (SFA) or saturated fats get their name because they hold the maximum number of hydrogens possible in their chains. In general, the longer and more saturated the chain, the harder the fat is at room temperature. Coconut oil is an exception. Foods contain a mixture of fatty acids, but SFA are concentrated in certain animal and vegetable foods, such as beef, chicken, pork, dairy products, palm and coconut oil. Reducing dietary SFAs has the biggest effect on decreasing blood cholesterol.
- Monounsaturated fatty acids (MFA) are getting good press in the fat world, with many experts advocating the Mediterranean eating style that is high in olive oil, fish, and vegetables. Mediterranean countries have low CHD incidence, but it is unknown how much other factors play a role. MFAs lower blood cholesterol when they replace SFAs. Aside from olive oil, other high MFA foods include canola oil, peanut and peanut oil, such nuts as pecans and almonds, and avocados.
- Polyunsaturated fatty acids (PUFA), such as margarine and sunflower oil, were recommended during the 1980s for lowering blood cholesterol. However, research shows PUFAs can lead to toxic products that promote cardiovascular disease, so heavy intake is not recommended. High sources include vegetable seeds and their oils. Research on a type of PUFA called omega-3 fatty acid is demonstrating benefits in such

inflammatory disease as rheumatoid arthritis and atherosclerosis. Seafood contains the most omega-3s, although tofu, soybean, canola oil and nuts all contain one type of omega-3. Two PUFAs, linoleic acid and α -linolenic acid, are called essential fatty acids because they cannot be synthesized in the body. If linoleic acid replaces other forms of fatty acid in the diet, then low-density lipoprotein (LDL) cholesterol decreases and high-density lipoprotein (HDL) cholesterol increases. If linoleic acid replaces saturated fat, total cholesterol decreases but HDL levels also decrease. Safflower oil has the most linoleic acid. α -linolenic acid comes mainly from fish oils. It results in decreased production of triglycerides but has little effect on total cholesterol levels.

- Trans fatty acids are the latest “bad guys,” with recent research showing they raise blood cholesterol. Trans fats are high in processed food products, in which manufacturers add hydrogen to liquid oils (hydrogenation) to increase stability. Major sources include stick margarine, commercial baked goods, and the frying fats used in most snack foods, restaurants and fast-food chains. Food labels will list trans fats as hydrogenated or partially hydrogenated fats. Healthy people should eat no more than 10% of total calories as saturated fats and trans fats. For those with CHD, diabetes or high LDL cholesterol, this percentage drops to 7%.
- Other types of dietary fats exist, including lecithin and cholesterol. Cholesterol, an essential component in brain and nerve cells, is found in animal foods, but is also produced and stored in the **liver**. The role of dietary cholesterol in blood cholesterol levels and CHD is less clear than in the past. Meat, poultry, seafood, egg yolks and dairy products all contain cholesterol, while plant foods such as fruits, vegetables, grains, nuts and seeds do not. Americans should not exceed the recommended level of 0.1 oz (300 mg) per day. The average American woman eats 0.07 oz (217 mg) cholesterol daily, the average man 0.12 oz (337 mg).

Complications

Treating high lipids

If a person’s blood lipid levels are high, dietary treatment is often initiated to lower the low density lipoprotein fraction and total blood cholesterol levels. Current American Heart Association recommendations include reducing saturated fat to less than 7% of calories; limiting cholesterol to < 200; losing weight if appropriate; and increasing soluble fiber to 0.35–0.88 oz (10–25 g) per day. High-density lipoprotein (HDL) levels, also

KEY TERMS

Atherosclerosis—Sclerosis or hardening and thickening of the arterial wall, causing a loss of elasticity.

Coronary heart disease (CHD)—A disease involving the blood vessels surrounding the heart; also called coronary artery disease (CAD).

High-density lipoprotein (HDL)—A plasma lipoprotein containing mostly protein and less cholesterol and triglyceride; high levels of HDL lower CHD risk.

Low-density lipoprotein (LDL)—The major cholesterol carrier in the blood, with high levels associated with increased coronary heart disease risk.

Fatty acid—Fatty acids are a group of carbon chains that make up fat. The body requires some, called essential fatty acids, to form membranes and synthesize important compounds.

Lipids—A group of compounds that include fats, oils and related compounds found in foods and the human body.

Omega-3 fatty acids—Named because their first double bond occurs at the third carbon from the methyl end, the three omega-3s (EPA, LNA and DHA) are believed to benefit inflammatory diseases.

Monounsaturated fatty acid (MUFA)—A fatty acid containing one double bond, which lowers plasma cholesterol when replacing SFAs and is believed to be safer than polyunsaturated fats.

Polyunsaturated fatty acid (PUFA)—A fatty acid that is liquid at room temperature, lowers plasma cholesterol when replacing SFAs, but too much can promote cardiovascular disease

Saturated fatty acid (SFA)—A fatty acid that has no double bonds, is solid at room temperature, and raises blood cholesterol levels.

referred to as the good cholesterol, is related more to genetic and other factors than to diet, although moderate alcohol consumption raises HDL.

