Stimulating a woman’s ovaries to produce multiple eggs may vary by program or patient, but the majority require several days of medications to be given by injection. Two main medications are used in the stimulation phase of an IVF cycle. The first is Lupron, which suppresses the ovaries by shutting down the body’s normal production of luteinizing hormone (LH) and follicle stimulating hormone (FSH). Both of these hormones are essential to produce ovulation. Lupron is given by injection subcutaneously (just under the surface of the skin). It shuts down the ovaries completely so that when the induction drugs are given the follicles will mature evenly. The second type of medication is either pure FSH or FSH in combination with LH. It is given by injection to stimulate the ovaries to produce eggs in a controlled but hyperstimulated manner and at a dosage that will produce the highest number of good-quality eggs. With IVF, egg retrieval may take thirty minutes to one hour.

The transfer process takes only about ten to twenty minutes and results in the transfer of one or more embryos because the presence of multiple embryos makes it more likely that at least one embryo will attach to the uterine lining. The transfer of multiple embryos also increases the chance of **multiple pregnancy**. A couple may choose to maintain additional embryos before the transfer procedure so that they can be frozen, thawed and transferred at a later date. In the United States in 1996, 300 clinics reported doing over 64,000 ART cycles, and 92% of these were IVF.

Gamete intrafallopian transfer (GIFT)

With GIFT, conception takes place in the fallopian tube. This technique should be utilized only when sperm quality is adequate and at least one fallopian tube is open and functional. The steps involved in this technique are similar to those with IVF up to the egg retrieval. As with IVF, egg retrieval occurs under **general anesthesia** and eggs and sperm are transferred immediately to a catheter that is used to inject the eggs and sperm into the fallopian tube during **laparoscopy**. There is no ability to document fertilization or to evaluate embryo quality in a GIFT procedure. This procedure requires two small incisions, one just outside the woman's navel and the other deep in her abdomen where a probe is inserted.

Zygote intrafallopian transfer (ZIFT)

This procedure is a combination of IVF and GIFT. Eggs are retrieved by transvaginal ultrasound aspiration, as with IVF, and are fertilized in a laboratory dish. The next day, before the fertilized eggs begin **cell division**, they are transferred into the woman's fallopian tubes by laparoscopy. This procedure is sometimes referred to as pronuclear stage transfer (PROST). Zygote is a term used to describe an egg that has been fertilized but has not yet undergone cell division, but now it is more commonly referred to as a pronucleus.

Tubal embryo transfer (TET)

This procedure involves the transfer of a more developed embryo than that used in GIFT or PROST. In this case, a fertilized egg that has reached the four- to eight-cell stage of division is transferred into the fallopian tube. This transfer usually occurs about 24 hours after fertilization and the developing embryo then proceeds to move into the uterus as in an unassisted pregnancy.

Techniques utilized to enhance fertilization or implantation include:

- Intracytoplasmic sperm injection (ICSI) uses a microsurgical needle to inject a single sperm directly into the egg to achieve fertilization.
- Microinsemination concentrates sperm into a small drop of fluid and placing it around the eggs to increase chances of fertilization.
- Assisted hatching is a micromanipulation technique performed after fertilization with IVF, designed to improve the implantation of the embryo by making a microscopic hole (with a microsurgical needle or chemicals) in the zona pellucida (the transparent, noncellular, secreted layer surrounding an ovum) to facilitate the release of the embryo from the egg membrane.

The micromanipulation techniques are relatively new procedures that may not be available in all fertility clinics. Their success depends on the quality of the man's sperm, the age of the woman, and the experience of the clinic.

Aftercare

Progesterone supplements are started the day after egg retrieval and continued until the **pregnancy test** is negative or throughout the first trimester of pregnancy. Vaginal suppositories or gel, intramuscular injections, and oral capsules are the form of progesterone used during IVF. Clinics vary regarding instructions about activity after embryo transfer. Some may suggest a few hours of bed rest and others suggest two to three days of minimal physical activity. The patient may also have her own opinion and choose to rest longer. About 10-12 days following embryo transfer, the physician will order a hCG (human chorionic gonadotrophin) test to determine pregnancy. If the test result is borderline, another **blood test** will be taken in two to three days. Five weeks after the transfer, an ultrasound is performed to document a heart-beat and confirm pregnancy.

Complications

Hyperstimulation syndrome is usually mild when it occurs, but it can become potentially serious. This is a result of ovaries that are extremely responsive to the medications, thereby causing them to become quite large. Hyperstimulation syndrome can lead to severe weight gain from fluid accumulation in the abdomen and low output of urine as well as potentially serious changes in blood chemistry. It is rare for a woman to experience such severe hyperstimulation that hospitalization occurs, but the syndrome can become serious enough to require close monitoring of intravenous fluids and weight, urine output, and blood chemistry.

Multiple gestation is another potential complication of ART and one that can have a long-term impact on a family. These pregnancies are physically and emotionally challenging to the mother and also have the potential of severe health risks associated with premature birth, which is quite common with multiple gestation. ART procedures have resulted in multiple gestation pregnancies about 43% of the time in women younger than 35 years. The risks to a woman carrying multiple fetuses include high **blood pressure**, **gestational diabetes**, increased risk of bleeding, premature labor, and cesarean section birth. Risks to the infant include prematurity, low birth weight, and respiratory and eye complications. **Premature infants** are also at higher risk for congenital (from birth) abnormalities and learning disabilities. The

KEY TERMS

Cryopreservation—Maintenance of the viability of excised tissue or organs by storing at very low temperatures.

Ectopic—Arising or produced at an abnormal site or in a tissue where it is not normally found.

Endometriosis—A condition in which tissue more or less perfectly resembling the endometrium (the mucous membrane lining the uterus) occurs outside the uterine cavity, usually in the pelvic cavity.

Follicle stimulating hormone—One of the hormones that promotes the formation of follicles within the ovary for ovulation.

Laparoscopy—Examination of the peritoneal cavity with an endoscope.

Luteinizing hormone—One of the hormones that promotes follicle formation within the ovary for ovulation.

Pronucleus—The haploid nucleus of a sex cell.

Ultrasound—A procedure in which high-frequency sound waves are used to create an image of a baby. Ultrasound can be used alone or with other antepartum testing.

risks of complications to the mother and the fetus increase dramatically with the number of fetuses carried. Couples may sometimes choose to undergo a procedure called multiple gestation reduction (MGR), which involves reducing the number of fetal sacs to improve the chance of having a healthy pregnancy and a healthy baby. This decision is an individual one that must be based on ethical, moral, and personal beliefs as well as medical information.

Another potential complication is the fact that a small number of ectopic, or tubal, pregnancies can occur after embryo transfer in an IVF cycle as a result of embryos traveling out into the fallopian tube from the uterine cavity. The chance of this occurring, however, is less than one percent. Twenty percent of all pregnancies, regardless of how established, are lost, and all patients should be aware of this statistic prior to treatments as well. Individuals who do become pregnant are sometimes unable to enjoy the pregnancy because of the fear surrounding the treatments needed to achieve it and fear of potential problems or adverse outcomes.

Results

If all goes well, the best result would be a healthy pregnancy and a healthy baby. If any of the complications occur, the individuals could undergo the procedure again, but it is essential that they have counseling to determine their expectations and emotional status.

Health care team roles

All health care workers who take part in assisted reproductive technology and care for the patients should be trained in bereavement counseling. Although it is essential to provide the appropriate physical care necessary to achieve pregnancy, the psychological and emotional impact of the treatments and adverse outcomes are much more difficult to handle. Nurses usually spend more time with the patients, and it is their responsibility to be a patient advocate. Patients will often tell the nurse things they would not discuss with the physician. In such a situation, the nurse needs to intercede for the patient to make the physician aware of problems and concerns. Often the patient simply needs a hand to hold during treatments and an understanding heart to listen, which every nurse can provide.

Fetal age study

Definition

A fetal age study, also called biometry, is part of an obstetric ultrasound exam. The study uses ultrasonography to take measurements of several fetal anatomic structures, compare the results to expected values, and convert that information into an estimated gestational age of the fetus.

Purpose

Biometry is used to determine fetal age. Serial biometry may be performed to assess fetal growth rate.

Precautions

As imaging technology has improved resolution of the fetal structures, care must be taken that the measurements start and end at the correct locations. The skill and experience of the ultrasound technologist are a critical component in obtaining reliable results. In general, ultrasonography dating of a **pregnancy** is more accurate than dating using the date of the mother's last menstrual period.

Description

Accurate dating of a pregnancy is the foundation on which obstetrical management relies. The date of the mother's last menstrual period is often used to estimate delivery date, but it is accurate to within only about two weeks. By comparison, the biometric crown-rump measurement of the six to 12-week fetus provides the most accurate measurement, within three days of true gestational age. First-trimester biometric measurements may be obtained using either an abdominal or transvaginal transducer. Transvaginal ultrasonography can visualize fetal structures about one week in advance of abdominal sonography. Since the fetal structures are better visualized in the second trimester than in the first, a routine ultrasound is usually performed during that period, usually between 16 and 20 weeks gestation. Early sonography may be performed if a first-trimester pregnancy appears to be threatened, or if there is maternal bleeding, pelvic **pain**, or a concern that the pregnancy may be ectopic. Biometric dating may be used to determine the best time to perform chorionic villi sampling or maternal alpha-fetoprotein levels.

Since many pregnancies are not dated until the pregnancy is more advanced, different structures are measured to obtain fetal age, depending on the suspected gestational age. As gestational age increases, normal variability between fetuses increases. To some degree,

then, biometric accuracy decreases with advancing gestational age. After about the twelfth week of gestation, the fetal position and movements make crown-rump measurements less accurate. Other anatomic structures will then be measured. From 12 to 18 weeks gestation, biometric measurements are usually accurate to within a week of gestational age. After 26 weeks gestation, fetal variability has greatly increased and the dating provided by biometric measurement is less accurate, but the method is still used. By late in the third trimester, measurements are accurate only within a two- to three-week window. In general, once the crown-rump measurement is no longer reasonable to obtain, the averaging of several anatomic measurements is more accurate than the use of one measurement alone. Results outside of the expected outcome should be further evaluated, to check for fetal anomalies.

The four most common measurements taken during biometry are the biparietal diameter (BPD), head circumference (HC), abdominal circumference (AC), and femur length (FL). Because normal fetal variability is present between the 10th and 90th percentiles, the basis for comparison is usually the 50th percentile. However, imaging technology is sufficiently advanced so that almost any fetal structure can be measured and compared against normal ranges.

Fetal growth is based on the fetal size in relation to the expected gestational age. Normal fetal size and weight values are expected between the 10th and 90th percentiles. Fetal size or weight below the 10th percentile is considered small for gestational age (SGA). A fetus with measurements above the 90th percentile is considered large for gestational age (LGA), and may be an indication of fetal response to maternal **gestational diabetes**. The diagnosis of an SGA or LGA fetus impacts the future obstetric management of the pregnancy, and assists in avoiding complications related to these conditions. Imaging technology software can estimate fetal weight using the measurements obtained for size and their relation to fetal mass. Estimated fetal weight may be used to check for fetal growth, or may be used in cases of fetal surgery or when the fetus needs to receive medication or a **blood** transfusion.

Preparation

Biometry is a non-invasive sonographic fetal assessment tool. In early pregnancy, the mother may need to drink water prior to the test, without urinating until after the test has concluded. A full bladder is necessary to allow for transmission of the sound waves. As pregnancy advances, sufficient amniotic fluid is present so that fluid consumption prior to the test is not required. In order to

KEY TERMS

Gestational diabetes—Diabetes that first occurs during pregnancy and resolves once the pregnancy is terminated.

Transducer—The external device or probe used in conjunction with the ultrasound machine. Applied on the outside of the abdomen with a special gel, it bounces sound waves into the area being visualized, and then sends the return waves back to the computerized ultrasound machine for interpretation and visualization on the monitor. A transvaginal transducer is inserted into the vagina in order to be closer to the structures being evaluated.

Trimester—The average length of pregnancy is 280 days. The pregnancy is often divided into three trimesters, as different fetal development takes place in each of the three time periods. The first trimester extends to 14 weeks, the second through 28 weeks, and the third until 40/42 weeks, or term.

perform the ultrasound, a transducer is placed externally to the mother's abdomen. Use of a special gel allows the transducer to glide over the surface of the abdomen during scanning. Because the abdomen is exposed, privacy should be provided either with the use of a curtain or with a closed door. The mother should be asked if she would like her partner or support person with her during the test. A comfortable room temperature and warmed transducer gel assist in putting the mother more at ease. A towel or cloth placed over the mother's clothes protect them from becoming wet from the gel.

Aftercare

When the test is completed, the abdomen should be wiped dry of the transducer gel. If the mother needed to consume water prior to the test, she may need to urinate. She may require assistance in getting up from the ultrasound table. If non-reassuring test results have been conveyed to the mother, she may need a health care professional to stay with her for emotional support and to answer questions.

Complications

Because a fetal age study is noninvasive and observational, no complications are anticipated. If the measurements were not obtained carefully, the wrong gesta-

tional age will be determined. Interventions undertaken based on inaccurate findings could be considered a complication or risk of the procedure.

Results

The biometric results obtained are compared with norms for size and age, in order to estimate fetal age. Results outside of the normal range may indicate an SGA or LGA fetus, and require additional evaluation. Biometry may be used later in pregnancy when the fetal age is unclear. In this case, serial measurements may be taken after a two- to three-week period. The fetal growth during this time period can be compared against normal growth rates to estimate the gestational age. Because of rapid periods of fetal growth, each gestational week is also broken down further into the number of days. For example, the fetus's weight and length at 27 1/7 weeks is different from that for a fetus of 27 6/7 weeks.

Health care team roles

The fetal age study is usually performed by an ultrasound technologist in the imaging department. Non-routine biometry testing may provoke maternal **anxiety** over her baby's well-being. The ability of the technician to provide a calm, professional environment can help put the mother at ease.

Fetal alcohol syndrome

Definition

Fetal alcohol syndrome (FAS) is a pattern of birth defects and learning and behavioral problems affecting

individuals whose mothers consumed alcohol during pregnancy.

Description

FAS is the most common preventable cause of mental retardation. This condition was first recognized and reported in the medical literature in 1968 in France and in 1973 in the United States. Alcohol is a teratogen—the term used for any drug, chemical, maternal disease, or other environmental exposure that can cause birth defects or functional impairment in a developing fetus. Some features may be present at birth, including low birth weight, prematurity, and microcephaly. Characteristic facial features may be present at birth, or may become more obvious over time. Signs of **brain** damage include delays in development, behavioral abnormalities, and mental retardation, but affected individuals exhibit a wide range of abilities and disabilities. Only since 1991 has the long-term outcome of FAS been observed. Emotional disorders as well as learning and behavioral problems are common in adolescents and adults with FAS. Fetal alcohol effect (FAE), a term no longer favored, is sometimes used to describe individuals with some, but not all, of the features of FAS. In 1996 the Institute of Medicine suggested a five-level system to describe the birth defects, learning, and behavioral difficulties in offspring of women who drank alcohol during pregnancy. This system contains a number of criteria that must be present, including confirmation of maternal alcohol exposure, characteristic facial features, growth problems, learning and behavioral problems, and birth defects known to be associated with prenatal alcohol exposure.

The incidence of FAS varies among different populations studied, and ranges from approximately one in 200 to one in 2,000 live births. However, a study reported in 1997, utilizing the Institute of Medicine criteria, estimated the prevalence of FAS in Seattle, Washington, from 1975-1981 at nearly one in 100 live births. Avoiding alcohol during pregnancy, especially during the earliest weeks of the pregnancy, can prevent FAS. Not even the smallest amount of alcohol consumed during pregnancy has been proven to be completely safe.

FAS is neither a genetic nor inherited disorder. It is a pattern of birth defects and learning and behavioral problems that result entirely from maternal alcohol use during pregnancy. Alcohol freely crosses the placenta and causes damage to the developing embryo or fetus. Alcohol use by the father cannot cause FAS. If a woman with FAS drinks alcohol during pregnancy, she, too, may have a child with FAS. Not all individuals from alcohol-exposed pregnancies have obvious signs or symptoms of FAS. Individuals of different genetic backgrounds may be

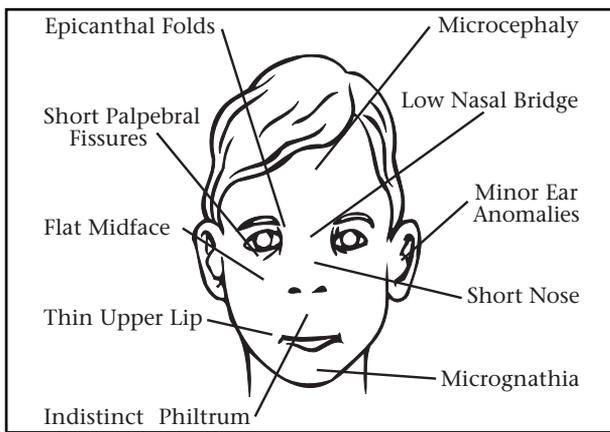

more or less susceptible to the damage that alcohol can cause. The dose of alcohol, the time during pregnancy at which the alcohol is used, and the pattern of alcohol use, all contribute to the different signs and symptoms that can be identified.

There is no racial or ethnic susceptibility to FAS. Individuals from different genetic backgrounds exposed to similar amounts of alcohol during pregnancy may exhibit different signs or symptoms of FAS. Several studies have estimated that between 25% and 45% of chronically alcoholic women will give birth to a child with FAS if they continue to drink during pregnancy. The risk of FAS appears to increase the older a chronically alcoholic woman becomes in her childbearing years and continues to drink. That is, a child with FAS will often be one of the last children born to a chronically alcoholic woman, although older siblings may exhibit milder features of FAS. Binge drinking, defined as the sporadic use of five or more standard alcoholic drinks per occasion, and moderate daily drinking (two to four 12 oz bottles of beer, 8 to 16 ounces of wine, 2 to 4 ounces of liquor) can also result in offspring with features of FAS.

Causes and symptoms

Classic features of FAS include short stature, low birth weight and poor weight gain, microcephaly, and a characteristic pattern of facial features. These facial features in infants and children may include small eye openings (measured from inner corner to outer corner); epicanthal folds (folds of tissue at the inner corner of the eye); small or short nose; low or flat nasal bridge; smooth or poorly developed philtrum (the area of the upper lip above the colored part of the lip and below the nose); thin upper lip; and small chin (micrognathia). Some of these features are nonspecific, meaning they can occur in other conditions, or be appropriate for age, racial, or family background. Other major and minor birth defects that have been reported include cleft palate, congenital **heart** defects, strabismus, **hearing loss**, defects of the spine and joints, alteration of the hand creases, and small fingernails and toenails.