Some people also have high plasma triglyceride (TG) levels, which accumulating evidence is showing may be an important heart disease risk factor. Dietary guidelines involve low simple sugars, low-saturated fat diets, restricted alcohol and weight loss if indicated. Drug therapy is often initiated.

Results

A diet containing 30% or less fat is considered compatible with good health. Diets with dietary fat intakes below 15% can negatively affect blood lipids in some people. For people with high blood lipid levels, dietary fat management goals involve moving the total cholesterol and LDL levels to normal. However, because diet modification lowers serum cholesterol levels by about 10–15%, patients whose blood levels remain high often seek drug therapy.

Health care team roles

- Registered dietitians are often sought out by patients and health professionals to assess fat intake and instruct on diet modifications, and for those seeking weight loss through dietary fat restriction.
- Nursing and allied health professionals can provide health histories and check laboratory test results for potential treatment. The American Heart Association provides dietary guidelines and **patient education** materials. All health professionals can play important roles in educating the public about dietary fat.

Fecal impaction removal

Definition

Fecal impaction removal is the digital (using the finger) means of breaking up and removing a fecal impaction, or mass of hardened, clay-like stool lodged in the rectum.

Purpose

Fecal impaction is the result of extreme constipation. As the patient is unable to expel the stool, it further accumulates into a larger, harder mass that is impossible to pass by normal defecation. This accumulated stool can

extend up into the sigmoid colon, the loop of large bowel above the rectum. Impaction is most common in inactive elderly people, but there are other causes beside inactivity. Among the other causes are:

- medications, including **antacids** that have aluminum as an ingredient; **calcium** and **iron** supplements; a category of anti-hypertensive drugs known as calcium channel blockers; allergy medicines (**antihistamines**); such psychotropic medications as antidepressants and tranquilizers; such hormones as estrogen and progesterin; and medications to reduce spasms such as those used in treating Parkinson's disease
- poor bowel habits; not having a regular schedule for evacuating the bowel
- inadequate fluid intake
- a diet that is lacking in such fibers as bran, fruit, and vegetables
- such rectal disorders as rectocele

In addition to the discomfort this condition creates, untreated fecal impaction can also become a serious health problem, producing a chronically over-dilated bowel, or megacolon, that can require surgical correction. It is possible for rectal tissue to become damaged, ulcerated, or even necrotic (lose its **blood** supply due to the pressure of the stool). The most serious potential complication is that the lower bowel can become completely obstructed. Such intestinal obstruction is potentially fatal.

The possibility that the patient has a fecal impaction should be considered if he or she shows any or all of the following symptoms:

- complaints of inability to have a bowel movement despite frequently feeling the urge to defecate
- upon defecation, the stool appears to be either **diarrhetic** or thin and pencil-like
- abdominal pain
- bloating and a swollen or hard abdomen
- anorexia, or lack of appetite; nausea; and vomiting
- complaints of general malaise, or not feeling well
- the presence of hard stool in the rectum
- increased restlessness in patients suffering from **Alzheimer's disease** or other forms of dementia

Precautions

This digital breaking up and removal of impacted stool can potentially damage the mucous membrane linings in the bowel, and the stimulation to the vagus nerve that has endings in the rectum can cause **heart** irregular-

ities. It is therefore a procedure that is undertaken only with extreme caution. Most often, nurses remove fecal impactions upon receiving a physician's order, or under a physician's supervision.

Description

As gently as possible, the nurse inserts a gloved, lubricated index finger and massages around the edges of the impaction, gradually working the gloved finger into the mass to break it up. The broken-up pieces of stool are dislodged by carefully working them downward toward the end of the rectum. During this procedure, the patient should be checked regularly to assure that there are no untoward effects such as weakness, diaphoresis or clamminess, or changes in pulse rate.

Preparation

The nurse positions the patient on his or her side, with knees flexed and back toward the nurse. A waterproof pad is placed under the patient's buttocks, and a bedpan to hold any removed stool is kept nearby. Occasionally, a patient will request to stand in the bathroom near the toilet during this procedure, but that is not advisable due to possible adverse reactions and the fact that this can be an exhausting process. The nurse then puts on rubber gloves and applies lubricant to the index finger that will be inserted to break up the impaction. Explanation of what is to be done, and reassurance that if the procedure is causing discomfort it will be stopped immediately, should be given before beginning.

Aftercare

After the disimpaction is completed, it may be necessary to administer an enema or give a suppository to complete the stool removal. The most important aspect of care is the prevention of the reoccurrence of problems with elimination.

Complications

Vagus nerve stimulation, causing cardiac irregularities with possible fainting or weakness, is the most serious potential complication. However, rectal bleeding, the result of trauma to the bowel mucosa, can also occur.

Results

Expected results will be the removal of the hardened stool from the patient's rectum, making the patient much more comfortable.

KEY TERMS

Megacolon—A massively swollen colon, usually associated with severe and chronic constipation that can exist as a congenital condition or develop later in life.

Sigmoid colon—The S-shaped part of the colon, part of the large intestine, positioned between the descending colon and the rectum.

Vagus nerve—The tenth and longest cranial nerve, responsible for control of the heart and other internal organs.

Health care team roles

This procedure is rarely undertaken, as normally health care staff try to prevent the occurrence of fecal impaction through medications, diet, and such treatment as **enemas** or suppositories. Such prevention is desirable due to the risks involved. However, if fecal impaction removal must be done, it should be done only by a physician or nurse, as they should be aware of the possible untoward effects.

- A nurse will normally be the person who actually removes impacted stool.
- Both registered nurses (RNs), or licensed practical nurses (LPNs) must complete a prescribed course in nursing and pass a state examination. RNs typically have a degree in nursing. If the physician does not disimpact the patient, usually it will be the job of a RN. However, in some situations, a LPN may be the person responsible for carrying out this procedure.

Fecal incontinence

Definition

Fecal incontinence is the inability to control the passage of gas or stools (feces) through the anus. For some people, fecal incontinence is a relatively minor problem that is limited to a slight occasional soiling of underwear, but for others it involves a considerable loss of bowel control. This loss can have a devastating effect on a patient's quality of life and psychological well-being. Fortunately, professional medical treatment is usually able to restore bowel control or at least substantially reduce the severity of the condition.

Description

Fecal incontinence, also called bowel incontinence, can occur at any age, but is most common among people over the age of 65, who sometimes have to cope with urinary incontinence as well. The condition is more common among women than men. The problem affects as many as 6.5 million Americans.

The wider **public health** impact of fecal incontinence is considerable. In the United States, more than \$400 million is spent each year on disposable underwear and other incontinence aids. Fecal incontinence is the second most common reason for seeking a nursing home placement. One-third of the institutionalized elderly suffer from this condition. Incontinence sufferers, however, often hesitate to ask their doctors for help because they are embarrassed or ashamed.

Causes and symptoms

Fecal incontinence can result from a wide variety of medical conditions, including childbirth-related anal injuries, other causes of damage to the anus or rectum, and nervous system problems.

Vaginal-delivery **childbirth** is a major cause of fecal incontinence. In many cases, childbirth results in damage to the anal sphincter, which is the ring of muscle that closes the anus and keeps stools within the rectum until a person can find an appropriate opportunity to defecate. Nerve injuries during childbirth may also be a factor in some cases. A study in 2000 by the Brigham and Women's Hospital in Boston, Massachusetts, found that women who had episiotomies were at higher risk for postpartum fecal incontinence. Childbirth-related incontinence is usually restricted to gas, but for some women it involves the passing of liquid or solid stools.

The removal of hemorrhoids by surgery or other techniques (hemorrhoidectomies) can also cause anal

damage and fecal incontinence, as can more complex operations affecting the anus and surrounding areas. Anal and rectal infections, as well as **Crohn's disease**, can lead to incontinence by damaging the muscles that control defecation. New-onset fecal incontinence can also be a sign of **colorectal cancer**. For some people, incontinence becomes a problem when the anal muscles begin to weaken in midlife or old age.

Dementia, mental retardation, strokes, **brain tumors**, **multiple sclerosis**, and other conditions that affect the nervous system can cause fecal incontinence by interfering with muscle function or the normal rectal sensations that trigger sphincter contraction and are necessary for bowel control. One study of multiple sclerosis patients discovered that about half were incontinent. Nerve damage caused by long-lasting **diabetes mellitus** (diabetic neuropathy) is another condition that can give rise to incontinence.

Diagnosis

Medical assessments in cases of fecal incontinence typically involve three steps: assessing the patient's medical history; performing a **physical examination** of the anal region; and testing for objective information regarding anal and rectal function.

Medical history

The medical history relies on questions that allow an evaluation of the nature and severity of the problem and its effect on the patient's life. The information obtained may include: how long the patient has been suffering from incontinence; how often and under what circumstances incontinence occurs; whether the patient has any control over defecation; and whether the patient has obstacles to defecation in his or her everyday surroundings, such as a toilet that can be reached only by climbing a long flight of stairs. For women who have given birth, a detailed obstetric history is also necessary.

Physical examination

The physical examination begins with a visual inspection of the anus and the perineum for hemorrhoids, infections, and other conditions that might explain the patient's difficulties. During this phase of the examination the doctor asks the patient to bear down. Bearing down enables the physician to check whether rectal prolapse or certain other problems exist. Rectal prolapse means that the patient's rectum has been weakened and drops down through the anus. Next, a pin or probe is used to stroke the perianal skin. Normally this touching causes the anal sphincter to contract and the anus to pucker

(the “anal wink”); if it does not, nerve damage may be present. The final phase of the examination requires the doctor to examine internal structures by carefully inserting a gloved and lubricated finger into the anal canal. This allows the doctor to judge the strength of the anal sphincter and a key muscle (the puborectalis muscle) in maintaining continence; to look for such abnormalities as scars and rectal masses; and to learn many other things about the patient’s medical situation. At this point the doctor performs the anal wink test again and asks the patient to squeeze and bear down.