The diagnosis is sometimes more difficult in older adolescents and adults. Short stature and microcephaly remain common features but weight may normalize, and individuals may actually become overweight for their height. The chin and nose grow proportionately more than the middle part of the face, so that dental crowding may become a problem. The small eye openings and the appearance of the upper lip and philtrum may continue to be characteristic. Pubertal changes typically occur at the normal time.

Facial features common in fetal alcohol syndrome. (EPD Photos. Courtesy of Gale Group.)

Newborns with FAS may have difficulties with feeding due to a poor sucking ability, have irregular sleep-wake cycles, decreased or increased muscle tone, seizures, or tremors. Delays in achieving developmental milestones such as rolling over, crawling, walking, and talking may become apparent in infancy. Behavior and learning difficulties typical in the preschool or early school years include poor attention span, hyperactivity, poor motor skills, and slow language development. Attention deficit-hyperactivity disorder (ADHD) is a common associated diagnosis. Learning disabilities or mental retardation may be diagnosed during this time. Arithmetic is often the most difficult subject for a child with FAS. During middle school and high school years, behavioral difficulties and learning difficulties can be significant. **Memory** problems, poor judgment, difficulties with daily living skills, difficulties with abstract reasoning skills, and poor social skills are often apparent by this time. It is important to note that animal and human studies have shown that neurologic and behavioral abnormalities can be present without the characteristic facial features. These individuals may not be identified as having FAS but may fulfill criteria for alcohol-related diagnoses as set forth by the Institute of Medicine.

In 1991 Streissguth and others reported some of the first long-term follow-up studies of adolescents and adults with FAS. Among the approximately 60 individuals they studied, the average IQ was 68. In the general population, 70 is the lower limit of the normal range. However, the range of IQ was quite large, from as low as 20 (severely retarded) to as high as 105 (normal). The average achievement levels for reading, spelling, and arithmetic were, respectively, fourth grade, third grade, and second grade. The Vineland Adaptive Behavior Scale was used to measure adaptive functioning in these individuals. The composite score for this group showed functioning at the level of a seven-year-old, daily living skills

at a level of nine years of age, and social skills at the level of a six-year-old.

In 1996 Streissguth and others published further data regarding the disabilities in children, adolescents, and adults with FAS. Secondary disabilities (that is, those disabilities not present at birth and that might be preventable with proper diagnosis), treatment, and intervention, were described. These secondary disabilities include mental health problems; disrupted school experiences; trouble with the law; incarceration for mental health problems, drug abuse, or a crime; inappropriate sexual behavior; alcohol and drug abuse; problems with employment and dependent living; and difficulties parenting their own children. In that study, only seven out of 90 adults were living and working independently and successfully. In addition to the studies by Streissguth, several other authors in different countries have now reported on the long-term outcome of individuals diagnosed with FAS. In general, the neurologic, behavioral, and emotional disorders become the most problematic for individuals with FAS. Because physical features change over time, correct diagnosis becomes more difficult in older individuals without old photographs and other historical data to review. Mental health problems included attention deficit disorder, depression, panic attacks, psychosis, and suicide threats and attempts, and overall were present in more than 90% of the individuals studied by Streissguth. A 1996 study from Germany reported that more than 70% of the FAS adolescents studied had persistent and severe developmental disabilities. Many had psychiatric disorders, the most common of which were emotional disorders, repetitive habits, **speech disorders**, and hyperactivity disorders.

Diagnosis

FAS is a clinical diagnosis, which means there are no **blood**, x ray, or **psychological tests** that can be performed to confirm a suspected diagnosis. The diagnosis is made based on the history of maternal alcohol use, and detailed **physical examination** for the characteristic major and minor birth defects, and characteristic facial features. It is often helpful to examine siblings and parents of an individual suspected of having FAS, either in person or by photographs, to determine whether findings on the examination might be familial, or if other siblings may also be affected. Sometimes, genetic tests are performed to rule out other conditions that may present with developmental delay or birth defects. Individuals with developmental delay, birth defects, or other unusual features are often referred to a clinical geneticist, developmental pediatrician, or neurologist for evaluation and diagnosis of FAS. Psychoeducational testing to deter-

mine IQ and the presence of learning disabilities may also be part of the evaluation process.

Treatment

There is no treatment for FAS that will reverse or change the physical features or brain damage associated with maternal alcohol use during pregnancy. Most of the birth defects associated with prenatal alcohol exposure, however, are correctable with surgery. Children with FAS should have psychoeducational evaluation to help plan appropriate educational interventions. Common associated diagnoses, such as ADHD, depression, or **anxiety** should be recognized and appropriately treated. Disabilities that present during childhood persist into adult life; however, some of the secondary disabilities may be avoided or lessened by early and correct diagnosis, better understanding of the life-long complications of FAS, and appropriate intervention. Streissguth has described a model in which an individual affected by FAS has one or more advocates to help provide guidance, structure, and support as the individual seeks to become independent, successful in school or employment, and develop satisfying social relationships.

Prognosis

The prognosis for FAS depends upon the severity of birth defects and brain damage present at birth. **Miscarriage** and stillbirth, or death in the first few weeks of life, may be outcomes in very severe cases. Some factors that have been found to reduce the risk of secondary disabilities in FAS individuals include diagnosis before the age of six years; stable and nurturing home environments; never having experienced personal violence; and referral and eligibility for disability services. The long-term data help in understanding the difficulties that individuals with FAS encounter throughout their lifetime, and can help families, caregivers and professionals provide care, supervision, education, and treatment geared toward their special needs.

Health care team roles

Pediatricians, obstetricians, family physicians, or nurse practitioners are most likely to make an initial diagnosis of FAS. A clinical geneticist, developmental pediatrician, or neurologist often confirms an initial diagnosis. Other physicians and surgeons may monitor and treat an affected baby. Nurses provide supportive care. Therapists provide support for parents of babies with FAS.

KEY TERMS

Cleft palate—An abnormal opening in the roof of the mouth, usually in the midline, so that there is a communication between the nose and mouth cavities.

Congenital—Present at the time of birth.

IQ—Abbreviation for Intelligence Quotient. Compares an individual's mental age, as measured by a test, to a true or chronological age and multiplies that ratio by 100.

Microcephaly—Small head circumference. Head circumference is an indirect measure of brain size.

Miscarriage—Spontaneous pregnancy loss.

Placenta—Organ unique to mammals that serves to exchange nutrients and waste between the maternal and fetal circulations; sometimes called the afterbirth.

Strabismus—Failure of the eyes to move together when focusing on an object; sometimes called lazy eye.

Teratogen—Any drug, chemical, maternal disease, or exposure that can cause physical or functional defects in the embryo or fetus of the exposed mother.

Prevention

Prevention of FAS is the key to effectively addressing the problem. Prevention efforts must include public education efforts aimed at the entire population, not just women of childbearing age; appropriate treatment for women with high-risk drinking habits; and increased recognition and knowledge about FAS by professionals, parents, and caregivers.

Fetal biophysical profile

Definition

The fetal biophysical profile (BPP) is a test performed to measure fetal well-being. It uses ultrasonography to measure fetal breathing, fetal movement, fetal tone, and amniotic fluid volume. A non-stress test is done to assess fetal **heart** rate. Each of these five variables is given a score of zero or two, for a potential total score of 10.

Purpose

The purpose of the BPP is to assess fetal well-being. It is a tool used near or at term by clinicians to assess the potential risk of fetal compromise or demise due to fetal hypoxia or acidosis. Intervention such as maternal hospitalization, or delivery may follow a BPP score of four or below.

Precautions

A reliable BPP score necessitates that a well-trained ultrasonographer perform the test. However, fetal parameters are recorded over a 30-minute time period, with an additional 30 minutes for the non-stress test (NST) component. Information on a very active fetus is obtained inconsiderably less time. The complete BPP can therefore be a time-consuming test. The NST records the relationship of fetal heart rate to fetal movement. It is associated, however, with a false-positive rate as high as 80%, and averaging about 50%.

Description

The BPP is a test scoring five fetal vital sign variables: fetal heart rate, fetal breathing, fetal movement, fetal tone, and amniotic fluid volume. An ultrasound is used to visualize the fetus to measure these variables. The fetal heart rate is assessed through an NST. Each

parameter is given a score of two or zero, based on specific criteria. The total potential score is a 10. The BPP may be ordered following a non-reactive NST; after a suspicious oxytocin challenge/contraction **stress test** (CST); or after term, especially if there is concern about low amniotic fluid volume (oligohydramnios). The first researchers to report the results of scoring these fetal biophysical variables as a group were Manning and colleagues in 1980.

Fetal breathing (FB) is measured by watching for movement of the fetal thorax and diaphragm. This is to assure breathing, and not just chest wall movement. A score of two is given if at least one occurrence of FB lasting at least 30 seconds during the 30-minute test is noted. A score of zero is given if no FB is seen, or if the FB lasted less than 30 seconds.

Fetal movement is defined by gross arm, leg, or body activity. A score of two is given if there are at least three separate limb/body movements during the 30-minute test. A score of 0 is given if there are two or fewer limb/body movements during the test. Facial movement is not scored.

Fetal tone is defined by active extension and flexion of the fetal limbs, trunk, or hand; or if the hand remains in a flexed position during the entire 30-minute test. A score of two is given if the hand and fingers are seen to fully extend and flex into a fist. A score of zero is given if no such movement is recorded, or with slow or partial flexion or extension.

Amniotic fluid volume is estimated for sufficiency. Since fetal anatomic structures do not allow full visualization of all the amniotic fluid, it is estimated by measuring *pockets* of fluid from 0.39 to 0.78 in (1 to 2 cm) in height on ultrasound. A score of two is given if at least one pocket of fluid measures 0.78 in (2 cm) or more in height. A score of zero is given when no such pockets can be measured. Normal amniotic fluid volume peaks at about 750 ml at 32 weeks gestation, stays stable until term at 40 weeks, and then declines to about 400 ml by 42 weeks. Excessive amniotic fluid amounts (hydramnios), such as might be seen in diabetic mothers, may be as high as 1700 to 1900 ml. Oligohydramnios is defined by about 300 ml of fluid volume. The amniotic fluid is produced as the fetus urinates and through lung secretions. The volume is controlled by fetal swallowing and by reabsorption through the membranes. The amniotic fluid index (AFI) is also used to determine sufficiency of amniotic fluid. In this method, the largest vertical column of fluid in each of the four uterine quadrants is measured. Because of the role of the fetus in the production and control of amniotic fluid, it is one variable in fetal well-being assessment.

Fetal heart rate (FHR) variability is measured during a NST. The fetal heart rate is normally variable in nature. Accelerations, or increases in FHR, are usually seen in response to fetal movements and are therefore reassuring. A score of two is given for two or more accelerations of at least 15 beats per minute that last at least 15 seconds each during a 30-minute period. A score of 0 is given if fewer than two accelerations are seen within 30 minutes.

Preparation

Because the BPP is done during the third trimester of **pregnancy**, there is sufficient amniotic fluid to provide contrast to clearly visualize the fetus. No preparation is usually required before the test is performed. The mother may be asked to have a snack prior to the test to encourage a more active fetus. Because the mother's abdomen is exposed, curtains or a closed door should provide privacy. A comfortable room air temperature and the warming of the transducer gel can assist in putting the mother at ease. The mother should be asked if she wants her partner or support person with her during the test. A towel or cloth should cover the mother's clothing to avoid its getting wet from the transducer gel.

Aftercare

The BPP uses an external transducer to visualize the fetus and the amount of amniotic fluid. A towel or cloth can be used to wipe off excess gel and dry the abdomen after the test. In the event that test results indicate fetal compromise, a health care professional should remain with the mother to provide emotional support and answer questions as needed.

Complications

Because the test is noninvasive in nature, complications from the test itself are unexpected. A non-reassuring test may be repeated four to 24 hours later for comparison. Efforts should be made to assess for false negatives or false positives. A low BPP score may be followed by interventions with their own potential complications.

Results

A score of eight or ten out of ten provides a reassuring BPP score. If the score is eight, with a decrease in amniotic fluid volume, delivery may be indicated, with fetal maturity. A score of six arouses suspicions of chronic fetal hypoxia. A repeat test within four to six hours may be ordered. Delivery may be indicated if there is a reduction in the amniotic fluid volume. A score of four is

KEY TERMS

Fetal demise—The death of the fetus in utero.

Transducer—The external device or probe used in conjunction with the ultrasound machine. Applied on the outside of the abdomen with a special gel, it bounces sound waves into the area being visualized, and then sends the return waves back to the computerized ultrasound machine for interpretation and visualization on the monitor.

Variability—The fetal heart rate is expected to change, or be variable in nature. While the adult heart rate remains stable, except with exertion, the rate of the fetal heart continually moves up and down. A flat fetal heart rate is considered an ominous sign.

suspicious of chronic fetal hypoxia. A fetal lung maturity test may be done to assess readiness for delivery. Delivery is indicated if a repeat BPP after 24 hours confirms a score of four or below. A score of zero to two elicits a strong suspicion of chronic fetal hypoxia. The BPP testing period may continue for two hours instead of the usual 30 minutes. If the two-hour score is four or below, delivery is indicated if the fetus has a good chance at extrauterine survival.

Health care team roles

The BPP should be performed by a trained ultrasonographer. The NST may be performed by a nurse or a radiology technician in the antenatal division of an obstetric department, in the radiology department, or in an obstetric office. As with any test, patient **anxiety** is heightened with concerns of fetal compromise. Therefore, the ability of the health care professional to convey accurate information in a calming manner is very important.

Fetal cell screen

Definition

The fetal cell screen is a procedure performed during **pregnancy** whereby **blood** is drawn from the mother and examined for the presence of fetal cells.

Purpose

The fetal cell screen is used to assess the degree of Rh (also called Rho [D] or D) sensitization in an Rh-negative mother during gestation of an Rh-positive fetus. Fetal red cells carrying the Rh positive antigen can leak into the maternal circulation and immunize the Rh-negative mother, possibly leading to hemolytic disease of the newborn. The potential degree of isoimmunization and severity of hemolytic disease increases with each Rh-incompatible pregnancy. The fetal cell screen quantifies the extent of the leakage and permits determination of how much Rh immune globulin (RhoGAM) to administer in order to prevent the mother from developing anti-D antibodies against the fetus.

Rho immune globulin is normally administered by **intramuscular injection** to Rh-negative mothers at 28-30 weeks of gestation and again within 72 hours postpartum. The dosage is higher for mothers who test positive for fetal red blood cells. The treatment is performed earlier when **amniocentesis** or **chorionic villus sampling** is performed, or following spontaneous or elective abortion.

Aside from Rh-incompatibility cases, the test may be ordered to investigate the severity of maternal-fetal hemorrhage following a trauma, or during post-mortem examination of a stillbirth.

Precautions

Although in principle the fetal cell screen is simple to perform, the procedure is subjective, labor-intensive, and time-consuming; and requires skill, experience, and strict attention to detail.

When possible, the procedure should be scheduled with the laboratory in advance. The specimen may be rejected by the laboratory if it is delivered too long after

being drawn; or if clotted, hemolyzed, or contaminated with heparin (as may happen when drawn at the same time as a sample for **blood gases**).

The possibility that the mother has an inherited blood disorder that might produce fetal hemoglobin should be considered when interpreting a positive result.

Description

The fetal cell screen allows discrimination of fetal from maternal red blood cells in a sample of maternal blood. This procedure is also known as the Kleihauer-Betke test; acid elution for fetal hemoglobin; fetal hemoglobin stain; and fetal-maternal hemorrhage test.

At the hospital or laboratory, 3–7 ml of maternal blood is drawn, usually from a vein on the back of the hand or the inside of the elbow. The venipuncture site is cleaned with antiseptic, a needle is inserted, and the blood sample is collected into a vacutainer containing either EDTA or citrate. The procedure takes about five minutes. The nurse or phlebotomist performing the venipuncture should observe **universal precautions** for the prevention of transmission of bloodborne pathogens. The sample should be kept at room temperature and transported to the laboratory for analysis within 6 hours.

The fetal screen test may be performed as a qualitative serological (antibody-based) test. In this method, a 3% suspension of the mother's blood in physiological saline is mixed with an antibody to the Rho (D) antigen. The antibodies will bind to any Rh-positive fetal cells present. After the cells are incubated with the antibody, the cells are washed to remove any unbound reagent antibody, and one drop of a 3% suspension of reagent Rh positive red cells is added. These cells serve as indicators. They bind to the remaining antigen-combining sites of the antibodies attached to fetal red cells, causing formation of rosettes. The number of rosettes found in five low-power microscopic fields is determined. When greater than or equal to seven rosettes are seen, the test is considered positive. A fetal-maternal bleed of at least 30 mLs is required to give a positive test result. If this test is positive, a quantitative test is used to more accurately determine the quantity of fetal blood in the maternal circulation.

The quantity of fetal cells in the maternal circulation is most often measured using a special staining technique known as the Kleihauer-Betke method. In urgent cases, such as with trauma, results can be returned in as little as one hour. The blood sample is smeared onto a **microscope** slide, fixed with ethanol, and allowed to air dry. The blood film is then treated with a weakly acidic phosphate solution and stained with eosin dye. Under acidic conditions, the adult hemoglobin elutes, or leaks, out of

the maternal cells, and they appear as pale “ghosts,” while the more acid-resistant fetal hemoglobin remains in the fetal red blood cells and becomes stained pink to red. The stained films are viewed under a light microscope, and the number of fetal and maternal cells found in 50 low-power fields is recorded. The number of fetal red blood cells is reported as a percentage of blood cells counted. The greater the amount of fetal blood leakage, the larger the dose of Rho immune globulin to be administered to the mother.

Rho immune globulin is a potent form of anti-D that is given to Rh negative mothers to prevent formation of an antibody to the D antigen. It acts by interfering with the recognition of D antigen by the mother's **immune system**. One dose can prevent immunization from up to 30 mL of fetal blood. The percentage of fetal cells is multiplied by 50 to give the mLs of fetal blood. (Each percent of fetal red cells represents 1/100th of the blood. Assuming an average maternal blood volume of 5000 mL, each percent is equivalent to $5000/100 = 50$ mL.) This number is divided by 30 to give the number of doses needed. If the number to the right of the decimal is lower than 5, one dose is added. Otherwise, two doses are added to the result.