Laboratory tests

Information from the medical history and physical examination usually needs to be supplemented by tests that provide objective measurements of anal and rectal function. One of the most common tests is a **colonoscopy**, which can be included in the physical examination or can be performed in a laboratory setting. Anorectal manometry, another common procedure, involves inserting a small tube (catheter) or balloon device into the anal canal or rectum. Manometry measures, among other things, pressure levels in the anal canal, rectal sensation, and anal and rectal **reflexes**. Tests are also available for assessing nerve damage. An anal ultrasound probe can supply accurate images of the anal sphincter and reveal whether injury has occurred. **Magnetic resonance imaging**, which requires the insertion of a coil into the anal canal, is useful at times.

Treatment

Fecal incontinence arising from an underlying condition such as diabetic neuropathy can sometimes be helped by treating the underlying condition. When that does not work, or when no underlying condition can be discovered, one approach is to have the patient use a suppository or enema to stimulate defecation at the same time every day or every other day. The goal is to restore regular bowel habits and keep the bowels free of stools. Medications such as loperamide (Imodium) and codeine phosphate are often effective in halting incontinence, but only in less severe cases involving liquid stools or urgency. Dietary changes and exercises done at home to strengthen the anal muscles may also help.

Good results have been reported for biofeedback training. In successful cases, patients regain complete control over defecation, or at least improve their control, by learning to contract the external part of the anal sphincter whenever stools enter the rectum. All healthy people have this ability. Biofeedback training begins with the insertion into the rectum of a balloon manometry device hooked up to a pressure monitor. When the bal-

loon is inflated, it simulates the presence of stools in the rectum by causing pressure changes that are recorded on the monitor. The monitor also records sphincter contraction. By watching the monitor and following instructions from the equipment operator, the patient gradually learns to contract the sphincter automatically in response to fullness in the rectum. Sometimes one training session is enough, but often several are needed. Biofeedback is not an appropriate treatment in all cases, however. It is used only with patients who are highly motivated; who are able, to some extent, to sense the presence of stools in the rectum; and who have not lost all ability to contract the external anal sphincter.

Some people may require surgery, and these procedures may themselves have complications. Sphincter damages caused by childbirth, as well as certain other kinds of incontinence-related sphincter injuries, are often effectively treated with surgery. Sometimes surgical treatment requires building an artificial sphincter using a thigh muscle (the gracilis muscle). At one time a **colostomy** was necessary for severe cases of incontinence, but this procedure is now rarely performed.

Prognosis

Fecal incontinence is a problem that usually responds well to professional medical treatment, even among elderly and institutionalized patients. If complete bowel control cannot be restored, the impact of incontinence on everyday life can still be lessened considerably in most cases. When incontinence remains a problem despite medical treatment, disposable underwear and other commercial incontinence products are available to make life easier. Physicians and nurses can offer advice on coping with incontinence, and people should not be embarrassed about seeking their assistance. Counseling and information are also available from support groups.

Health care team roles

A patient may report fecal incontinence to a health care professional, or it may be assessed by the nurse or physician in an inpatient setting. The physician may order diagnostic testing to determine the etiology of the incontinence. It is the nurse’s responsibility to insure the patient maintains adequate levels of hygiene. In addition, the nurse should instruct the patient and/or caregivers regarding measures of coping with incontinence and minimizing its impact.

Prevention

Since fecal incontinence develops for a variety of reasons, there is no single way to prevent it. Patients should

KEY TERMS

Anus—The opening at the lower end of the rectum.

Colostomy—A surgical procedure in which an opening is made in the wall of the abdomen to allow a part of the large intestine (the colon) to empty outside the body.

Crohn's disease—A disease marked by inflammation of the intestines.

Defecation—Passage of stools through the anus.

Hemorrhoids—Enlarged veins in the anus or rectum. They are sometimes associated with fecal incontinence.

Rectum—The lower section of the large intestine that holds stools before defecation.

Sphincter—A circular band of muscle that surrounds and encloses an opening to the body or to one of its hollow organs. Damage to the sphincter surrounding the anus can cause fecal incontinence.

Stools—Undigested food and other waste that is eliminated through the anus.

Suppository—A solid medication that slowly dissolves after being inserted into the rectum or other body cavity.

be encouraged to report incontinence as soon as it occurs, in order to find the most appropriate treatment for it.

Fecal occult blood test

Definition

The fecal occult **blood** test (FOBT) is a rapid test for detecting the presence of blood hidden in the stool and caused by gastrointestinal bleeding.