The Kleihauer-Betke is currently the standard method used to detect fetal red blood cells in maternal circulation, although it is labor-intensive, subjective, and not suitable for automation. Since the mid-1990s, automated methods for quantifying fetal cells by flow cytometry have been under development. In these methods, the blood sample is treated with anti-D or anti-fetal hemoglobin antibodies that are labeled with fluorescein isothiocyanate (FITC). The antibodies react only with the fetal cells. In the flow cytometer, the suspended blood cells in the specimen stream through a sample tube in single file past a beam of ultraviolet light and are counted as the light beam is broken. The light also causes the FITC label to fluoresce, and light detectors in the flow cytometer allow differential counting of the fluorescently tagged fetal cells as they pass. Compared to the Kleihauer-Betke test, the automated flow cytometry method offers superior objectivity, sensitivity, specificity, and reproducibility.

Preparation

No special preparation is necessary.

Aftercare

After the blood sample is drawn, pressure should be applied to the puncture site until the bleeding stops to reduce bruising, and a bandage may be applied to the site. The woman may resume normal activities.

KEY TERMS

Amniocentesis—A prenatal screening procedure in which a needle inserted through the abdominal wall is used to take a sample of amniotic fluid from the amniotic sac in the uterus of a pregnant woman.

Chorionic villus sampling (CVS)—A prenatal screening procedure in which a needle inserted through the vagina and cervix or through the abdominal wall is used to remove chorionic villi.

Fetal hemoglobin—The oxygen-carrying pigmented protein of fetal red blood cells, distinct from adult hemoglobin.

Flow cytometry—The measurement of cells or cellular properties as they move in a fluid stream past stationary detectors.

Fluorescein isothiocyanate (FITC)—An organic molecule that can be covalently bound to other molecules, and that emits visible light when exposed to ultraviolet radiation.

Hemoglobin—The oxygen-carrying pigmented protein of red blood cells.

Hemolytic disease of the newborn (HBN)—Also known as erythroblastosis neonatorum, severe neonatal anemia caused by Rh incompatibility and subsequent lysis of red blood cells.

Isoimmunization—The development of antibodies in a species in response to antigens from the same species.

Rh- incompatibility—The development of anti-Rh antibodies in an Rh-negative mother in response to antigens from her Rh-positive fetus.

Rhogam—Trade name for Rho [D] immunoglobulin used to immunize Rh-negative mothers.

Vacutainer—A glass tube fitted with a rubber stopper from which air is evacuated to produce a slight vacuum, used for blood specimen collection.

Venipuncture—The puncture of a vein for therapeutic purposes or to collect a specimen.

Complications

There is no risk to the mother or fetus. Complications associated with venipuncture are negligible when

the procedure is performed correctly. Minor discomfort while blood is drawn or bruising at the puncture site may occur, and there is a slight risk of **infection**.

Results

The percentage of fetal red blood cells in the circulation of normal non-pregnant adults is generally <0.1%. A level of >0.6% fetal cells is reported as positive.

Health care team roles

A physician, usually an obstetrician, orders the test. A nurse, phlebotomist, or laboratory technician collects the blood sample by venipuncture and arranges transport to the laboratory for analysis. The patient should be observed to ensure that bleeding from the puncture site stops.

In the laboratory, a clinical laboratory scientist/medical technologist trained in the Kleihauer-Betke staining procedure prepares, treats, and examines the blood smear, and counts and reports the numbers of maternal and fetal cells. A physician uses the reported ratio of fetal to maternal cells to calculate the amount of Rh immune globulin to be prescribed for the mother.

Fetal development

Definition

The progressive growth that occurs between fertilization of an egg to the birth of a baby.

Description

Pre-embryonic stage

The pre-embryonic stage starts with fertilization and lasts through the first two weeks of pregnancy.

FERTILIZATION. During intercourse, the male ejaculates and releases semen into the woman's vagina. The semen contains 50 to 200 million spermatozoa per milliliter that reach the cervix within 90 seconds and the outer end of the fallopian tubes within five minutes. Fertilization results when a single sperm, or spermatozoon, penetrates an ovum. The chromosomal material of the ovum and spermatozoon then combine, forming a zygote.

IMPLANTATION. After fertilization, the zygote travels three or four days through the fallopian tube toward the body of the uterus. During this time, the cell starts to divide. By the time the zygote reaches the body of the uterus, it consists of 16 to 50 cells and is called a morula. The morula collects large cells at the periphery of the ball and becomes an outer casing with a connected inner group of cells surrounded by a fluid space. At this stage, the structure is termed a blastocyst. The blastocyst implants on the inner layer of the uterus, called the endometrium, approximately eight to 10 days after fertilization, where it will obtain nourishment. In as many as 50% of all pregnancies, the zygote fails to reach the implantation stage, in which it becomes an embryo.

Embryonic stage

The embryonic stage spans the third week to the eighth week of pregnancy.

Body organs form out of layers of tissue called germ cells. The three distinct layers of germ cells are called the endoderm, the ectoderm, and the mesoderm. Newborns with a congenital defect originating from one of the three layers should be evaluated for malformations that devel-

KEY TERMS

Fetus—Infant during intrauterine life.

Sonogram—Ultrasound; uses sound waves to take pictures and view the fetus.

oped from the same germ cells. For example, the **heart** and **kidneys** form from the mesoderm. A baby born with a heart defect should also have an x ray or ultrasound of the kidneys.

During the embryonic period, the baby is most susceptible to invasion by teratogens, which are substances that can result in birth defects. Women should be instructed on ways to reduce their contact with teratogens.

Milestones of fetal development

The life of the fetus is commonly calculated from the time of ovulation or fertilization (ovulation age), but the duration of the **pregnancy** is usually calculated from the first day of the last menstrual period (gestational age). The following outline of fetal development milestones is based on 40 weeks of gestation.

END OF FOUR WEEKS GESTATION.

- Fetus reaches a length of 0.75 to 1 cm and weighs 400 mg.
- Spinal cord forms and fuses at the center.
- Lateral wings bend forward meeting at the center and will eventually form the body.
- Head tilts forward and makes up about one-third of the entire structure.
- The rudimentary heart beats a regular rhythm.
- Arms and legs have the appearance of small buds.
- The beginnings of eyes, ears, and a nose are evident.

END OF EIGHT WEEKS GESTATION.

- Fetus reaches a length of 1 in (2.5 cm) and weighs 20 g.
- The heart has a definite septum and valves.
- Extremities have lengthened.
- External genitalia are evident, but gender is not obvious.

END OF 12 WEEKS GESTATION.

- Fetus reaches a length of 2.8-3.6 in (7-9 cm) and weighs 45 g.
- Some movement occurring, but usually too faint for the mother to feel.

- Fetal heart can be heard with an electronic device called a Doppler.

END OF 16 WEEKS GESTATION.

- Fetus reaches a length of 4-7 in (10 to 17 cm) and weighs 55 to 120 g.
- Liver and pancreatic secretions are present.
- Fetus starts to make sucking motions with the mouth.

END OF 20 WEEKS GESTATION.

- Fetus reaches a length of 10 in (25 cm) and weighs 223 g.
- The mother starts to feel fetal movement.
- Fetal heart tones can be heard with a stethoscope.

END OF 24 WEEKS GESTATION.

- Fetus reaches a length of 11-14 in (28-36 cm) and weighs 550 g.
- Eyebrows and eyelashes are clearly formed.
- Eyelids, which fused in the 12th week, start to open.
- Pupils are reactive to light.
- Fetus could possibly be viable if born now and cared for in a neonatal intensive care unit.
- Surfactant, a phospholipid substance essential to lung function, is formed and excreted by cells in the alveoli.

END OF 28 WEEKS GESTATION.

- Fetus reaches a length of 14-15 in (35-38 cm) and weighs 1200 g.
- Testes begin descent into the scrotal sac from the lower abdominal cavity if the fetus is male.
- The **brain** is rapidly developing.

END OF 32 WEEKS GESTATION.

- Fetus reaches a length of 15-27 in (38-43 cm) and weighs 1600 g.
- Fetus hears sounds and responds with movement.
- Delivery presentation (vertex or breech) may be assumed.
- Iron stores begin to develop.

END OF 36 WEEKS GESTATION.

- Fetus reaches a length of 17-20 in (42-49 cm) and weighs 5-6 lbs (1900-2700 g).
- Soles of the feet have only one or two creases.
- The **central nervous system** has greater control over body functions.

END OF 40 WEEKS GESTATION.

- Fetus reaches a length of 19-21 in (48-52 cm) and weighs 7-7.5 lbs (3000 g).
- Fingernails have grown over the fingertips.
- There are creases covering at least two-thirds of the soles of the feet.
- Fetus kicks vigorously and may cause the mother discomfort.

Role in human health

Knowledge of fetal development can assist the mother and other family members in visualizing the fetus at the various stages of development. The parent-infant bonding that results can be an incentive for the mother to engage in healthful behaviors.

Fetal lung maturity test *see* **Lipid tests**

Fetoscopy**Definition**

Fetoscopy utilizes an instrument called a fetoscope to evaluate or treat the fetus during **pregnancy**.

Purpose

There are two different types of fetoscopes. One resembles a **stethoscope**, but with a headpiece. It is used externally, on the mother's abdomen, to auscultate (listen to) the fetal **heart** tones. The second type of fetoscope is a fiber-optic **endoscope**. It is inserted into the uterus either transabdominally or transcervically to visualize the fetus, to obtain fetal tissue samples, or to perform fetal surgery.

Precautions

The external fetoscope requires no preparation, nor does it have any associated risks. Its usefulness and accuracy depend on the skill of the practitioner. The endoscopic fetoscope is inserted internally and thus carries risks of **infection** (both maternal and fetal), premature rupture of membranes, premature labor, and fetal death. The American College of Obstetricians and Gynecologists expressed their opinion in a February 28, 2001 press release that fetal surgery should be considered experimental.

Description

The external fetoscope is used to auscultate fetal heart tones for rate and rhythm. The earpieces and the headpiece allow auscultation via both air and bone conduction. It is inexpensive, is not invasive, and does not require electricity. It is difficult to clearly hear the fetal heart tones prior to 18 to 20 weeks gestation. Doppler ultrasound can measure fetal heart tones around weeks 10 to 12. External fetoscopy is compromised in a noisy environment, with an obese mother due to the large abdomen, and in the case of hydramnios.

Endoscopic fetoscopy uses a thin (1 mm) fiberoptic scope. Developed in the 1970s, the endoscope was originally inserted transabdominally to visualize the fetus for gross abnormalities suspected by ultrasound or to obtain tissue and **blood** samples. It was performed after about 18 weeks gestation. Even with practitioner expertise, associated fetal loss was three to seven percent. In the 1980s ultrasound-guided needle sampling of cord blood replaced fetoscopy when samples of fetal blood were required. As laparoscopic and microsurgical techniques have become more common and the instrumentation has become more advanced technologically, the expertise gained has carried over to fetoscopy, improving its use for fetal diagnostic and therapeutic purposes. Fetal surgery performed through an open maternal abdomen has a higher risk of such complications as infection, premature rupture of membranes, **preterm labor**, or fetal death. If surgery is performed via fetoscopy, which requires a very small transabdominal incision, the risks are much smaller. Techniques have advanced enough to allow some fetoscopy to be performed in the first trimester via the cervix. The term obstetrical endoscopy may be used for surgery on the placenta, umbilical cord or on the fetal membranes. The term endoscopic fetal surgery is used for such procedures as the repair of a fetal congenital diaphragmatic hernia, enlarged bladder, and spina bifida.

KEY TERMS

Auscultation—Auscultation uses the sense of hearing to evaluate such internal organs as the heart or bowel. While the practitioner may simply use his or her ears directly, most commonly auscultation is performed with an instrument, such as a fetoscope or stethoscope.

Hydramnios—Hydramnios is the excessive production of amniotic fluid due to either fetal or maternal conditions.

Supine—Lying horizontally on one's back.

Preparation

The use of external fetoscopy requires access to the maternal abdomen, with the mother lying supine or in a semi-seated position. Afterwards, the mother is able to get up and resume a normal activity level.

Preparation for endoscopic fetoscopy will depend on the extent of the procedure, and whether it is performed transcervically or transabdominally. Obtaining a small fetal tissue sample is a smaller procedure by comparison to fetal surgery. Other factors include outpatient versus inpatient stay and anesthesia (both maternal and fetal). For some procedures medication may be administered to temporarily decrease fetal movement to lower the risk of fetal injury. Maternal anesthesia may be local, regional, or general.

Aftercare

External fetoscopy does not require aftercare. The care following fetal endoscopic use will depend on the extent of the procedure and the type of anesthesia used. If done on an outpatient basis, the mother and fetus will be monitored for a period of time to assure well-being before discharge. More extensive surgery will require inpatient hospital care.

Complications

The only potential complication with external fetoscopy is the potential for missing an abnormal heart rate or rhythm. Endoscopic fetoscopy has the potential for infection to the fetus and/or mother, premature rupture of the amniotic membranes, premature labor, and fetal death. When endoscopic fetal surgery is done instead of open-uterus fetal surgery, the risks to the mother and fetus are decreased. This is because the incision is significantly smaller, with less potential blood loss,

decreased uterine irritability, and decreased risk for early pregnancy termination.

Results

The normal fetal heart rate is 120 to 160 beats per minute, regardless of the method used for auscultation (external fetoscopy or Doppler ultrasound). Some variability of fetal heart rate is expected, as the heart rate increases with fetal activity and slows with fetal rest.

Results expected using endoscopic fetoscopy will vary depending on the procedure undertaken. The goal is for the maximum benefit with the minimum of risk or complication to both the mother and fetus.

Health care team roles

Individuals utilizing the external fetoscope include a nurse practitioner, nurse midwife, and obstetrician. For endoscopic fetoscopy, the procedures require a high level of skill and experience by fetal surgeons. During the procedures, a radiology technician may perform an ultrasound and a laboratory technician may be involved in blood sampling. Nurses will participate in both outpatient as well as inpatient procedures.

Fever

Definition

Fever is defined as an abnormally high body temperature or a regulated rise to a new set point of body temperature. While a body temperature above 100°F (37.8°C) is considered to be a fever by some clinicians, a significant fever is usually defined as an oral temperature of 102°F (39°C) or a rectal temperature of 103°F (39.5°C). Fever is a sign of inflammation and represents the body's response to microbial invasion or to a disease process.

Hyperthermia is defined as abnormally high body temperature caused by disruption of the body's thermoregulatory mechanisms. Hyperthermia occurs when the body's metabolic heat production or environmental heat load exceeds the normal heat loss capacity (or when normal heat loss is impaired).

Description

The normal temperature of the human body fluctuates between 97°F (36.1°C) and 100°F (37.8°C), with the average being 98.6°F (37°C). There is a diurnal pattern of temperature variation in humans, with body temperature being lowest in the morning and highest in late afternoon. In women of childbearing age, there is a small rise in temperature following ovulation during the menstrual cycle, and during the first trimester of **pregnancy**.

The body's thermoregulatory mechanisms include changes in muscle tone, vascular tone, and sweat production, which serve to balance body heat produced by **metabolism** with heat lost to the environment. This balance is regulated by the hypothalamus, a small structure in the **brain** below the thalamus. The body's temperature regulation can be upset by environmental factors (external heat and humidity); by disorders or conditions that inhibit sweat production or evaporation; and by infectious diseases.

Fever occurs when the hypothalamus raises the body's temperature to a new set point. White **blood** cells called monocyte-macrophages release **proteins** called pyrogens when the cells encounter pathogenic microorganisms. The pyrogens act on the hypothalamus, causing it to reset the body's "thermostat" upward. The vessels that supply the skin with blood often narrow as the body's temperature is rising. This process, which is called vasoconstriction, reduces sweating and causes the body to retain more heat than it loses. Vasoconstriction in the skin and extremities allows the body to move blood toward its core, which increases the rate of metabolism and induces shivering. The chills that often accompany a fever are caused by this movement of blood to the body's core, which leaves the skin surface and extremities relatively cool. When the **infection** or disease process resolves, the hypothalamus attempts to reset the body's **thermoregulation** at its normal set point. The body's cooling mechanisms switch on as the blood returns to the extremities and skin surface, and sweating occurs.

Fever is an important component of the immune system's inflammatory response, though its role is not completely understood. A rise in body temperature has several effects. The pyrogens that trigger the resetting of the body's thermostat also increase the production of macrophages, which fight off invading **bacteria** or **viruses**. Higher temperatures also inhibit the growth of some bacteria, while at the same time activating the **immune system**. In addition, the increased **heart** rate that accompanies vasoconstriction also speeds the arrival of white blood cells to the sites of inflammation.

Causes and symptoms

Causes

Fever can be caused by a wide variety of diseases and disorders, including:

- infectious diseases, which may be caused by viruses, bacteria, **fungi**, rickettsiae, or parasites
- **autoimmune disorders**, including systemic lupus erythematosus, rheumatic fever, adult rheumatoid arthritis, Wegener's granulomatosis, polyarteritis nodosa, and Still's disease
- disorders of the **central nervous system** (CNS), including head injuries, multiple sclerosis, tumors of the brain or **spinal cord**, and cerebral hemorrhage
- cancers, including primary cancers of the colon, rectum, kidney, and **liver**, and metastatic cancers of the liver
- cardiovascular disorders, including **myocardial infarction** and pulmonary embolism

- reactions to such medications as methyldopa, quinidine, hydralazine, phenytoin, chlorpromazine, carbamazepine, anti-cancer drugs, and antibiotics
- endocrine disorders, including hyperthyroidism (thyroid storm) and pheochromocytoma
- gastrointestinal disorders, including alcoholic hepatitis, inflammatory bowel disease (IBD), and liver abscess
- inflammation associated with indwelling catheters, intravenous lines, and nasogastric tubes
- neuroleptic malignant syndrome, which is a rare and potentially fatal reaction to certain antipsychotic medications

Fever patterns

Fevers may be classified as intermittent (the patient's temperature falls to normal at some point during the day); sustained (the temperature remains high); or relapsing (periods of fever are followed by several days of normal temperatures). The fever pattern may be helpful in the differential diagnosis; for example, fevers related to medication reactions are more often sustained than intermittent. A relapsing pattern suggests **malaria**.

The degree of temperature elevation in a fever does not necessarily correspond to the seriousness of the illness. In general, children with fevers run higher temperatures than adults, while elderly persons and newborns may have less marked fevers.

Diagnosis

The differential diagnosis of fever is complicated by the variety of possible causes. In most cases, the patient's history—including a medication history and history of exposure to infectious diseases—vital signs, a **complete blood count**, and blood cultures will help to narrow the number of possible causes. In fevers of unknown origin (FUOs), however, the physician may need to schedule a chest x-ray or ultrasound and CT imaging.