Purpose

This test is performed to detect the presence of blood in the feces. It is also routinely used (in conjunction with a rectal examination performed by a physician) to screen for **colorectal cancer**, particularly after age 50. However, a positive result does not necessarily indicate **cancer**, as positive results can be associated with a wide variety of conditions, such as:

- peptic, gastric, or **stress** ulcers
- esophageal varices
- colon or pancreatic cancer
- tumors
- gastritis
- gastrointestinal bleeding
- hemorrhage
- ulcerative colitis
- diverticulitis
- alcohol abuse
- Crohn's disease
- intussusception

Precautions

Certain foods and medicines can influence the test results. Diets rich in red meat, poultry and fish could cause false-positive FOBT results, as can excessive amounts of green leafy vegetables. Certain drugs can also

cause false-positive results; they include aspirin, cortisone, **iron**, potassium preparations, nonsteroidal antiinflammatory (NSAID) drugs, thiazide diuretics, colchicine, and reserpine. False-negative findings may result from the ingestion of large amounts of ascorbic acid (**vitamin C**) from dietary supplements or foods such as citrus fruits. It is also important that the specimen not be contaminated by menstrual discharge.

Description

In most cases, the collection of stool samples can be done at home, using a kit supplied by the physician. The kit contains a specially prepared card onto which a small sample of stool is spread, using a stick provided in the kit. The sample is placed in a special envelope and either mailed or brought to the physician's office or test site for analysis.

Most tests for occult blood test are based upon the fact that hemoglobin, the oxygen-carrying protein in blood, has peroxidase activity. In the presence of hydrogen peroxide, hemoglobin will catalyze the oxidation of a dye such as gum guaiac, benzidine, or o-toluidine, creating a blue color. The dye is present on the card. When hydrogen peroxide is applied to the card and mixed with the stool, the blue color will form if an abnormal amount of blood is present. Rapid immunochemical tests are also available.

Preparation

The patient may be requested to avoid meat, fish and poultry for two or three days prior to the test.

Aftercare

There is no aftercare required for this test.

Complications

There are no complications associated with this test.

Results

As described above, many factors can result in false-positive and false-negative findings. Therefore, it is important to note that a true-positive finding signifies only the presence of blood; it is not necessarily an indication of cancer. The National Cancer Institute states that, in their experience, less than 10% of all positive results are caused by cancer. Alternatively, a negative result (meaning no blood was detected) does not guarantee the absence of colon cancer, which may bleed only occasionally or not at all. The physician will want to fol-

KEY TERMS

Occult blood—Blood in the stool that is not visible or easily detected.

low up on a positive result with further tests, depending upon other factors in the patient's history or **physical examination**. Endoscopic exam is often recommended when the cause of GI bleeding is unknown.

Health care team roles

Nurses should determine if the patient has been experiencing signs of a peptic ulcer (epigastric **pain** between meals), and should note any recent bleeding episodes related to dental problems. The physician, laboratory technician, or scientist should ensure that the sample is analyzed within 48 hours of collection.

Feedback systems

Definition

A feedback system uses as input the total or partial output of the system. Feedback systems are used to control and regulate processes. They use the consequences of the process (i.e. too much or too little produced) to regulate the rate at which the process occurs (to decrease or increase the rate of the process).

Description

A typical feedback system consists of a sensor, a control center that receives the signals of the sensor, and an effector pathway, meaning a pathway for the commands of the control center as it reacts to the information received from the sensor.

In complex organisms, such as humans, feedback systems constantly monitor and regulate numerous factors, including the levels of gases like oxygen and carbon dioxide, nutrients, hormones, and chemical substances. The feedback systems insure that the amounts of these substances in body tissues and fluids remain unchanged within appropriate limits, despite changes in the external environment.

Feedback systems function with the help of the nervous and endocrine systems. While nerve cells detect changes in the body and quickly respond to the **brain** for a rapid response, hormones of the **endocrine system** regulate the system more slowly. For example, hormones and nerves regulate the progress of labor contractions. When labor begins, nerve cells in the uterus alert the hypothalamus (a control center in the brain). A hormone called oxytocin is released into the **blood**, which causes the uterus to contract.

Feedback control or regulation can be either negative or positive. With negative feedback, the activity of a system is reduced, slowed down or minimized by the presence of high amounts of a substance it produces. An example is the increased breathing resulting from the presence of high levels of carbon dioxide in extracellular fluids. The purpose of breathing is to provide the oxygen required by the body for its functioning (**metabolism**) and to eliminate waste carbon dioxide. In the presence of high levels of carbon dioxide, breathing increases, which increases the supply of oxygen present in the air in the lungs, thus counteracting the high amounts of carbon dioxide, which are harmful to the body. With positive feedback, the activity of a system is increased by the presence of high amounts of a substance it produces. Positive feedback systems thus speed up or maximize the rates of processes. For example, they are used in the production of nerve impulses and blood clotting. In the above example, labor contractions are a positive feedback system. As oxytocin reaches the uterus, causing contractions, more stretching causes an increase in oxytocin levels, which causes more forceful contractions.

Function

Almost all body functions and processes operate using feedback systems. The body maintains its overall chemical and physical internal environment constant

(homeostasis) using a control system activated by several feedback systems. This is because normal cell function depends on maintaining relatively constant intracellular and extracellular environments, such as pH, temperature, and the amounts of all the substances needed by the body. The body keeps these quantities within the range required to maintain life and proper function with the help of feedback systems.