Fevers of unknown origin (FUOs)

The origin of some fevers is difficult to determine. The term “fever of unknown origin” (FUO) has been applied to cases of fever in which the patient's temperature remains over 101°F (38.3°C) for three weeks and in which the diagnosis is not apparent after seven or more days of studies. The most common cause of FUOs is an infectious disease of some kind, although many cancers present initially as FUOs. About 15% of FUOs never receive a definite diagnosis.

Temperature measurement

A variety of different devices are available to register body temperature, including the traditional glass thermometers used for oral or rectal temperature readings. More recently, sophisticated electronic devices have been introduced that register body temperature as a digital readout. For younger children and infants, there are forehead meter strips and pacifiers with temperature-sensitive readouts.

Treatment

Routine measures

Most fevers are caused by common infections, are short-lived, and do not require symptomatic treatment. The patient's comfort, however, may be improved by measures to remove body heat, antipyretic medications, and fluid replacement. Measures to remove body heat include alcohol or cold sponges; ice bags; and ice baths. The most common antipyretic medications are aspirin or acetaminophen, 350–650 mg every four hours. Children or adolescents with influenza-like symptoms should not be given aspirin without consulting a physician because of the possibility of developing Reye's syndrome, a rare disorder characterized by vomiting and liver dysfunction.

Fluid replacement is an important part of fever treatment. Extra fluid is required to prevent electrolyte imbalance as well as to replace fluid lost through perspiration.

Emergency treatment

Body temperature over 105.8°F (41°C) in an adult is a medical emergency and requires immediate treatment.

The following indications in specific patient groups may require emergency treatment:

- newborns (three months or younger) with fever of 100.5°F (38°C) or higher
- infants or children with fever of 103°F (39.4°C) or higher
- adults with fever of 101°F or higher lasting longer than three days; or a temperature of 100.5°F lasting longer than three weeks without other symptoms

A very high fever in a small child can trigger febrile seizures, and therefore requires immediate treatment. A fever accompanied by a stiff neck, severe headache, throat swelling, and changes in mental status may indicate the presence of **meningitis** or another serious infection, and should be brought to the immediate attention of a physician. High fever does not always produce sweating or diaphoretic symptoms, which indicates weakness in the body's defenses against severe disease.

Prognosis

Most fevers caused by infection end as soon as the immune system rids the body of the pathogen and do not produce any lasting effects. Exceptions include fevers associated with meningitis, typhoid, or scarlet fever. High fevers can produce major disturbances of the body's metabolism and alter the body's responses to medications. In addition, a high fever during the first trimester of pregnancy increases the risk of such birth defects as anencephaly (absence of a portion of the **skull** and brain).

The prognosis for fevers associated with such chronic conditions as autoimmune disorders depends on the stage of the disease and its management.

Health care team roles

Nurses assess and record the fever patient's signs and symptoms. Nurses as well as physicians can obtain relevant information from the patient's medical history. Home health care and visiting nurses may also help to educate patients about at-home treatment of fevers. In some cases, **home care** nurses may counsel patients and caregivers over the phone, advising when the condition warrants in-person medical attention.

Prevention

Since most fevers are caused by infectious agents, careful attention to proper methods of food handling, hand washing, and similar **public health** measures is an important form of prevention. Fevers related to medication reactions can sometimes be prevented by substitution of drugs that are less likely to produce such reactions. Fevers related to indwelling catheters and similar devices may be avoided by removing them as soon as they are no longer required.

Hyperthermia related to environmental conditions may be prevented by proper attention to climatic conditions, adequate fluid and electrolyte intake, and acclimatization to hot environments. Educating the public about the early signs of **heat disorders** is another important preventive measure.

KEY TERMS

Antipyretic—A drug that lowers body temperature, such as aspirin or acetaminophen.

Autoimmune disease—A disorder in which the immune system attacks the body's own cells.

Febrile seizure—Convulsions brought on by high body temperature and inflammation of the brain or brain covering.

Hyperthermia—Abnormally high body temperature that occurs when the body's metabolic heat production or environmental heat load exceeds the normal heat loss capacity (or when heat loss is impaired). Heat stroke is an example of hyperthermia.

Hypothalamus—A region in the posterior section of the forebrain that regulates body temperature, sleep cycles, and the activity of the pituitary gland.

Intermittent—A fever pattern marked by the patient's temperature returning to normal at some point during the day.

Macrophage—A type of large white blood cell that helps the body fight off pathogenic microorganisms by ingesting them.

Malignant hyperthermia—A rare inherited condition in which a person develops a very high fever when given general anesthetics or muscle relaxants in preparation for surgery.

Pyrogen—A substance that produces a rise in body temperature. Bacterial toxins are one type of pyrogen.

Relapsing—A fever pattern in which periods of fever alternate with several days of normal temperatures.

Reye's syndrome—A rare disorder that occurs primarily in children recovering from a viral illness and associated with aspirin usage. It is characterized by vomiting, swelling of the brain, and liver dysfunction.

Vasoconstriction—Narrowing of the blood vessels, which serves to conserve body heat and maintain or raise blood pressure.

Fibrin degradation products test

Definition

When injury occurs to a **blood** vessel wall, thrombin (a coagulation enzyme) is formed in the first stage of a complicated series of steps called the coagulation cascade. In the second phase, fibrinogen, a coagulation protein made by the **liver**, is converted to fibrin, which results in the formation of a gel-like meshwork at the site. This fibrin mesh is altered by the action of factor XIIIa which cross-links fibrin polypeptides, forming a stable clot. As the site heals, the clot is broken down by the enzyme plasmin. This process, called fibrinolysis, is initiated by a protein called tissue plasminogen activator that is released from blood vessel cells adjacent to the injured site. Plasminogen activator converts plasminogen to an enzyme called plasmin. The plasmin splits polypeptides from the fibrin clot. These fragments are known as fibrin degradation products (FDP).

Fibrin degradation products are fragments (polypeptides) produced when either fibrin or fibrinogen is broken down by the enzyme plasmin. There are four principal fibrin degradation products called X, Y, D, and E that are liberated in various combinations. When a fibrin clot is broken down by plasmin, the last fragment to be degraded is one consisting of two D and one E subunits. This is split, releasing the E fragment and two D fragments that are covalently linked together. This fragment is called D-dimer, and it is produced from fibrin but not from fibrinogen degradation.

Purpose

A test for FDP may be requested by a physician when excessive bleeding occurs and thrombosis or other serious disorder in the coagulation mechanism is suspected. The FDP assay measures amounts of the fibrin and fibrinogen split products in the blood and directly indicates the level

of activity of the fibrinolytic system. High levels of FDP will indicate increased fibrinolysis. Excessive fibrin degradation products are released into the plasma in three main conditions: disseminated intravascular coagulation (DIC), thromboembolytic therapy, and primary fibrinogenolysis. Fragments X, Y, E, and D are released whenever either fibrin or fibrinogen is broken down by plasmin. This degradation occurs in all three situations.

Normal blood plasma does not have significant amounts of D-dimer. It is present in the blood in detectable amounts in several conditions, most notably in disseminated intravascular coagulation (DIC), a rare disruption in normal coagulation in which rapid intramicrovascular (within the **blood vessels**) coagulation occurs at the same time as fibrinolysis (clot dissolution mechanism). The D-dimer test is used to diagnose DIC. It is also frequently used to help diagnose deep-vein thrombosis (clots in veins); pulmonary embolism (clots in the **lungs**); the thrombosis of malignancy; and sickle cell anemia (a form of anemia characterized by bleeding episodes); and to monitor the effects of thrombolytic drugs. Thrombolytic drugs that may increase D-dimer levels are barbiturates, heparin, streptokinase, and urokinase. Levels of D-dimer will be elevated in these conditions.

Description

When functioning normally, coagulation and fibrinolysis maintain hemostasis (the normal fluid state of blood in the circulatory system) by regulating clot formation and dissolution. When bleeding occurs, coagulation results in production of a clot at the site of injury, and subsequent fibrinolysis dissolves the clot as the vessel wall heals. The fibrinolytic system is highly complex. A deficiency of plasminogen will result in increased risk of thrombosis. Plasmin is inactivated by several proteases, which are enzymes that catalyze the breakdown of polypeptides. A deficiency of one of these can result in spontaneous bleeding. FDPs themselves can neutralize the activity of some coagulation factors and interfere with normal clot formation. In three conditions, disseminated intravascular coagulation, thromboembolytic therapy, and primary fibrinogenolysis the fibrinolytic activity of the plasma is increased. When this occurs, depletion of coagulation factors, including fibrinogen, results in uncontrolled bleeding. Measurement of FDP and D-dimer are used to identify these causes of hemorrhage.

DIC results in the formation of circulating small fibrin clots formed by a condition that triggers the coagulation cascade. Coagulation factors become depleted and hemorrhage results. DIC is a rapidly progressing condition caused by an underlying disease or trauma, such as the clinical conditions shown below.

- complications of **pregnancy**, such as toxemia, abortion, cesarean section, **placenta previa**, and other conditions
- tissue trauma, such as major surgery, severe trauma and **burns**, rejection of transplant, and heatstroke
- hemolytic processes (destruction of red blood cells), such as transfusion of mismatched blood, drowning, complications of **infection**, and certain types of poisoning
- malignancies, such as solid tumors, leukemia, and other forms of cancer
- infections, such as bacterial infections, septicemia, Rocky Mountain spotted **fever**, some viral infections, and parasitic infections
- miscellaneous clinical conditions, such as diseases of the liver and **pancreas**, uremia, **shock**, stroke, severe **heart failure**, and aortic aneurysm (rupture of the aorta)

Coronary artery disease can result in the formation of a blood clot at the site of blockage in the **heart** vessels. One alternative form of treatment is the administration of a thrombolytic agent such as streptokinase or tissue plasminogen activator. These drugs act by stimulating fibrinolysis, and consequently they may cause both the fibrin clot and fibrinogen to break down. Fibrinogen depletion and accumulation of FDP can interfere with coagulation, causing spontaneous hemorrhage.

Primary fibrinogenolysis is a condition in which fibrinogen is broken down to fibrin in the absence of a clot. Unlike DIC, the formation of intravascular thrombi does not occur. However, if severe, hemorrhage can result because the body's supply of fibrinogen becomes depleted. Causes include shock, hypoxia, heat stroke, hemorrhage, surgery, and liver disease.

FDP tests will yield abnormal results in all three conditions described above because the fragments detected are produced when either fibrin or fibrinogen is split by plasmin. Therefore, the FDP test is not specific for thrombotic diseases such as DIC or deep vein thrombosis. The FDP test uses latex particles coated with anti-D and anti-E. When mixed with plasma, these antibodies react with D and E fragments of both fibrin and fibrinogen, forming a clump.

The D-dimer test measures only the D fragments of fibrin that are covalently bound together. When a fibrin clot is stabilized by factor XIIIa, the D domains of adjacent molecules become linked together. The action of plasmin causes these to be released from the clot as a dimer, which is a molecule composed of two identical simpler molecules. Therefore, the D-dimer test will be positive only when fibrin degradation has occurred. This happens in DIC, after thromboembolytic therapy, and in such throm-

bolic conditions as deep vein thrombosis and pulmonary embolism, but does not occur in primary fibrinogenolysis.

D-dimer is detected by a latex agglutination test. Latex particles coated with anti-D that bind only to D-dimer are used. These particles will clump when mixed with serum that has an increased level of D-dimer. Since D-dimer levels parallel the amount of fibrinolytic activity in DIC, a quantitative test is often used to evaluate the severity of the disease. The test used is a two-site double antibody sandwich immunoassay.

Precautions

Blood for FDP testing is collected by venipuncture into tubes containing EDTA, citrate, or heparin anticoagulant. The nurse or phlebotomist performing this procedure should follow **universal precautions** for the prevention of transmission of bloodborne pathogens. Performing a venipuncture to obtain a blood sample for the D-dimer test may be contraindicated if the patient is exhibiting prolonged bleeding from other sites. In this case the nurse or phlebotomist should consult the testing physician, who will determine an alternate means of obtaining a blood sample (such as placement of a catheter). There are no other notable precautions associated with performing the D-dimer test.

Preparation

There is no special preparation for the D-dimer test. No fasting is required.

Aftercare

Following venipuncture to obtain blood samples for the D-dimer test, the laboratory technologist, nurse, or phlebotomist drawing the sample should apply pressure to the site to stop any residual bleeding. The venipuncture site should then be carefully inspected to make sure that the wound has closed and no bleeding is present. If bleeding continues even after pressure is applied, this event should be reported to the testing physician.

Complications

DIC often involves a rapidly changing hemostatic condition. Patients with DIC or thrombosis may be in serious condition and will likely not be ambulatory; more typically, patients with suspected DIC or thrombosis will be hospitalized. Nurses should be alert to any change in the patient's condition. Noticeable changes in the patient's condition at the time of venipuncture should be reported to the patient's physician. The venipuncture site should be examined for bleeding and any prolonged

KEY TERMS

D-dimer—A fibrin degradation fragment or product that is produced by the action of plasmin on fibrin in the clot dissolution process.

Disseminated intravascular coagulation (DIC)—A disruption in hemostasis in response to an underlying disease or trauma. It is associated with the release of a tissue factor that triggers coagulation and activates rapid thrombin formation and fibrinolysis throughout the vascular system.

Fibrin—A protein formed in the blood as an important component of the coagulation process.

Fibrin degradation products—Known also as fibrin split products, fibrin degradation products are formed when the fibrinolytic system is activated in response to the formation of clots in the vascular system. Fibrin degradation products, including D-dimer, will be present in fibrinolysis or thrombosis.

Fibrinolysis—The dissolution of clots by an activated fibrinolytic system. When clot formation occurs, the fibrinolytic system activates factors that lead to the formation of plasmin, which degenerates the fibrin in the clot.

Hemostasis—A regulating process that maintains blood in a fluid state and prevents the loss of blood through clot formation when the vascular system is compromised.

Plasmin—Plasmin is an enzyme formed in the activation of the fibrinolytic system to dissolve clots. Plasmin breaks down the fibrin in a clot into the fragments that are known as fibrin degradation products.

Thrombolytic drugs—Anticoagulants used to inhibit clotting. Thrombolytic therapy is used when increased fibrin degradation products are present, such as in patients who have had a heart attack or who have a compromised coagulation mechanism or a history of thrombosis.

Thrombosis—The presence of a clot or clots in the vascular system.

bleeding that cannot be stopped by applying pressure should be reported to the physician immediately.

Results

Reference ranges for FDP tests will vary according to the test method used and the laboratory performing the

test. Qualitative results may be reported only as positive or negative. Typical FDP results are listed below.

- Undiluted plasma is negative (no clumping): FDP is reported as less than 2 micrograms/mL.

A clumping reaction is reported as positive. If plasma is diluted, reporting is as follows:

- If the undiluted plasma only is positive: equal to or greater than 2 mcg/mL but less than 10 mcg/mL.
- If a 1:5 dilution of plasma is positive: equal to or greater than 10 mcg/mL but less than 80 mcg/mL.
- If a 1:20 dilution is positive: equal to or greater than 80 mcg/mL.

D-dimer results are reported as follows.

- Qualitative negative: less than 250 nanograms/mL.
- Qualitative positive: equal to or greater than 250 ng/mL.
- Quantitative: normally less than 250 ng/mL or less than 250 micrograms/L.

Health care team roles

A physician orders the FDP tests and interprets them. The testing physician must obtain an accurate patient history, especially to determine if the patient is taking any drugs that can affect the test results and to learn about any recent illness, trauma, or symptoms that could be related to DIC or thrombosis. The procedure should be explained to the patient by the unit nurse, who should be aware of the degree of seriousness of the patient's condition. FDP tests are performed by clinical laboratory scientists/medical technologists or by clinical laboratory technicians/medical laboratory technicians.

Training

Laboratory technologists performing D-dimer tests will have studied hematology and coagulation, enabling them to understand coagulation and the fibrinolytic system. Hands-on clinical laboratory training will prepare technologists to perform agglutination tests or monoclonal antibody tests for D-dimer. Nursing personnel responsible for patients undergoing D-dimer testing will understand the patient's condition and will be trained to observe changes that may signal a critical hemostatic event.

Fibrinogen test *see* **Coagulation tests**

Fibromyalgia

Definition

Fibromyalgia (formerly known as fibrositis) is an inflammation of the fibrous or connective tissue (muscles, joints, ligaments, and tendons) of the body. Widespread **pain**, fatigue, and multiple tender points characterize this condition. Other symptoms may include sleep disturbance, headache, and bowel disturbances.

Description

Fibromyalgia is more common than previously thought, with as many as 3–6% of the population affected by the disorder. Fibromyalgia is more prevalent in adults than children, with more women affected than men—particularly women aged 35 to 55. Fibromyalgia symptoms have often been characterized as psychosomatic in origin. Recent research has proved that belief false, and fibromyalgia is now regarded as a disorder that can be diagnosed and treated effectively with ongoing care and follow-up.

Causes and symptoms

The exact cause of fibromyalgia is not known. There are events that can precipitate the symptoms of fibromyalgia, including **sports injuries**, car accidents, **falls**, or other trauma to the body. Sometimes it occurs in several members of a family, suggesting that there may be an inherited tendency for the disorder. People with fibromyalgia are most likely to complain of three pri-

mary symptoms: pain in muscles, joints, and ligaments; stiffness; and excessive fatigue. Widespread, ongoing pain is characteristic of fibromyalgia. A careful history and **physical examination** may uncover additional areas of pain when the chief complaint lies in only one area of the body. The most significant area of pain may shift over time, and the pain can be intermittent.

Pain is the major symptom of fibromyalgia, with aches, tenderness, and stiffness of multiple muscles, joints, and soft tissues. The pain may also tend to move from one part of the body to another. It is most common in the neck, shoulders, chest, arms, legs, hips, and back. Although the pain is present most of the time and may last for years, the severity of the pain is variable and dependent on individual patient perception.

Symptoms of sleeplessness and overall fatigue may result from the individual’s chronic pain, coupled with **anxiety** about the problem and how to find relief. The body’s inflammatory response also produces chemicals in the **brain** that are known to contribute to fatigue. Other common symptoms are tension headaches, difficulty swallowing, recurrent abdominal pain, **diarrhea** (irritable bowel syndrome), and numbness or tingling of the extremities. **Stress**, anxiety, depression, lack of dietary control, or lack of sleep can increase symptoms. Intensity of symptoms varies. Some patients gradually improve, while others have recurrent episodes of their symptoms.

Diagnosis

Diagnosis is difficult, and the disease may be overlooked because symptoms of fibromyalgia are vague and general. In addition, fibromyalgia may mimic symptoms of other diseases and conditions. Support staff should question the patient regarding sleep and **exercise** patterns, diet, and emotional conditions. Coexisting nerve and muscle disorders, such as rheumatoid arthritis, spinal arthritis, or Lyme disease, may further complicate the diagnostic process. Presently, there are no tests available to specifically diagnose fibromyalgia. The final diagnosis is frequently made after a period of time in which the physician observes the patient and rules out other medical conditions with similar symptoms.

Because of the emotional distress experienced by people with this condition and the influence of stress on the symptoms themselves, fibromyalgia has often been labeled a psychosomatic condition. Recognition of the underlying inflammatory process involved in fibromyalgia has helped promote the validity of this disease. Nurses, nurse practitioners or physician’s assistants should inquire into the emotional state of the patient, and be prepared to note it in the chart. Mental health consultation may be necessary due to depression or anxiety, and

emphasis on the importance of a support group for fibromyalgia patients should be given.

In 1990, the American College of Rheumatology developed standards for fibromyalgia that health care practitioners can use to diagnose this condition. According to these standards, a person is thought to have fibromyalgia if he or she has widespread pain in combination with tenderness for at least three months in at least 11 of the 18 sites known as trigger points. Trigger point sites include the neck, spine, hip, elbow, knee, and shoulder.

Treatment

There is no known cure for fibromyalgia. Therefore, the goal of treatment is successful symptom management. Treatment usually requires a combination of therapies, including exercise, proper rest, and diet, and pharmacologic treatment. **Patient education** by the health care team is imperative so that the patient has a clear understanding of his or her role in the recovery process and the successful management of this condition.

Physical regimens found to be helpful include a regular stretching program and low-impact aerobic activities that increase the **heart** rate. Exercise programs should be approved by a physician or physical therapist, and include both warm-up and cool-down sessions, with special attention given to avoiding exercises that cause joint pain. Adequate rest is essential in the treatment of fibromyalgia.

Nutrition is an important component in the management of this condition. The patient's diet should include a wide variety of fruits and vegetables to provide the body with trace elements and **minerals** that are necessary for healthy muscles. Avoidance of stimulating drinks (such as coffee, tea, or any drink containing **caffeine**), avoidance of alcohol (may lead to sleeplessness) and such medications as decongestants prior to bedtime is advised. If diet, exercise, and adequate rest do not relieve the symptoms of fibromyalgia, medication may be prescribed.

Medications that have been found to have some benefit include **antidepressant drugs**, **muscle relaxants**, and **nonsteroidal anti-inflammatory drugs** (NSAIDs).

People with fibromyalgia often need a rheumatology consultation (a meeting with a doctor who specializes in disorders of the joints, muscles, and soft tissue) to decide the cause of various rheumatic symptoms, to be educated about fibromyalgia and its treatment, and to exclude other rheumatic diseases. A physician must recommend a treatment program that is individualized to meet the patient's needs.

Alternative treatment

Massage therapy can be helpful, especially when a family member is instructed on specific massage techniques to manage episodes of increased symptoms. Specific attention to mental health, including behavior modification and psychological consultation, may also be important because depression and anxiety may precede or accompany an incident of fibromyalgia. Other alternative therapies, including homeopathic medicine, Chinese traditional medicine (both acupuncture and herbs), polarity therapy, and Western botanical medicine, can assist the person with fibromyalgia in day-to-day functioning and contribute to alleviation of symptoms.

Prognosis

Fibromyalgia is a chronic condition, but causes no body damage or deformity. It does not cause damage to internal organs, as opposed to conditions such as rheumatoid arthritis, which leads to joint deformity. Treatment is based on the relief of symptoms, so a cure is not a realistic goal. Management of the condition may allow patients to return to a higher level of function at work, play, and home.

Health care team roles

Fibromyalgia can be a stressful and frustrating condition for a majority of patients. Successful treatment often requires a period of trial and error to pinpoint which agents and activities work best for the individual patient. Patience while waiting for diagnosis and treatment should be stressed by support staff, along with reassurance that the physician is working to find a treatment regimen that will provide relief. However, there is no set treatment that works for every patient. Even the process of diagnosing fibromyalgia can take time, which also leads to patient frustration. Therefore, support from the health care team and coordination of care through follow-up calls to outside health care providers is needed to avoid actually worsening the patient's condition due to undue stress. Nursing parameters are **pain management**, improved sleep management, introduction of **relaxation** techniques (including massage and biofeedback if needed), and monitoring alternative treatments and medication. There could be a wide variety of health care providers on a patient's health care team: nurses, physicians, a rheumatologist or other subspecialist, nutritionist, physical therapist, alternative medicine caregiver, or mental health care providers. This requires that the health care providers who most frequently see the patient coordinate and record in the patient's medical chart all treatments being undertaken at any given time. Coordination

of care increases patient compliance, and may boost the patient's perception of his or her level of function. Patient education is an integral part of the treatment and management of fibromyalgia and its symptoms. Patients should be supported both physically and emotionally. Chronic pain may make it more difficult to communicate with a patient in a manner that promotes professionalism and optimal care. Constant cognizance of the treatment goals (to control pain and increase level of function) is needed as well as positive reinforcement of compliance with treatment suggestions and monitoring of patient milestones.

Prevention

There is currently no way to specifically prevent fibromyalgia. However, adequate sleep and nutrition, stress management, safe levels of exercise, and annual check-ups are important in the avoidance of this condition.

Fine motor skills

Definition

Fine motor skills encompass the abilities required to control the smaller muscles of the body for writing, playing an instrument, artistic expression, and craft work.

The muscles required to perform fine motor skills are generally found in the hands, feet, and head.

Description

Fine motor skill involves deliberate and controlled movements requiring both muscle development and maturation of the **central nervous system**. Although newborn infants can move their hands and arms, these motions are **reflexes** that a baby cannot consciously start or stop. The development of fine motor skills is crucial to an infant's ability to experience and learn about the world and thus plays a central role in the development of intelligence. Like **gross motor skills**, fine motor skills develop in an orderly progression, but at an uneven pace characterized by both rapid spurts and, at times, frustrating but harmless delays. In most cases, difficulty with acquiring certain fine motor skills is temporary and does not indicate a serious problem. However, medical help should be sought for children who are significantly behind their peers in multiple aspects of fine motor development; or if they regress, losing previously acquired skills.

Function

Fine motor skills develop over a long period of time, primarily during childhood. However, athletes, musicians, jewelry makers, physicians, machinists, and others who engage in activities requiring high degrees of manual dexterity and control may spend decades improving their level of muscle coordination and fine motor skills.

Infancy

The hands of newborn infants are closed most of the time and, like the rest of their bodies, are not well controlled. If its palm is touched, an infant will make a very tight fist, but this is an unconscious action called the Darwinian reflex, and it disappears within two to three months. Similarly, an infant will grasp at an object placed in the hand, but without any conscious awareness of the act. At some point, hand muscles will relax, and an infant will drop an object, equally unaware that it has fallen. Babies may begin flailing at objects that interest them by two weeks of age but cannot grasp them. By eight weeks, they begin to discover and play with their hands, at first solely by touch, and then, at about three months, by sight as well. At this age, however, the deliberate grasp remains largely undeveloped.

Hand-eye coordination begins to develop between the ages of two and four months, inaugurating a period of trial-and-error practice at sighting objects and grabbing at them. At four or five months, most infants can grasp an

A six-month-old baby demonstrates fine motor skills.
(Photo Researchers, Inc. Reproduced by permission.)

object that is within reach, looking only at the object and not at their hands. Referred to as “top-level reaching,” this achievement is considered an important milestone in fine motor development. At the age of six months, infants can typically hold on to a small block for a brief period, and many have started banging objects. Although their grasp is still clumsy, they have acquired a fascination with grabbing small objects and trying to put them in their mouths. At first, babies will indiscriminately try to grasp things that cannot be grasped, such as pictures in a book, as well as those that can, such as a rattle or ball. During the latter half of the first year, they begin exploring and testing objects before grabbing, touching them with an entire hand and eventually poking them with an index finger.

One of the most significant fine motor accomplishments is the pincer grip, which typically appears between the ages of 12 and 15 months. Initially, an infant can only hold an object, such as a rattle, in the palm, wrapping fingers (including the thumb) around it from one side—an

awkward position called the palmar grasp, which makes it difficult to hold on to and manipulate the object. By the age of eight to ten months, a finger grasp begins, but objects can only be gripped with all four fingers pushing against the thumb, which still makes it awkward to grab small objects. The development of the pincer grip, the ability to hold objects between the thumb and index finger, gives infants a more sophisticated ability to grasp and manipulate objects, and also to drop them deliberately. By about the age of one, an infant can drop an object into a receptacle, compare objects held in both hands, stack objects, and nest them within each other.

Toddler period

Toddlers develop the ability to manipulate objects with increasing sophistication, including using their fingers to twist dials, pull strings, push levers, turn book pages, and use crayons to produce crude scribbles. Dominance of either the right or left hand usually emerges during this period as well. Toddlers also add a new dimension to touching and manipulating objects by simultaneously being able to name them. Instead of only random scribbles, their drawings include such patterns as circles. Their play with blocks is more elaborate and purposeful than that of infants, and they can stack as many as six blocks. They are also able to fold a sheet of paper in half (with supervision), string large beads, manipulate snap toys, play with clay, unwrap small objects, and pound pegs.

Preschool

The more delicate tasks facing preschool children, such as handling silverware or tying shoelaces, represent more of a challenge than most of the gross motor activities learned during this period of development. The central nervous system is still in the process of maturing sufficiently for complex messages from the **brain** to get to a child’s fingers. In addition, small muscles tire more easily than large ones, and the short, stubby fingers of preschoolers make delicate or complicated tasks more difficult. Finally, gross motor skills call for energy, which is boundless in preschoolers, while fine motor skills require patience, which is in shorter supply. Thus, there is considerable variation in fine motor development among children of this age group.

By the age of three, many children have good control of a pencil. Three-year-olds can often draw a circle, although their attempts at drawing people are still very primitive. It is common for four-year-olds to be able to use scissors, copy geometric shapes and letters, button large buttons, and form clay shapes with two or three parts. Some can print their own names in capital letters.

A human figure drawn by a four-year-old is typically a head atop two legs with one arm radiating from each leg.

School age

By the age of five, most children have clearly advanced beyond the fine motor skill development of the preschool age. They can draw recognizably human figures with facial features and legs connected to a distinct trunk. Besides drawing, five-year-olds can also cut, paste, and trace shapes. They can fasten visible buttons (as opposed to those at the back of clothing), and many can tie bows, including shoelace bows. Their right- or left-handedness is well established, and they use the preferred hand for writing and drawing.

Role in human health

Nurturing the development of fine motor skills is considerably more complicated than developing gross motor skills. Helping a child succeed in fine motor tasks requires planning, time, and a variety of play materials. Fine motor development can be encouraged by activities that youngsters enjoy, including crafts, puzzles, and playing with building blocks. Helping parents with everyday domestic activities, such as baking, can be fun for a child in addition to developing fine motor skills. For example, stirring batter provides a good workout for hand and arm muscles, and cutting and spooning out cookie dough requires hand-eye coordination. Even a computer keyboard and mouse can provide practice in finger, hand, and hand-eye coordination. Because the development of fine motor skills plays a crucial role in school readiness and cognitive development, it is considered an important part of a preschool curriculum. Montessori schools in particular were early leaders in emphasizing the significance of fine motor tasks and the use of learning aids such as pegboards and puzzles in early childhood education. The development of fine motor skills in children of low-income parents, who often lack the time or knowledge required to foster these abilities, is a key ingredient in the success of such programs as Head Start.

Common diseases and disorders

There are a range of diseases that decrease one's ability to perform tasks that require fine motor skills. Among young persons, such developmental problems as genetic disorders, **muscular dystrophy**, **cerebral palsy** and some neurological conditions adversely impact fine motor skill development. Among older persons, arthritis is a common condition. Arthritis affects the joints of the hands and feet, thus impairing the ability of muscles to perform fine movements. Stroke can impair fine motor

KEY TERMS

Darwinian reflex—An unconscious action in infants in which if a palm is touched, the infant makes a very tight fist. This instinct disappears within two to three months.

Gross motor skills—The abilities required to control the large muscles of the body for walking, running, sitting, crawling, and other activities. The muscles required to perform gross motor skills are generally found in the arms, legs, back, abdomen and torso.

Locomotion—Such movements as walking.

Motor—A term referring to muscles and movement.

Palmar grasp—A young infant's primitive ability to hold an object in the palm by wrapping fingers and thumb around it from one side.

Pincer grip—The ability to hold objects between thumb and index finger, which typically develops in infants between 12 and 15 months of age.

Top-level reaching—The ability of an infant to grasp an object that is within reach, looking only at the object and not at their hands. Typically develops between four and five months of age.

coordination. **Parkinson's disease** affects fine motor movements. **Alcoholism** and drug use or withdrawal all cause fine motor problems.

First aid

Definition

First aid is the initial basic treatment of an injured or ill person. First aid requires an observer first to evaluate the injured or ill person and then to intervene, using a small amount of supplies.

Purpose

First aid is provided to a person immediately following an accident or onset of illness to decrease complications and to offer psychological (emotional) and physical comfort. It is performed to decrease the individual's **pain** and suffering until **emergency medical technicians** (EMTs) or other health care givers arrive on the scene.

Precautions

The provision of first aid should never postpone the initial contact with the emergency medical system. The bystander should wear disposable latex gloves if available, in case of contact with **blood** or body fluids. If gloves are not available, plastic bags or wrap can be used as a protective barrier.

Description

First aid is a universal term that encompasses many general concepts for rapid assessment of health crises and intervention. The following sections present the most common injuries and illnesses requiring first aid, and the interventions appropriate in these situations.

Changes in mental status

ASSESSMENT. With any sudden changes in a person's **brain** functioning, first aid should start immediately. Assess the person for:

- unconsciousness
- lightheadedness
- weakness on one side of body
- aggressiveness
- confused state

- changes in orientation
- headache
- blurred or double vision
- unsteady balance

INTERVENTION. Initiate **cardiopulmonary resuscitation (CPR)** if the person is not breathing. Secure the area around the person by removing any potential hazards, and maintain a favorable environment by providing an adequate area ventilation and room temperature. The person should be placed in a side-lying position.

Bleeding (hemorrhage)

ASSESSMENT. Assessing an injured person for bleeding must be done promptly, with first aid started immediately if there is active bleeding. All blood and body fluids must be regarded as potentially infectious, and protective barriers used.

INTERVENTION. Direct pressure should be applied to the hemorrhaging (bleeding) area by placing a clean pad or bandage over the site and pressing down with the palm of the hand. If bleeding persists, increase the amount of pressure to the area. If the person is awake and no latex gloves or other protective barriers are available, have him or her apply direct steady pressure to the hemorrhaging area. If the bleeding occurs on an arm or leg, elevate the bleeding part higher than the person's **heart**; this position will help decrease the amount of blood flow to the injured area. When a person is losing blood, body temperature tends to decrease. Maintaining body temperature is an essential first-aid intervention.

Poisoning: inhalation, ingestion, or exposure

ASSESSMENT. Initial evaluation of a poison victim is done after the threat of exposure to the rescuer is determined. If noxious gas or fumes remain in the environment, the rescuer must first protect him- or herself and others. The rescuer must move the person to a secure environment as promptly as possible to start first aid.

INTERVENTION. The first and most important intervention is to call a poison control center and get instructions on how to proceed. Having information on the type of poison ingested, if possible, as well as reading the label over the phone or spelling out the active ingredients on the bottle, will help the poison control center in determining the appropriate interventions. The rescuer must never induce vomiting or give any substance unless directed by the poison control center.

Burns

ASSESSMENT. **Burns** are categorized by the extent of damage to the skin or underlying tissue. First-degree burns are the least critical; they cause reddening of the skin without blistering. Second-degree burns cause damage to the superficial (outer) and the internal (inner) layers of skin, creating bubble-like sores (blisters) that contain clear, watery liquid. Third-degree burns are the most severe and most damaging of all burns; the destruction of all layers of skin occurs and the burnt area is left open and charred. When applying first-aid concepts to burns, the rescuer must quickly assess the extent of damage to the person's skin. The rescuer needs to determine through assessment what to do next.

INTERVENTION. First-degree burns can usually be treated at home with a sterile burn gel, and complete healing should take place within one week. A person with a second-degree burn greater than the size of his or her palm should seek medical treatment, or if the burn is in a sensitive area like the groin. Third-degree burns need medical attention immediately. Ice application is not recommended for severe burns because ice can cause trauma to the area. Cool to lukewarm water is recommended. The burn victim must be covered, preferably with clean blankets, in order to maintain a normal body temperature.

Head/neck injuries

ASSESSMENT. It is vital for the rescuer to determine the nature of the head/neck injury, as well as if the person has had any loss of consciousness. This information should be conveyed to the emergency medical responders to help determine the need for further testing.

INTERVENTION. It is important to limit the movement of the victim of a head or neck injury, because it could result in more damage. Do not move the head or neck unless absolutely necessary—for example, if vomiting starts. In such a situation, the rescuer must carefully turn the person to the side in order to prevent inhalation of vomit into the **lungs**.

Seizure

ASSESSMENT. A seizure occurs when the brain emits irregular electrical signals. The person having a seizure usually falls to the ground and shakes. The person may lose urinary or bowel functioning.

INTERVENTION. It is important to clear a safe area for a seizure victim. Protecting the **skull** with a cushion or blanket will help decrease injuries to the head and neck. The rescuer should never restrain the victim or put anything in the mouth. When the seizure stops, place the

KEY TERMS

Emergency medical technician (EMT)—A person who is trained and certified to provide basic life support.

Hemorrhage—To be actively bleeding.

Superficial—A term meaning outermost or not deep.

victim in a side-lying position to avoid the breathing in of mucus and other secretions.

Muscle/bone injuries

ASSESSMENT. When there have been muscle or bone injuries, the person initiating first aid should assume that the arm or the leg is broken.

INTERVENTION. If the arm or leg appears misshapen, the rescuer should not try to align it. The rescuer wants to stabilize the injured body part in order to protect it from further injury. Ice application can reduce swelling and pain. Heat should not be used, because it increases circulation to the injured site.