Feedback systems are active at all levels of body organization, whether molecular (e.g. regulation of enzymes); cellular (e.g. regulation of cell volume or chemical contents); organ (e.g. regulation of blood flow in the **heart** or **lungs**); systemic (e.g. **regulation of breathing** in the **respiratory system**), and whole-body (e.g. regulation of body temperature through shivering and sweating). Some examples include:

- Enzymatic feedback inhibition. At the molecular level, a mechanism called feedback inhibition operates to limit the amount of chemical product produced by an enzyme system. An enzyme system consists of several enzymes that act one after the other to convert a substance into an end product the body needs. Overproduction of the end product is prevented by the inhibitory effect of the end product on the first enzyme in the sequence, which is called the regulatory enzyme. As the end product is used up in other chemical conversions, however, its inhibitory effect on the regulatory enzyme decreases, so that more end product can be formed by the enzyme system. In this way, the level of end product is maintained at a fairly constant level.
- The pH of body fluids. The pH is a measure of the acidity of a solution, or of its hydrogen ion concentration. The normal pH of body cells and fluids is 7.4. When this value steps out of the normal range as a result of the presence of chemical substances that either increase it or decrease it, a feedback control system is triggered to remove or increase the amount of substance so as to bring back the pH to its normal value.
- The amounts of small ions. The cells of the body consist of a nucleus surrounded by a fluid cytoplasm that contains several structures (organelles) required for functioning, all enclosed in a membrane. Cells can be thought of as little chemical powerhouses that require specific amounts of chemical substances, among which several small ions (elements that have a positive or negative charge) that need to be made available either inside or outside the **cell membranes**. For example, the potassium ion (K^+ is the major intracellular positive ion (cation) and the sodium ion (Na^+ is the major extracellular cation). Likewise, the major extracellular negative ions (anions) are Cl^- and HCO_3^- . Both the amounts

KEY TERMS

Acidity—Refers to a compound that is acid or sour. When dissolved in water, acids yield hydrogen ions.

Cell—The individual units from which all the tissues and fluids of the body are formed. They consist of a nucleus surrounded by a fluid cytoplasm enclosed in a membrane. Intracellular refers to all substances found inside the membrane and extracellular refers to all substances outside the cell membrane.

Chemoreceptors—Specialized cells that can detect chemical substances in the body and relay that information to the central nervous system. The substances detected may be external, such as when an individual smells or tastes something; or they can be internal, such as the carotid bodies, located in the carotid arteries, that detect the amounts of oxygen or carbon dioxide present in the blood.

Cytokine—A protein secreted by tissues or leukocytes (a type of white blood cell) that has a regulatory function.

Enzyme—A type of protein produced by the body that speeds up chemical reactions. Some enzymes regulate certain functions due to their ability to change their activity by modifying their structure.

Homeostasis—Stability of the body's internal environment, achieved by a system of integrated control systems activated by feedback systems. Homeostasis is thus the maintenance of a constant internal environment (the immediate surroundings of cells) in response to changes occurring in a) the conditions of the external environment and b) the conditions of the internal body environment.

Hormone—A substance secreted by specialized glands in the body that affects the behavior of other cells. Hormones serve as messengers to coordinate activities of various parts of the body.

Ion—Elements consist of positively charged nuclei surrounded by negatively charged electrons. These charges are balanced and the overall charge of an element is zero. An element becomes an ion, that is a charged species, if it gains or losses electrons.

Metabolism—The sum of all the physical and biochemical processes occurring in the body to produce what is required to maintain life. Metabolism includes the transformation of nutrients into energy and the use of energy by the body.

pH—A measure of the acidity of a solution, or of its hydrogen ion concentration. In the human body, the solution can be the blood or the cerebrospinal fluid. The normal pH of body fluids is 7.4.

of these ions and their transport across the cell membranes are controlled by feedback systems.

- Arterial oxygen partial pressure. Another feedback system regulates the oxygen partial pressure $P(O_2)$ and carbon dioxide partial pressure $P(CO_2)$ in the arteries. This is because the cells of the body obtain their energy by combining oxygen with various foodstuffs, producing carbon dioxide as a waste product, so they need a constant supply of oxygen and also need to have the carbon dioxide removed. Normally, if the arterial blood reaching a special chemical sensor (chemoreceptor), called the carotid body, has a partial pressure of oxygen lower than the normal range or an excessive carbon dioxide partial pressure, then there is an immediate and marked increase in breathing.
- Internal body temperature. Body temperature is regulated by a feedback system that maintains it nearly constant at 98.6°F (37°C) throughout the day, week, month or year. As a consequence, a person can remain active

and working in the hot summer months or on cold winter days.

Role in human health

The role of the many feedback systems of the human body is to maintain the homeostasis required for life.