Preparation

A first-aid kit can have a variety of equipment in it. The basic items should include:

- ace bandages in a variety of sizes
- antibiotic ointment
- latex gloves
- a protective barrier/shield for use in CPR
- sterile gauze pads and wraps in a variety of sizes
- sealed alcohol packets
- scissors
- tape
- tweezers

Aftercare

The care needed after first aid varies widely, depending on the type of injury or illness sustained. Health care professionals are excellent resources to consult about appropriate individualized aftercare.

Complications

Many unexpected complications can happen while providing first aid. The most severe complication is if the patient stops breathing or the heart stops beating. In such a situation, the rescuer should immediately start CPR.

Results

The results of first aid vary with the case. Successful first aid results in the improved health and recovery of the patient.

Health care team roles

All health care professionals have a professional obligation to know the basics of first aid. Accidental injuries account for 2.6 million hospital admissions annually. Unplanned injury is the fifth-leading cause of fatalities in the United States.

Patient education

Health care professionals are in a position that allows them to provide education about first aid to patients. Emphasis on the importance of having a first-aid kit available and well stocked is valuable information to pass on to patients. Information about local areas that offer first-aid training should be offered.

Training

Extensive training is not needed for first aid. The Occupational Safety and Health Administration (OSHA) advises that retraining in first aid should occur every three years.

Good Samaritan Law

Legally, health care professionals coming to a person's aid in an emergency situation are covered under the federal Good Samaritan Law. Protection under this law requires that the situation is deemed an emergency, that no monetary compensation for the treatment is provided, and that the care provided is done "in good faith." In most U.S. states, health care professionals have no mandatory obligation to help in an emergency situation, but the Good Samaritan Law is in place to protect from liability those who do offer assistance.

First aid kit

Definition

The **first aid** kit is a portable container of medicines, supplies, and information. It is kept for situations in which quick medical attention is needed for minor injuries.

Purpose

A first aid kit is used to treat minor illnesses and injuries in or outside the home, thereby reducing the risk of complications from minor injuries.

Description

The American College of Emergency Physicians recommends that every home have a first aid kit to respond to common medical emergencies. The contents of a well-stocked kit should include the following items:

- thermometers for infants, children, and adults
- rubbing alcohol to clean tweezers, needles, and thermometers
- tweezers and needles to remove slivers and ticks
- adhesive bandages in assorted sizes
- sterile gauze pads (2x2, 4x4, and 5x9 inches)
- non-adherent dressings, as **burns** or abrasions need a non-stick dressing

KEY TERMS

Cardiopulmonary resuscitation (CPR)—A series of steps to establish normal breathing following cardiac or respiratory arrest.

- triangular bandage to make a sling or use as a tourniquet
- elastic bandage to support a sprain
- safety pins to fasten bandages
- medical tape to affix a gauze pad to a large wound
- plastic resealable bag
- scissors
- **CPR** shield
- butterfly closures to pull the edges of small **wounds** together
- latex gloves
- medicine dropper to administer medicine to children
- medicine spoon
- petroleum jelly to lubricate rectal thermometers for infants under one year old
- heating pad/hot water bottle
- tongue depressors
- antiseptic wipes to cleanse hands or wounds
- cotton-tipped swabs for cleaning wounds
- iodine swabs for cleaning around a wound
- topical calamine lotion or antihistamine cream for **allergies**, insect bites, and rashes
- acetaminophen in appropriate doses for infants, children, and adults
- cough suppressant to relieve coughing in appropriate doses for infants, children, and adults
- antibacterial cream
- oral rehydration fluid for the treatment of diarrhea
- sunscreen
- insect repellent
- first aid manual
- an emergency information list

Operation

The items in the kit can be stored in a box or a tote bag where adult members of a family or other group

A well-stocked first aid kit is essential for every home and workplace. (Custom Medical Stock Photo. Reproduced by permission.)

know where it is located. The kit should be stored out of reach of children, and products should have child safety caps. Follow the manufacturer's guidelines for the correct use of medications and supplies.

The kit should be compact enough to be transported in a car, suitcase, or rucksack if traveling.

Maintenance

The kit should be inspected monthly to ensure that the contents are not damaged or out of date.

Health care team roles

All members should have knowledge of the appropriate use of all equipment and medication, and the ability to recognize situations in which immediate medical attention is required. The emergency information list should include the following:

- telephone numbers of family physicians and pediatricians
- the regional Poison Control Center number
- numbers of local police, fire, and ambulance services

In addition, a list should be compiled of any allergies that a family or team member has, and the treatment required.

Training

Adults with access to the first aid kit should have an understanding of the first aid manual and the correct use of all medications and equipment. Attendance at a course in basic first aid will enable them to respond quickly and appropriately to any emergency, equipping them with a knowledge of life-threatening situations and the first aid treatment to be given. At least one person in every large group should be trained in first aid and **cardiopulmonary resuscitation (CPR)**.

Fitness testing see **Endurance testing**

Flow cytometry analysis

Definition

Flow cytometry analysis is the classification of cell populations based upon the analysis of light scattering and fluorescence facilitated by a laser. Cells are counted and analyzed as they pass singly through the counting area created by a liquid sheath that flows past the laser. Cells scatter the light from the laser; forward and right-angle scatter are measured to determine size and granularity. This initial light scattergraph (dot plot) is used to select a specific cell population for testing using specific antibodies covalently bound to fluorescent dyes. The laser excites the fluorochrome causing it to emit visible light, so that the cells bound to the dye can be detected.

Purpose

Principles of flow cytometry are incorporated into some automated hematology analyzers to determine the reticulocyte (stage preceding a mature red cell) count and the percentage of each type of white **blood** cell (automated differential count). Flow cytometers are specialized instruments that can measure specific cell subpopulations in blood, bone marrow aspirates, body fluids and tissues. Flow cytometry has many applications including:

- Counting of lymphocyte subpopulations to evaluate immunological function and **immunodeficiency** states. The number of B, T and NK lymphocytes can be counted by flow cytometry to evaluate a person's cellular immune status. T helper and suppressor cells can be counted to assist in the diagnosis and staging of persons with HIV disease.
- Counting of immature white blood cells (blasts) to determine the cell lineage. Cell lineage must be defined to properly classify acute and **chronic leukemias** and non-Hodgkins lymphomas. Flow cytometry tests for surface markers on early white blood cells to determine the cell lineage (lymphoid vs myeloid), and to determine the stage of cell maturation.
- Determining the DNA content of cells. Malignant cells often possess an abnormally high DNA content.

Determination of DNA content, called ploidy analysis, is used to investigate tumor cell populations. Cells from solid tissues (for example, breast tissue) can be made into a suspension and analyzed.

- Physically sorting cell subpopulations by applying an electrostatic charge to the cells and using a fluid collecting device to harvest them from droplets passing through the flow chamber.
- Evaluation of autoimmune thrombocytopenia, transplant rejection, and autoimmune diseases.

Precautions

Universal precautions for the prevention of transmission of bloodborne pathogens is observed when collecting and processing blood, bone marrow, body fluids and tissues for flow cytometry analysis. Blood or bone marrow aspirate specimens may be submitted in sodium heparin (green top tube), EDTA (lavender top tube), or ACD (yellow top tube). Of these, the preferred anticoagulant is sodium heparin. Lithium heparin and other anticoagulants are not used.

Lymph node or other tissue specimens are not placed in fixative. They should be submitted fresh, in isotonic saline or transport medium. Specimens should be kept at room temperature if the analysis is done within 24 hours. Otherwise the specimen should be refrigerated, but not frozen.

Description

A flow cytometer consists of a laser light source, flow measurement chamber, and an optical system consisting of lenses, filters, and light detectors. Two photomultiplier tubes (light detectors), one at 180 degrees and one at 90 degrees to the laser, are used to measure forward and right-angle scatter, respectively. Three fluorescence detectors, each consisting of a filter and photomultiplier tube, are used to detect fluorescence. The three detectors sense green, orange, and red fluorescence. Cells are identified by sort logic applied to all five of the detector signals using a computer.

A typical analysis of blood is performed by first measuring the right-angle and forward light scatter of the cells. The resulting scattergraph is used to identify the counting gate, a set of parameters used to select a subpopulation of cells for further study. The gated area of the scattergraph is the portion in which the cells of interest are found. The gate parameters are selected so that only this cell subpopulation is reported in subsequent fluorescence studies.

Portions of the specimen are treated with two monoclonal antibodies, each specific for a cell surface antigen. Each monoclonal antibody is covalently bound to a dif-

KEY TERMS

Aneuploidy—An abnormal number of chromosomes within a cell.

Antigen—A molecule, usually a protein, that elicits the production of a specific antibody. In flow cytometry studies, an antigen is a cell surface marker that is recognized by a specific antibody and referred to by its cluster of differentiation (CD) number.

CD marker—A monoclonal antibody for a specific CD antigen.

Gating—The selection of cells that fit a specific set of parameters for further analysis. Only those cells belonging to the gated cell subpopulation are measured.

Immunophenotyping—Identification of antigens on the surface of cells using fluorescent-labeled antibodies. The phenotype profile is used to classify the cell.

Immune system—The body's system of defenses against infectious diseases, which includes both cellular and humoral (antibody) responses.

ferent fluorescent dye. There are approximately two dozen fluorochromes in use with flow cytometry, but the most commonly used labels are fluorescein isothiocyanate (FITC) which produces apple-green light and phycoerythrin (PE) which produces orange-red light when excited by the laser. For DNA analysis of cells the label most often used is propidium iodide (PI), which binds to DNA of nuclei and emits orange-red light when excited. The specific surface antigen to which an antibody binds is defined by the cluster of differentiation (CD) number. Each CD number represents a specific antibody combining site on the white cell surface. When the white cell surface marker is recognized by a fluorescent-labeled monoclonal antibody, the antibody binds to the cell membrane. When the cell passes through the flow chamber, the laser will excite the fluorochrome and it will emit light stimulating one of the detectors. This process is interpreted by the computer as an event. An event is a cell that meets a set of criteria required to register a dot on the scattergraph.

The process of determining the specific cell type from a panel of antibody-conjugated fluorescent stains is called immunophenotyping. For example, CD45 is a marker common to all white blood cells. CD2, CD3, CD5, and CD7 are markers for T lymphocytes. CD4 is

the site that defines a T-helper lymphocyte and CD8 is the marker or surface antigen that defines a suppressor or cytotoxic T lymphocyte. Therefore, a cell subpopulation that tests positive (i.e., produces a significant number of events) with antibodies to CD45, CD2, CD3, CD5, CD7 and CD4 is defined as a T-helper cell. Normally, a panel of antibodies is selected for use depending upon the characteristics of the gated population. For example, if the gated (selected) population is located in the region of the scattergraph where lymphocytes normally are seen, then lymphocyte markers are used. Two fluorescent-labeled antibodies are mixed with a small portion of the sample and measured simultaneously. One will be labeled with FITC and the other with PE. The events are shown as a plot of colored dots. The most commonly used plot consists of a square divided into four quadrants. The position of a dot (event) on the plot depends upon whether the cell is positive for one marker, both, or neither. For example, a positive staining reaction with FITC but not PE causes a dot in the lower right quadrant of the square. The percentage of events that fall into each quadrant is reported by the computer, and this report correlates with the density of the dots in the respective quadrant. A typical immunophenotyping for lymphocytes consists of the markers mentioned above and CD19 and CD20, which recognize B cells; HLA-DR, which recognizes B cells, T cells, monocytes and precursor cells; and anti-lambda and anti-kappa, which recognize the light chains of surface immunoglobulin molecules. The corresponding profile of positive results will identify the type of lymphocyte and its stage of maturation.

Preparation

If possible, a person should avoid eating a heavy meal within hours of the test or engaging in strenuous **exercise** for the 24 hours preceding the blood test.

Aftercare

The puncture site or biopsy site should be observed for excessive bleeding or **infection**.

Complications

In rare cases, the puncture site or biopsy site may show excessive bleeding or become infected.

Results

Interpretation of immunophenotyping requires the careful evaluation of known control cells to insure that the signals measured are not the result of background or nonspecific fluorescence. When performing the test to

determine the lineage of a cell line as in leukemia, the percentage of cells that are positive for each marker is reported. These results are evaluated along with the morphology of the cells in blood and bone marrow, and the use of cytochemical stains to determine the type of precursor cell (lymphocytic, monocytic, granulocytic) and its maturation stage.

When performing immunophenotyping of lymphocytes for the evaluation of immunological function, such as the staging of HIV disease, the percentage of cells positive for the defining marker is multiplied by the absolute lymphocyte count (i.e., number of lymphocytes per microliter). The absolute lymphocyte count is measured by the automated hematology analyzer used for the **complete blood count**. For example, to quantify the number of T-helper cells, the percentage of CD4-positive gated cells is multiplied by the lymphocyte count.

DNA content is measured by comparing the cells in the G0/G1 phase (resting or presynthesis of DNA) of the cell cycle to the G0/G1 phase of a normal diploid control. The ratio of G0/G1 DNA peaks is called the DNA index (DI), and is normally 1.00. Values greater than 1.00 indicate that an increased amount of DNA is present in the sample. A DI of 2.0 indicates that the cells are tetraploid (i.e., have twofold the normal number of chromosomes). Benign tissues do not display aneuploidy (an abnormal number of chromosomes), so the finding of aneuploidy points to a malignant state. Some malignant cells do not display aneuploidy, so a normal finding cannot rule out malignancy. In general DNA aneuploidy is not well correlated with prognosis, since the course of malignant disease is dependent upon the stage (progression), histological type of the tumor, and the tissue of origin. However, in some malignancies, the **cancer** is associated with a greater chance of recurrence or decreased survival when aneuploidy is present

Health care team roles

The physician will order the specific type of flow cytometry study, and if a biopsy is needed, will obtain a sample of the tissue. If blood is needed, the nurse or phlebotomist will draw the blood and transport the specimen to the laboratory. A clinical laboratory scientist/medical technologist with special training in flow cytometry will perform the analysis. Results are interpreted by a clinical pathologist who issues an interpretive report of the cell subpopulation(s) studied.

Fluid balance

Definition

When water intake equals water loss, the body is in fluid balance. When water loss is greater than intake, or vice versa, a fluid imbalance may result.

Description

Total body water content averages 60% of body weight in young normal-weight men and is slightly lower in women at approximately 55%. Total body water can be significantly lower in obese individuals and the elderly. Approximately two-thirds of the body water is located inside the cells (intracellular) while the remaining is outside the cells (extracellular). About three-quarters of the extracellular fluid is present in the interstitial space and connective tissues surrounding cells, while the remainder is intravascular. Approximately 8% of body water is in the bloodstream. This fairly small volume of water in the bloodstream must be kept relatively constant because it is critical for proper body function.

KEY TERMS

Antidiuretic hormone—A hormone that encourages the kidneys to retain water when body stores are low.

Dehydration—A deficit of body water that results when the output of water exceeds intake.

Diuretic—An agent or drug that eliminates excessive water in the body by increasing the flow of urine.

Electrolyte—A substance that dissociates into electrically charged atoms (ions) when dissolved in water.

Homeostasis—An organism's regulation of body processes to maintain internal equilibrium in temperature and fluid content.

Overhydration—An excess of body water that results when water intake exceeds output.

Function

The kidney is responsible for maintaining fluid balance through the elimination of waste products and excess water. Water is primarily absorbed through the gastrointestinal tract and excreted by the **kidneys** as urine. Water intake can vary widely on a daily basis, influenced by such factors as access to water, thirst, habit, and cultural factors. The variation in water volume ingested is dependent on the ability of kidneys to dilute and concentrate the urine as needed. There is a reservoir of water outside of the bloodstream that can replace or absorb excess water in the **blood** when necessary.

The body also works to maintain water balance through mechanisms such as the thirst sensation. When the body requires more water, nerve centers in the hypothalamus of the **brain** are stimulated to encourage a person to drink in order to replenish the water stores. The **pituitary gland** in the brain is also involved in maintaining fluid balance through secretion of antidiuretic hormone (ADH) into the blood. This hormone encourages the kidney to retain water when body stores are low. During water conservation by the kidneys, water is transferred from a large reservoir in the cells into the blood in order to maintain **blood pressure** and blood volume until water intake is increased. The thirst mechanism is suppressed when the body has excess water, small amounts of ADH are secreted, and through function of the kidneys, excess water is excreted in the urine.

Role in human health

For a normal adult, a daily intake between 0.74-0.84 US quarts (700-800 ml) is required to meet water losses and maintain fluid balance. To protect against **dehydration** and developing **kidney stones**, a greater water consumption between 1.5-2 US quarts/day (1.4-2 L/day) is advised. Water losses occur through evaporation in expired air and through the skin. Sweat losses are usually minimal but can be significant in warmer climates or with accompanying **fever**.

The body can accommodate extreme changes in water intake when the brain and kidneys are functioning normally. It is usually possible for a person to consume enough water to maintain blood volume and **electrolyte balance** in the blood. However, if a person is unable to consume enough water to equal excessive water loss, dehydration may result.

Common diseases and disorders

Dehydration

Dehydration is a deficit of body water that results when the output of water exceeds intake. Dehydration stimulates the thirst mechanism, instigating water consumption. Sweating and the output of urine both decrease. If water intake continues to fall short of water loss, dehydration worsens.

Causes of dehydration may include:

- vomiting
- **diarrhea**
- diuretics
- excessive heat
- excessive sweating
- fever
- decreased water intake

Dehydration induces water to move from the reservoir inside cells into the blood. If dehydration progresses, body tissues begin to dry out and the cells start to shrivel and malfunction. The most susceptible cells to dehydration are the brain cells. Mental confusion, one of the most common signs of severe dehydration, may result and can lead to **coma**. Dehydration can occur when excessive water is lost with such diseases as **diabetes mellitus**, diabetes insipidus, and Addison's disease.

Dehydration is often accompanied by a deficiency of electrolytes, sodium and potassium in particular. Water does not move as rapidly from the reservoir inside of the cells into the blood when electrolyte concentration is decreased. Blood pressure can decline due to a lower

volume of water circulating in the bloodstream. A drop in blood pressure can cause lightheadedness, or a feeling of impending blackout, especially upon standing (orthostatic hypotension). Continued fluid and electrolyte imbalance may further reduce blood pressure, causing **shock** and damage to many internal organs including the brain, kidneys, and **liver**.

TREATMENT OF DEHYDRATION. Consumption of plain water is usually sufficient for mild dehydration, although when both water and electrolyte losses have occurred after vigorous **exercise**, electrolytes must be replaced; sodium and potassium in particular. Adding a little salt to drinking water or consuming such drinks as Gatorade during or following exercise can replace lost fluids. Individuals with **heart** or kidney problems should consult a physician regarding the replacement of fluids after exercise.

Sodium chloride may be administered intravenously by medical personnel if blood pressure decreases enough to induce shock or risk of shock. The underlying cause of dehydration must be addressed along with treatment to replace fluids. For example, if the cause of dehydration is due to diarrhea, then drugs may be given to alleviate diarrhea as well. Following treatment of the cause, individuals may be monitored to ensure that oral fluid intake is adequate to maintain fluid hydration.

Overhydration

Overhydration is an excess of body water that results when water intake exceeds output. Drinking large amounts of water does not typically lead to overhydration if the kidneys, heart, and pituitary gland are functioning properly. An adult would have to drink more than 2 US gallons per day (7.6 L per day) to exceed the body's ability to excrete water. Excessive body water causes electrolytes in the blood, including sodium, to become overly diluted. Overhydration occurs in individuals whose kidneys do not function normally, primarily in kidney, heart, or liver disease. People with these conditions may have to limit their water and dietary salt intake. Similar to dehydration, the brain is the most sensitive organ to overhydration. The brain cells can adapt to increased fluid volume when overhydration increases slowly; however, when it occurs rapidly, mental confusion, seizures, and coma can result.

Overhydration can occur alone or in conjunction with excess blood volume. Distinguishing between the two conditions may be quite complicated. Overhydration induces water accumulation within and around the cells but does not typically show symptoms of fluid accumulation. On the other hand, with excess blood volume, there is an accumulation of sodium and the body cannot

transfer water into the reservoir within cells. Conditions such as **heart failure** and liver cirrhosis may induce volume overload, whereby fluid accumulates around cells in the abdomen, chest, and lower legs.

TREATMENT OF OVERHYDRATION. Treatment of overhydration depends somewhat upon the cause, although whatever the underlying condition, fluids must be limited. Drinking less than about 1 US quart (1 L) of fluid a day usually improves overhydration over several days. Fluids should only be limited at a physician's request. A diuretic may be prescribed to increase water output by the kidneys. Diuretics are particularly beneficial for treatment of excess blood volume where overhydration is accompanied by excess blood volume.

Fluoride therapy

Definition

Fluoride therapy is the use of fluoride products topically (applied to the tooth surface) or systemically

(ingested in supplements or water) to prevent or reduce the incidence of **dental caries** (tooth decay).

Purpose

Fluoride therapy may be initiated systemically before a child's teeth emerge during tooth development in order to strengthen tooth enamel (the hard outer surface of a tooth) and prevent dental caries. Fluoride may also be applied in the form of gels, foams, and varnishes to the tooth surface, which provides temporary protection. Topical methods are effective for adults and children. The use of fluoridated toothpaste and mouth rinses is another means of delivering fluoride therapy.

Precautions

Fluoride therapy is contraindicated for children who are drinking fluoridated water and/or who are also receiving the optimal fluoride dosage (about 1.0 ppm) from foods and bottled beverages. Fluoride in dentifrices (toothpastes) and mouth rinses also has the potential of being ingested. Overexposure to fluoride while a child's teeth are forming under the gums results in **fluorosis**, an abnormal condition that affects the appearance of tooth enamel and can be very mild (a few white spots on a tooth) to severe (etching, pitting, and brown discoloration on many teeth).

Pediatricians, oral care professionals, and dental hygienists assess the amount of fluoride in a child's natural environment and caries risk before prescribing fluoride supplements or topical fluoride therapy. Usually, if a child lives in an area where fluoride has been added to the drinking water, supplements are not necessary. A pediatrician or oral care professional may recommend supplements if the child exhibits moderate-to-high risk for dental caries. However, supplementation should be done with caution, weighing the risks of fluoride overexposure against slightly more added protection.

Description

Fluoride therapy can be administered through fluoride supplements, fluoridated water, and some bottled beverages containing fluoride. Carbonated drinks, juices, and bottled waters can contain fluoride in varying amounts. Often, the fluoride in these products is not printed on the labels. Some other foods and beverages are high in fluoride, including fish with bones, tea, poultry products, cereals, or infant formula made with fluoridated water. Food cooked in Teflon-coated pans also provides fluoride.

Breast-fed infants usually do not need supplements until after they are six months old. By that time, they may be drinking water from a cup or eating some foods that contain fluoride, so supplements still may not be necessary.

Fluoride supplements are dispensed in the United States and Canada as lozenges, oral solutions, tablets, and chewable tablets. Fluoride can also be prescribed in combination with a vitamin supplement as chewable tablets or in an oral solution. In the United States, common brand names for fluoride supplements are Fluoritab, Fluorodex, Flura, Flura-Drops, Flura-Loz, Karidium, Luride, Luirde Lozi-Tabs, Pediaflor, Pharmaflur, and Phos-Flur. The vitamin/fluoride combination is sold as Adeflor, Cari-Tab, Mulvidren-F, Poly-Vi-Flor, Tri-Vi-Flor, and Vi-Daylin/F. These supplements are available only by prescription from a pediatrician or a oral care professional.

Dosing of fluoride supplements is different for every child. When determining the amount to prescribe, pediatricians and oral care professionals should consider all fluoride exposure in the child's environment and prescribe supplements with fluoride limits in mind. Recommended total daily fluoride intake has been set at 0.1 to 1.5 mg for the infant and child to three years of age, 1–2.5 mg for the four-to-six-year old, 1.5–1.5 mg for the seven-to-ten year old, and 1.5–4 mg for an adolescent and an adult.

Calcium supplements, or any products with aluminum hydroxide, should not be taken along with fluoride supplements. Each dose should be spaced at least two hours apart to achieve the maximum benefit of each.

Overexposure to fluoride is a concern to pediatricians and oral care professionals because it can result in fluorosis. Fluorosis, which is caused by exposure to excessive amounts of fluoride while the enamel is being formed, can affect both the primary (baby) teeth and permanent teeth. It does not affect the permanent teeth once they have fully developed. Most often, the fluorosis appears on the front incisors (front teeth) and less frequently on the molars. This characteristic poses a high cosmetic problem because the front teeth are most exposed when children speak or smile. There is no cure for fluorosis except cosmetic restoration, which can be costly.

Fluoride gels and foams are the most common form of topical fluoride application at the oral care professional's office. A flavored gel containing a concentration of fluoride is offered in a tray to the patient. There is one tray for the upper teeth and one for the lower teeth. The patient should sink his or her teeth into the tray and let the teeth bathe in the fluoride for a specific amount of

time. The mouth should be emptied but not rinsed; then, the patient is instructed not to eat or drink for 30 minutes.

Fluoride varnishes that are being used in Europe have been found to be easier to apply and more durable for the patient; however, varnishes have not been approved for use as a fluoride treatment in the United States. With the varnishes used in Europe, the patient may also eat or drink soon after application. The residue is removed only when the patient's teeth are brushed.

Finally, the use of fluoride toothpaste and fluoridated mouth rinses may also be recommended for adults and children. According to the American Dental Association, young children under six often use too much fluoride toothpaste, and consistently swallow it. This has contributed significantly to excess fluoride ingestion. Careful monitoring of toothpaste amounts by parents and encouragement to spit, instead of swallowing the toothpaste, can drastically decrease the amount of fluoride a child ingests from dentifrices.

Composite resins and adhesives with fluoride are used by oral care professionals when filling cavities and cementing crowns into place. Sufficient amounts of topical fluoride are applied to protect adjacent teeth that normally are at risk for further wear and decay due to the location of the cavity (e.g., deep pits in molars) or the stress due to bridge and crown fittings.

Dental and medical insurance usually cover fluoride therapy as "routine care."

Preparation

The oral care professional should thoroughly dry the patient's teeth before applying fluoride gels or foams. The varnishes, however, can be applied to damp teeth and still produce the desired effect. Fluoride dentifrices and mouth rinses require no special preparation.

Aftercare

When varnishes are used, the patient can generally eat before 30 minutes, the time he or she is required to wait after a fluoride treatment. This detail can be extremely important for patients with diabetes, who must eat frequently.

Results

Fluoride treatments provide temporary protection against dental caries. They are not as effective as systemic intake of fluoridated water, but they can be extremely helpful to children who are at moderate-to-high risk for dental caries. Furthermore, they can also

KEY TERMS

Dental caries—Tooth decay.

Dentifrices—Toothpastes.

Enamel—The hard outer surface of a tooth.

Fluoride—A fluorine ion used to treat water or apply directly to tooth surfaces to prevent dental caries.

Incisors—Front teeth used for biting. Includes central and lateral incisors.

Primary teeth—The teeth a child has before permanent ones; primary teeth; baby teeth.

Systemic—Ingested as tablets or drops and circulates throughout the human body.

Topical—On the surface of a tooth.

help in patients who need extra protection against root caries due to gum recession and xerostomia (dry mouth).

Health care team roles

The pediatrician has an important role in a child's oral health. The first person to be consulted about a child's dental needs, the pediatrician can monitor a child's **oral hygiene**, determine when to make referrals, and regulate fluoride therapy.

Oral care professionals and dental hygienists provide fluoride therapy, monitor oral hygiene, and also assess the amount of fluoride in a person's environment. The oral care professional also makes detailed repairs and suggests therapeutic plans for the child's dental health.

The pediatrician plays an important role in the education of parents regarding fluoride excess and safety issues about fluoride toothpastes and mouth rinses. Nurses and teachers also participate in parent education about fluoride usage and good dental habits. They can teach children about proper tooth brushing, especially the amount of toothpaste to use. These are lessons all adults need to learn as well. The educators can also encourage periodic testing of the water for fluoride levels in the community or at home, especially if water filters are used.

Fluoroscope

Definition

A fluoroscope is an x-ray device that allows live images to be projected onto a viewing monitor during diagnostic and interventional procedures.

Purpose

A fluoroscope is used for real-time imaging of various anatomical areas during a diagnostic or interventional procedure. Fluoroscopy produces a live image of the area of interest, and can be used to view such motion as **blood** flow and catheter insertion. In contrast, radiography, or x-ray imaging, produces a still image on film.

Specific procedures that use fluoroscopy include aneurysm repair, hip and knee replacement, **arthroscopy**, catheter placement, needle biopsy, location of **foreign bodies**, swallowing studies, fracture reduction, discography, **lithotripsy**, brachytherapy, pacemaker insertion, endoscopic retrograde cholangiopancreatography (ERCP), and gastrointestinal evaluation (e.g., bowel studies). Fluoroscopy may also be used to detect bone **cancer** or digestive cancers, and digestive ulcers; however, computed tomography (CT) imaging is now routinely used to detect these conditions.

Description

The term fluoroscope generally refers to a mobile radiographic/fluoroscopic unit, also called a mobile C-arm because of its shape. A mobile C-arm system consists of two wheeled units: one carries the imaging arm, x-ray generator, and control console, and the other carries the image display monitors and image processing and recording devices. The imaging arm, which is shaped like the letter C, has an x-ray tube mounted on one end and an image intensifier mounted on the other end. The x-ray generator supplies the power to the x-ray tube, which emits x rays that pass through the patient and are absorbed by the image intensifier. The image intensifier is a phosphor screen that converts the x rays into light, which is then scanned and transmitted by a charge-coupled device (CCD) camera to a display monitor.

Fluoroscopy is also performed using larger stationary radiographic/fluoroscopic systems that include a patient table, an x-ray generator, an x-ray tube, an image intensifier, and an image display system configured in a shielded room. The term fluoroscope may be used to refer to the components of this stationary system that perform fluoroscopy, but it is most commonly used in reference to a mobile system.

Fluoroscopy is performed in surgical, orthopedic, critical care, emergency care, and diagnostic radiology settings. In addition, mobile fluoroscopes are used to image patients on stretchers, beds, or examination/procedure tables when they cannot be transported to the radiology department.

Scaled-down compact fluoroscopes that can be handheld are also available and are designed for fast, continuous imaging of the extremities at various angles. Mini C-arms may be used in the emergency department, during surgery, in a physician's office, in sports medicine and **physical therapy**, and in the field such as an accident site.

In 2000, a fluoroscope with a navigational or surgical guidance computer was introduced to improve instru-

ment placement and imaging during minimally invasive surgical procedures, particularly those involving the spine.

Operation

The fluoroscope is maneuvered in such a way that the patient, and the anatomical area of interest, is positioned between the x-ray tube and the image intensifier. The operator uses the control console to set imaging parameters. The intensity of the x rays is controlled with the milliamperage (mA) setting, and the energy and intensity of the x rays are controlled with the peak kilovoltage (kVp) setting. A typical fluoroscopy image setting is 70 kVp at 2 mA. Most mobile C-arms have capabilities for magnified views, automatic brightness stabilization to maintain a constant brightness during the exam, and last-image hold to freeze the last acquired image on the monitor.

During fluoroscopic imaging, the patient is exposed to radiation; continuous fluoroscopy for long periods (e.g., during a surgical procedure) can deliver a significant radiation dose. Therefore, most systems have a pulsed fluoroscopy mode, which allows the x-ray output to be pulsed for periods ranging from 10 milliseconds to 30 times per second, and displays the image acquired with each pulse. Although the image on the monitor may be jumpy, radiation exposure to the patient can be reduced by as much as 75% with this mode. Dose reduction is especially important in pediatric patients and young adult patients of reproductive age. Clinical staff are also exposed to radiation, and portable radiation shields, lead aprons, and radiation badges should be worn by all staff present during fluoroscopy.

All images displayed on the monitor can be saved to a disk, video disk, compact disk, or tape. Some systems have digital capabilities that allow storage in digital **memory** or on a computer network. A videocassette recorder or digital recorder can be used to record several minutes of real-time fluoroscopy. Snapshot images can also be printed as hard copy using video printers, thermal printers, or a multi-format camera (a camera that records and prints multiple images; for example, four images on one film).

Maintenance

A fluoroscope is usually maintained either through a service contract with the manufacturer, a third-party service company, or by the hospital **biomedical engineering** department. The x-ray technologist operating the fluoroscope may perform periodic performance testing to check image quality, radiation dose, and other imaging parameters. A quality control program should be imple-

KEY TERMS

Brachytherapy—A radiation therapy treatment in which a radioactive source material is inserted, injected, or implanted into the cancerous area; fluoroscopy is frequently used to guide placement of brachytherapy sources.

Discography—A radiographic/fluoroscopic imaging procedure that involves injecting contrast material into an intervertebral disk.

Endoscopic retrograde cholangiopancreatography (ERCP)—A procedure that involves inserting an endoscope through the mouth, esophagus, stomach, and into the first part of the small intestine (the duodenum) to examine the pancreas, pancreatic ducts, and bile ducts. A catheter is threaded through the endoscope to inject dye, and x-ray and fluoroscopic imaging are performed.

Lithotripsy—A procedure that uses fluoroscopic guidance to locate and break up stones in the urinary tract and gallbladder.

Myelography—A fluoroscopic imaging procedure that examines the spinal cord and is used for diagnosing such conditions as spinal abscesses, tumors, and dislocated intervertebral disks.

mented to ensure optimal image quality and minimal radiation doses.

Health care team roles

Fluoroscopic imaging may be performed by x-ray technologists, radiologists, surgeons, cardiologists, and other health care professionals. For such diagnostic procedures as an upper gastrointestinal (GI) series, the fluoroscopic examination is performed by a radiologist and an x-ray technologist in a hospital radiology department or an outpatient imaging center. For such orthopedic procedures as arthroscopy, an orthopedic surgeon and x-ray technologist perform the fluoroscopic examination. For interventional diagnostic and therapeutic procedures, an interventional radiologist, cardiovascular specialist, and x-ray technologist are involved in the fluoroscopic procedure. Nursing staff may be present to assist during fluoroscopic procedures, depending on the condition of the patient and whether medication administration is necessary. Mini-C-arms have clinical applications outside the hospital, and thus may be used in medical emergencies at

sporting events, and in sports medicine and physical therapy facilities.

Training

Use of a fluoroscope requires training in radiographic and fluoroscopic principles and techniques. X-ray technologists should have completed appropriate educational programs (registered technologist programs). Any staff using fluoroscopic equipment should participate in clinical training provided by the equipment manufacturer.

Fluorosis

Definition

Fluorosis is an abnormal condition of the tooth enamel caused by excessive exposure to fluoride (a nutrient used to prevent tooth decay) while a child's teeth are forming under the gums. Excessive fluoride affects the formation of tooth enamel (the hard outer surface of a

Classification and descriptive criteria for dental fluorosis

Classification	Descriptive criteria
Normal	Enamel shows no evidence of fluorosis. The surface of the tooth is smooth, glossy, and typically has a pale, creamy white color.
Very mild	Evidence of fluorosis in the enamel is shown by areas with parchment-white color that total up to 25% of the tooth surface. This includes fluorosis seen only on the incisal edges of anterior teeth and cusp tips of bicuspids or molars ("snowcapping").
Mild	Parchment-white fluorosis can be seen on more than 25% but less than 50% of the tooth surface.
Moderate	Light to very dark brown staining occurs on the enamel, along with the parchment-white coloration of fluorosis.
Severe	All enamel surfaces are affected, and the anatomy of the tooth may be altered. Discrete or confluent pitting of the enamel surface exists. Dark-brown stain is usually present and may be widespread, presenting a corroded appearance of the teeth.

tooth). Fluorosis can be very mild, as a few white spots on a tooth; or severe, showing etching, pitting, and brown discoloration on many teeth.

Description

Fluoridated community water systems and toothpaste with fluoride have significantly contributed to the prevention and mitigation of **dental caries** (tooth decay) in developed countries, reducing the number of cavities by 70%. Even at the safe level of 1 ppm of fluoride in drinking water, 22% of the people drinking that water have reported some form of fluorosis. In some areas, the rate of incidence is 50%.

Though fluorosis is mainly a cosmetic problem, it has become a marker for overexposure to fluoride in a child's environment.

Causes and symptoms

Fluorosis does not affect the permanent teeth once they have fully appeared. Fluorosis may occur in primary (baby) teeth as well as permanent teeth. Most often, the condition appears on the front incisors (front teeth) and less frequently on the molars. This characteristic poses a high cosmetic problem because the front teeth are most exposed when children speak or smile.

Symptoms can range from mild to severe. Very mild fluorosis is seen as tiny white spots on 25% of a tooth surface. Mild fluorosis covers 26% to 50% of a tooth surface. Moderate fluorosis compromises all of a tooth's surface and is most characterized by brown discoloration

of the tooth. Severe fluorosis involves pitting of the enamel and more serious brown staining. Approximately 94% of dental fluorosis is very mild to mild.

Excess fluoride exposure is often accidental. Naturally occurring fluoride in well water can sometimes be much higher than water from artificially fluoridated, community or municipal systems that are kept at strict levels. Drought conditions can also concentrate fluoride levels.