Feedback systems are activated as soon as disturbances occur in the narrow range of conditions which cellular processes need to be able to function at a level required for the continuation of life. For example, the body temperature feedback system will act to make sure that the body's internal temperature is maintained constant in spite of the weather. The Na^+ feedback regulatory system will adjust the body cells and fluids to the dietary intake of sodium (salt) from foodstuffs. The breathing feedback system will likewise seek to maintain proper oxygen and carbon dioxide pressures and amounts when disturbed, say by heavy **exercise**. Another feedback system will regulate blood flow and pressure whenever these quantities are increased or decreased by events

such as disease, injury, or blood donation. In other words, whenever anything happens that changes the narrow range of the normal values of body parameters, feedback regulatory systems step in to counteract the effect of the change. And if the change is too drastic for the feedback system to handle, the result is disease and even death.

Common diseases and disorders

The function and development of all body components are controlled by a variety of feedback systems. Any malfunctioning of a given regulatory feedback system will not only affect the body part or process directly controlled by that system but will also affect those functions controlled by other related feedback systems. For example, at the organ level, it is known that many use hormones and cytokines as effectors in regulatory feedback loops. It is now believed that these feedback systems are involved in some forms of human **cancer**. For instance, the disruption of a negative feedback system by a cancer transformation can result in the loss of growth control or in increased malignant behavior of tumor cells. Also, abnormal positive feedback loops can develop that increase tumor growth by allowing the excessive release of stimulatory factors.

Fertility treatments

Definition

Infertility is a problem with the reproductive system that results in the inability of a man or woman to achieve a **pregnancy** or of a woman to carry a pregnancy to live birth. The accepted definition within the medical profession is the absence of conception after at least one year of regular intercourse without birth control. Regular intercourse refers to intercourse at least two to three times per week. The term is also used to cover women unable to carry a pregnancy to term because of **miscarriage**. Infertility is not sterility, which is the term used to mean conception is not possible under any circumstances. Infertility is not a new disease or condition, but it appears as if there has been an increase in infertility rates in the past few decades. Some factors that may relate to this increase include an increase in the age of women wanting to conceive, an increase in the spread of sexually transmitted diseases, and the rise in the level of toxic chemicals in our environment. Infertility does affect people of all ages, ethnic backgrounds, socioeconomic groups, and both sexes.

Purpose

The purpose of fertility treatments is to achieve a successful pregnancy and outcome. Male factors account for approximately 30-40% of all cases of infertility and female factors cause about 40% of cases. Close to 15% of cases are a result of a combination of male and female factors; whereas in 5-10% of cases, no cause can be found.

Many couples may begin their quest for fertility with their primary care physician, who is usually a medical doctor certified in family medicine. The primary physician can do a physical exam on both individuals but should refer the couple to a specialist in obstetrics and gynecology to initiate the infertility evaluation process. Infertility is described as either primary or secondary. A couple who has never achieved pregnancy is experiencing primary infertility, whereas a couple who has had a pregnancy in the past, regardless of the outcome, is experiencing secondary infertility.

For an egg to be fertilized, sperm produced in the testes must not only be present in sufficient number in the semen but they must be capable of moving far enough and fast enough to travel through the **female reproductive system** (motility), and capable of penetrating the outer layer of an egg. Male infertility may be a result of small quantities of sperm; prenatal exposure to diethylstilbestrol (DES) (a medication given to women to pre-

vent miscarriage in the 1950s); exposure to radiation, certain pesticides or heavy metals (lead); or diseases that reduce the body's ability to produce sperm. Female infertility may be related to irregularities of the fallopian tubes; endometriosis (tissue resembling the lining of the uterus growing in the abdomen); irregular ovulation or lack of ovulation; abnormalities of the uterine cavity; and/or cervical problems such as abnormal mucus.

A couple should consider seeing an infertility specialist (a physician certified in reproductive endocrinology and infertility) for any of the following reasons:

- a woman experiencing irregular menstrual cycles or irregular ovulation
- a woman with a history of three or more miscarriages
- a woman older than 35 years of age
- a woman with a history of pelvic **infection** or previous pelvic surgery
- a woman who needs microsurgery for endometriosis or for tubal damage
- a man with a poor **semen analysis** such as low count, poor motility, abnormal appearance, or requiring microsurgery
- a couple with unexplained infertility whose tests came back normal but still have not conceived after two years
- a couple who needs more advanced treatment, such as injectable ovulation-induction medications or assisted reproductive technology (ART)

There are over 300 fertility clinics in the United States and each one has a varying rate of success. A couple should investigate the services of the ones they are considering to save time, money and emotional upheaval. In 1992, Congress passed the Fertility Clinic Success Rate and Certification Act, which requires the Centers for Disease Control and Prevention (CDC) to publish the success rates of clinics throughout the United States where ART is performed. This report is intended for laypersons who are considering using ART to achieve pregnancy and provide an objective review utilizing a common method of reporting success. Besides success rates, a couple should consider the following:

- Is the physician board certified in reproductive endocrinology?
- How much experience has the physician had with diagnosing and treating infertility?
- What are the fees for office visits and are payment plans available?
- What is the policy regarding cancellation of appointments and filing of insurance claims?

- Will a physician or someone else on staff be available twenty-four hours a day, seven days a week, including weekends and holidays?
- Will lab and ultrasound facilities be open seven days a week?
- Will the couple see the same physician for their visits?
- Will decisions on tests, treatments and referrals be made jointly between the couple and the physician?

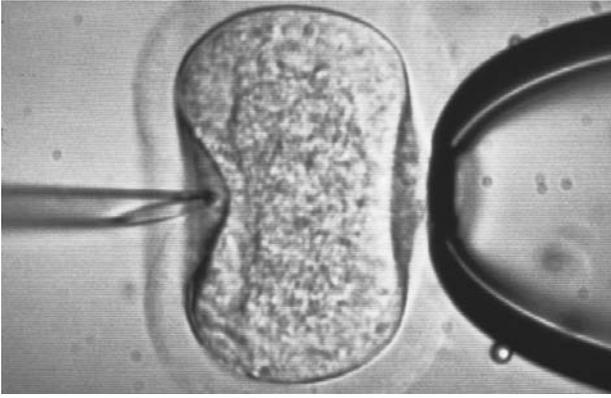

Precautions

Couples involved in fertility treatments face many legal, ethical, psychological, emotional and financial questions. It is imperative to explore these issues before beginning a course of treatment in order to maintain a realistic attitude. It is difficult, if not impossible, to identify problems that may arise during treatment, but it is important to make an attempt to set limits, physically, financially, and emotionally, on what can be handled during the course of treatment. It is likewise crucial to consider potential legal, practical and ethical problems associated with each choice of treatment and to contact resources available to individuals with infertility problems for an objective viewpoint. Just because the treatment is available does not mean it has to be utilized. All individuals have their own ethical standards and limitations and need to investigate all courses of treatment before undergoing them.

Informed consent is a medical term that means a patient gives permission for a test or invasive procedure to be performed, after being informed by the physician in clear language exactly what the test or procedure involves. If at any point in the course of treatment a patient does not understand something, he or she should be encouraged to ask questions; and if the answer is not satisfactory, the patient should know that a second opinion may be solicited.

Prior to undergoing assisted reproductive technology (ART), women should be advised to avoid all **pain** medications other than Tylenol and discuss prescription medications with the specialist. They should not smoke cigarettes or drink alcohol, avoid caffeine-containing beverages, and inform the physician if they have active **genital herpes**. They should also maintain a healthy well-rounded diet and take a multiple vitamin containing **folic acid** every day.

Men should report any fevers within three months before ART treatment, as fevers may adversely affect sperm quality. They should avoid hot tubs or saunas for three months, as the heat can affect sperm function. Men should also avoid alcohol, drug use, and cigarette smoking for three months prior to treatment and during the

A microscopic image of a needle (left) injecting sperm cells directly into a human egg (center). The broad object at right is a pipette used to hold the ovum steady. (Phototake NYC. Reproduced by permission.)

ART cycle as well. Any prescription drugs should be reported to the specialist along with active genital herpes. It is preferable to avoid intercourse for three days but not more than seven days before collection of semen for an ART cycle.

Description

Assisted reproductive technology (ART) is defined by the U.S. Centers for Disease Control and Prevention (CDC) as “all treatments or procedures that involve the handling of human eggs and sperm for the purpose of helping a woman become pregnant.” Types of ART include in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), embryo cryopreservation, egg or embryo donation, and gestational carriers. ART does not include intrauterine insemination (IUI) with either partner or donor sperm.

In vitro fertilization (IVF)

This name comes from the fact that fertilization occurs outside the body in a laboratory, instead of in the woman’s fallopian tube. *In vitro* is a Latin term that means ‘in the glass’ and refers to procedures performed outside of a living body in a laboratory or other artificial environment. Thus, IVF involves joining an egg and a sperm in a laboratory dish; if fertilization occurs, the resulting pre-embryo is transferred into the woman’s uterus for possible implantation. IVF was developed as a technique to assist women who had blocked, damaged or absent fallopian tubes to become pregnant. The first successful IVF procedure was performed in the United Kingdom and resulted in the birth of Louise Brown in 1978. Today IVF is utilized to treat infertility caused by

endometriosis; certain types of male factor infertility; tubal factors; and unexplained infertility.

The procedure utilized for IVF may vary somewhat from clinic to clinic, but generally it involves the following:

- Stimulating the woman’s ovaries to produce multiple eggs during a specific time of her menstrual cycle.
- Detecting the presence of multiple eggs through the use of vaginal ultrasound.
- Retrieving eggs from her ovaries (while under intravenous sedation) by means of guiding a needle through the wall of the vagina and into the follicles and aspirating them.
- Determining the maturity of the eggs and adding sperm to them once mature.
- Transferring the embryo into the uterus by a catheter (long, slender tube with a syringe on one end) is relatively simple and requires no anesthesia.