According to the ADA, young children under six often use too much toothpaste that contains fluoride, and they consistently swallow it. This alone has been the biggest cause of excess fluoride ingestion.

Some children drink fluoridated water and also drink large amounts of bottled beverages that have fluoride in them. Carbonated drinks and juices have fluoride in varying amounts. Often, the fluoride in these products is not printed on the labels. Still other children are offered foods high in fluoride (fish with bones, tea, poultry products, cereals, or infant formula made with fluoridated water) in addition to fluoridated water.

Finally, fluorosis may be caused by some pediatricians who prescribe fluoride supplements without determining the amount of fluoride exposure the child has in his or her environment.

Topical applications of fluoride gels applied by dentists to the surfaces of a child's teeth and fluoride mouth rinses available through dentists or over the counter (OTC) are other ways that a child can add to her fluoride quota. These methods are extremely helpful for older children and adults, but they often add to the cumulative fluoride exposure a young child can have, especially if she swallows fluoride residues.

Diagnosis

Fluorosis can be identified through examination by a dentist or dental hygienist. Very mild fluorosis sometimes can be detected only through x rays. Often the dentist uses the Fluorosis Index to classify the severity of the condition from very mild to severe. (See Causes & Symptoms for details of each classification.)

Treatment

There is no treatment for fluorosis except cosmetic restoration.

Prognosis

There are many more ways to deliver fluoride than through drinking water and toothpaste. These methods,

KEY TERMS

Deciduous teeth—The teeth a child has before permanent ones; baby teeth.

Dental caries—Tooth decay.

Enamel—The hard outer surface of a tooth.

Fluoride—A fluorine compound used to treat water or apply directly to tooth surfaces to prevent dental caries.

Incisors—Front teeth used for biting.

however, remain the most effective ways to discourage dental caries (tooth decay). With more awareness of the amount of fluoride in a child's environment, pediatricians and dentists are becoming more accurate in prescribing fluoride supplements to infants and young children. Parents are becoming educated about the risks of their children swallowing fluoride toothpaste and fluoride mouth rinses.

Health care team roles

The pediatrician has an important role in a child's oral health because the pediatrician is usually the first health-care professional a child sees about his or her dental needs. The pediatrician can monitor a child's **oral hygiene**, determine when to make referrals, and regulate **fluoride therapy** in relation to a child's specific fluoride needs. The pediatrician can also educate parents about fluoride excess and safety issues.

The dentist regulates the amount and frequency of fluoride therapy, monitors a child's oral hygiene, and also assesses the amount of fluoride in a child's environment. The dentist also suggests and implements therapeutic plans for the child's dental health. Parent education is also a part of the dentist's role.

Dental hygienists, nurses, and teachers participate in parent education about fluoride usage and good dental habits, teach children about proper tooth brushing—especially the amount of toothpaste to use—and encourage periodic testing of the water for fluoride levels in the community or at a child's home, where filters that may lower fluoride concentrations in tap water may be used.

Prevention

Fluorosis can be prevented by monitoring the amount of fluoride children are exposed to before the age of six. Professionals can educate parents about diet,

fluoridated water, proper tooth brushing, and safe amounts of toothpaste to use. Children under six should be monitored during tooth brushing, shown to use only a pea-sized drop of toothpaste, and encouraged to not swallow toothpaste. Children under six should also not use fluoridated mouth rinses. Parents should limit the amount of fluoride in bottled beverages, and substitute milk for between-meal snacks. Pediatricians and dentists should adhere to the new guidelines for fluoride supplements. These supplements are not recommended for children who are exposed to adequate amounts of fluoridated water.

Folate see **Folic acid**

Folic acid

Description

Folic acid is a water-soluble vitamin belonging to the B-complex group of **vitamins**. These vitamins help the body break down complex **carbohydrates** into simple sugars to be used for energy. Excess B vitamins are excreted

from the body rather than stored for later use. This is why sufficient daily intake of folic acid is necessary.

Folic acid is also known as folate or folacin. It is one of the nutrients most often lacking in the Western diet, and there is evidence that deficiency is a problem on a worldwide scale. Folic acid is found in leafy green vegetables, beans, peas and lentils, **liver**, beets, brussels sprouts, poultry, nutritional yeast, tuna, wheat germ, mushrooms, oranges, asparagus, broccoli, spinach, bananas, strawberries, and cantaloupes. In 1998, the U.S. Food and Drug Administration (FDA) required food manufacturers to add folic acid to enriched bread and grain products to boost intake and to help prevent neural tube defects (NTD).

General use

Folic acid works together with **vitamin B₁₂** and **vitamin C** to metabolize protein in the body. It is important for the formation of red and white **blood** cells. It is necessary for the proper differentiation and growth of cells and for the development of the fetus. It is also used to form the nucleic acid of DNA and RNA. It increases the appetite and stimulates the production of **stomach** acid for digestion and it aids in maintaining a healthy liver. A deficiency of folic acid may lead to anemia, in which there is decreased production of red blood cells. Anemia reduces the amounts of oxygen and nutrients that are able to get to the tissues. Symptoms may include fatigue, reduced secretion of digestive acids, confusion, and forgetfulness. During **pregnancy**, a folic acid deficiency may lead to preeclampsia, premature birth, and increased bleeding after birth.

People who are at high risk of strokes and **heart** disease may greatly benefit by taking folic acid supplements. An elevated blood level of the amino acid homocysteine has been identified as a risk factor for some of these diseases. High levels of homocysteine have also been found to contribute to problems with **osteoporosis**. Folic acid, together with vitamins B₆ and B₁₂, helps break down homocysteine, and may help reverse the problems associated with elevated levels.

Pregnant women have an increased need for folic acid, both for themselves and their child. Folic acid is necessary for the proper growth and development of the fetus. Adequate intake of folic acid is vital for the prevention of several types of birth defects, particularly NTDs. The neural tube of the embryo develops into the **brain, spinal cord**, spinal column, and the **skull**. If this tube forms incompletely during the first few months of pregnancy a serious, and often fatal, defect results in spina bifida or anencephaly. Folic acid, taken from one year to one month before conception through the first

four months of pregnancy, can reduce the risk of NTDs by 50-70%. It also helps prevent a cleft lip and palate.

Research shows that folic acid can be used to successfully treat cervical dysplasia, a condition diagnosed by a Pap smear, of having abnormal cells in the cervix. This condition is considered to be a possible precursor to cervical **cancer**, and is diagnosed as an abnormal Pap smear. Daily consumption of 1,000 mcg of folic acid for three or more months has resulted in improved cervical cells upon repeat Pap smears.

Studies suggest that long-term use of folic acid supplements may also help prevent lung and colon cancer. Researchers have found that alcoholics who have low folic acid levels face a greatly increased possibility of developing colon cancer.

Preparations

To correct a folic acid deficiency, supplements are taken in addition to food. Since the functioning of the B vitamins is interrelated, it is generally recommended that the appropriate dose of B-complex vitamins be taken in place of single B vitamin supplements. The Recommended Dietary Allowance (RDA) for folate is 400 mcg per day for adults, 600 mcg per day for pregnant women, and 500 mcg for nursing women. Medicinal dosages of up to 1,000-2,000 mcg per day may be prescribed.

Precautions

Folic acid is not stable. It is easily destroyed by exposure to light, air, water, and cooking. Therefore, the supplement should be stored in a dark container in a cold, dry place, such as a refrigerator. Many medications interfere with the body's absorption and use of folic acid. This includes sulfa drugs, sleeping pills, estrogen, anti-conulsants, birth control pills, **antacids**, quinine, and some **antibiotics**. Using large amounts of folic acid (e.g., over 5,000 mcg per day) can mask a vitamin B₁₂ deficiency and thereby risk irreversible nerve damage.

Side effects

At levels of 5,000 mcg or less, folic acid is generally safe for use. Side effects are uncommon. However, large doses may cause nausea, decreased appetite, bloating, gas, decreased ability to concentrate, and insomnia. Large doses may also decrease the effects of phenytoin (Dilantin), a seizure medication.

KEY TERMS

Homocysteine—An amino acid involved in the breakdown and absorption of protein in the body.

Preeclampsia—A serious disorder of late pregnancy in which the blood pressure rises, there is a large amount of retained fluids, and the kidneys become less effective and excrete proteins directly into the urine.

Raynaud's disease—A symptom of various underlying conditions affecting blood circulation in the fingers and toes and causing them to be sensitive to cold.

Recommended Daily Allowance (RDA)—Guidelines for the amounts of vitamins and minerals necessary for proper health and nutrition established by the National Academy of Sciences in 1989.

Water-soluble vitamins—Vitamins that are not stored in the body and are easily excreted. They must, therefore, be consumed regularly as foods or supplements to maintain health.

Interactions

As with all B-complex vitamins, it is best to take folic acid with the other B vitamins. Vitamin C is important to the absorption and functioning of folic acid in the body.

Food poisoning

Definition

Food **poisoning** is a general term for health problems arising from eating contaminated food. Food may be contaminated by **bacteria**, **viruses**, environmental toxins, or toxins present within the food itself, such as the poisons in some mushrooms. Symptoms of food poisoning usually involve the prompt onset of vomiting and **diarrhea**. Some toxins also affect the nervous system.

Description

Every year millions of people suffer from bouts of vomiting and diarrhea that they blame on “something I ate.” These people are generally correct. The Centers for Disease Control and Prevention (CDC) estimates that there are from six to 33 million cases of food poisoning in the United States each year. Many cases are mild and pass so rapidly that they are never diagnosed. Occasionally a severe outbreak creates a newsworthy **public health hazard**.

Classical food poisoning, sometimes incorrectly called ptomaine poisoning, is caused by a variety of dif-

ferent bacteria. The most common are *Salmonella*, *Staphylococcus aureus*, *Escherichia coli* O157:H7, *Shigella*, and *Clostridium botulinum*. Each has a slightly different incubation period and duration, but all except *C. botulinum* cause inflammation of the intestines and diarrhea. Sometimes food poisoning is called bacterial gastroenteritis or infectious diarrhea. Food and water can also be contaminated by viruses (cholera, rotavirus), environmental toxins (heavy metals), and poisons produced within the food itself (mushroom poisoning or fish and shellfish poisoning).

Careless food handling creates conditions for the growth of bacteria that make people sick. Food can become contaminated at many different points during its trip from farm to table. Vegetables that are eaten raw, such as lettuce, may be contaminated by bacteria in soil, water, and dust during washing and packing. Home canned and commercially canned food may be improperly processed at too low a temperature or for too short a time to kill the bacteria.

Raw meats carry many foodborne bacterial diseases. The United States Food and Drug Administration (FDA) estimates that 90% or more of raw poultry sold at retail carries some disease-causing bacteria. Other raw meat products and eggs are contaminated to a lesser degree. Thorough cooking kills the bacteria and makes the food harmless. However, properly cooked food can become recontaminated if it comes in contact with plates, cutting boards, counter tops, or utensils that were used with raw meat and not cleaned and sanitized.

Cooked foods can also be contaminated after cooking by bacteria carried by food handlers or from bacteria in the environment. It is estimated that 50% of healthy people have the bacterium *Staphylococcus aureus* in their nasal passages and throat, as well as on their skin and hair. Rubbing a runny nose, then touching food can introduce the bacteria into cooked food. Bacteria flourish at room temperature and will rapidly grow into quantities capable of making people sick. To prevent this growth, food must be kept hot or cold, but never just warm.

Although the food supply in the United States is probably the safest in the world, anyone can get food poisoning. Serious outbreaks are rare. When they occur, the very young, the very old, and those with **immune system** weaknesses have the most severe and life-threatening cases. For example, this group is 20 times more likely to become infected with the *Salmonella* bacterium than the general population.

Travel outside the United States to countries where less attention is paid to sanitation, water purification, and good food handling practices increases the chances that a person will get food poisoning. People living in institu-

tions such as **nursing homes** are also more likely to get food poisoning.

Rotavirus is the most common cause of severe diarrhea in children and accounts for the hospitalization of an estimated 55,000 children in the United States and over 600,000 deaths of children worldwide per year.

Other less common but serious food-borne illnesses may arise from consuming animals infected with *Bovine spongiform encephalopathy*. Bovine spongiform encephalopathy (BSE) is a degenerative disorder affecting the **central nervous system** in cattle. It is also commonly referred to as “mad cow disease.” BSE results from an “unconventional transmissible agent” which is yet to be determined precisely but is thought to be a pathogenic protein. Cell death leads to holes in the **brain**, creating a “sponge-like” consistency, which results in the animal’s death. As of November 2000, there have been more than 177,500 cases of BSE confirmed in the United Kingdom (UK). However, no cases have been reported in the United States, where the food supply has been monitored closely. Imports of ruminants (suborder of mammals that includes sheep) and ruminant products have been restricted to some degree from countries where BSE was reported and has extended to all European countries. BSE is believed to be linked to a new variation of **Creutzfeldt-Jakob disease** (CJD) in humans, which is a progressive neurological disorder that can lead to death.

Causes and symptoms

The symptoms of food poisoning occur because foodborne bacteria release toxins or poisons as a byproduct of their growth in the body. These toxins (except those from *C. botulinum*) cause inflammation and swelling of the **stomach, small intestine** and/or **large intestine**. The result is abdominal muscle cramping, vomiting, diarrhea, **fever**, and the chance of **dehydration**. The severity of symptoms depends on the type of bacteria, the amount consumed, and the individual’s general health and sensitivity to the bacterial toxin.

Salmonella

According to the CDC, approximately 1.4 million cases of *Salmonella* contamination occur annually in the US, with about 40,000 being culture-confirmed cases reported to the CDC. *Salmonella* is found in egg yolks from infected chickens, in raw and undercooked poultry and in other meats, dairy products, fish, shrimp, and many more foods. The CDC estimates that one out of every 50 consumers is exposed to a contaminated egg yolk each year. However, thorough cooking kills the bacteria and makes the food harmless. *Salmonella* is also found in the feces of such pet reptiles as turtles, lizards, and snakes.

About one out of every 1,000 people get food poisoning from *Salmonella*. Of these, two-thirds are under age 20, with the majority under age nine. Most cases occur in the warm months between July and October. *Salmonella* poisoning manifests itself as *salmonellosis*, mostly caused by *Salmonella enteritidis* and *Salmonella typhimurium*. The incidence of salmonellosis has increased dramatically during the last two decades, due in part to the growing popularity of pet iguanas.

Symptoms of food poisoning begin 12–72 hours after eating food, water, or contact with animals contaminated with *Salmonella*. These include the traditional food poisoning symptoms of abdominal **pain**, diarrhea, vomiting, and fever. The symptoms generally last two to five days. Dehydration can be a complication in severe cases. People generally recover without antibiotic treatment, although they may feel tired for a week after the active symptoms subside. The CDC estimates that there are over 500 fatalities per year in the US, with 2% of the cases complicated by chronic arthritis.

Staphylococcus aureus

Staphylococcus aureus is found in dust, air, and sewage. The bacteria are spread primarily by food handlers using poor sanitary practices. Almost any food can be contaminated, but salad dressings, milk products, cream pastries, and any food kept at room temperature, rather than hot or cold, are likely candidates.

It is difficult to estimate the number of cases of food poisoning from *Staphylococcus aureus* that occur each year, because its symptoms are so similar to those caused by other foodborne bacteria. Many cases are mild and the victim never sees a doctor.

Symptoms appear rapidly, usually two to eight hours after the contaminated food is eaten. The acute symptoms of vomiting, diarrhea, and severe abdominal cramps usually last only three to six hours and rarely more than 24 hours. Most people recover without medical assistance. Deaths are rare.

Escherichia coli (*E. coli*)

There are many strains of *E. coli*, and not all of them are harmful. The strain that causes most severe food poisoning is *E. coli* O157:H7. Food poisoning by *E. coli* occurs in three out of every 10,000 people. Foodborne *E. coli* is found mainly in food derived from cows such as dairy products and beef, especially ground beef.

Symptoms of food poisoning from *E. coli* are slower to appear than those caused by some of the other foodborne bacteria. *E. coli* produces toxins in the large intestine rather than higher up in the **digestive system**. This

factor accounts for the delay in symptoms and the fact that vomiting rarely occurs in *E. coli* food poisoning.

One to three days after eating contaminated food, the victim with *E. coli* O157:H7 begins to have severe abdominal cramps and watery diarrhea that usually becomes bloody within 24 hours. There is little or no fever, and rarely does the victim vomit. The bloody, watery diarrhea lasts from one to eight days in uncomplicated cases. *E. coli* is the most common cause of “travelers’ diarrhea,” affecting people travelling to many high-risk areas such as Latin America, Asia, Africa, and the Middle East. It is most often caused by water or foods contaminated with fecal matter.

Campylobacter jejuni (*C. jejuni*)

According to the FDA, *C. jejuni* is the leading cause of bacterial diarrhea in the United States. It is responsible for more cases of bacterial diarrhea than *Shigella* and *Salmonella* combined. Anyone can get food poisoning from *C. jejuni*, but children under five and young adults between the ages of 15 and 29 are more frequently infected.

C. jejuni is carried by healthy cattle, chickens, birds, and flies. It is not carried by healthy people in the United States or Europe. The bacterium is also found in ponds and stream water. The ingestion of only a few hundred *C. jejuni* bacteria can make a person sick.

Symptoms of food poisoning begin two to five days after eating food contaminated with *C. jejuni*. These symptoms include fever, abdominal pain, nausea, headache, muscle pain, and diarrhea. The diarrhea can be watery or sticky and may contain **blood**. Symptoms last from seven to 10 days, and relapses occur in about one quarter of people who are infected. Dehydration is a common complication. Other complications such as arthritis-like joint pain and hemolytic-uremic syndrome (HUS) are rare.

Shigella

Shigella is a common cause of diarrhea in travelers to developing countries. It is associated with contaminated food and water, crowded living conditions, and poor sanitation. The bacterial toxins affect the small intestine.

Symptoms of food poisoning by *Shigella* appear 36 to 72 hours after eating contaminated food. These symptoms are slightly different from those associated with most foodborne bacteria. In addition to the familiar watery diarrhea, nausea, vomiting, abdominal cramps, and fever, up to 40% of children with severe infections show neurological symptoms, including seizures caused

by fever, confusion, headache, lethargy, and a stiff neck that resembles **meningitis**.

The disease runs its course in two to three days. Dehydration is a common complication. Most people recover on their own, although they may feel exhausted. Children who are malnourished or have weakened immune systems may die.

Clostridium botulinum (*C. botulinum*)

C. botulinum, which causes both adult botulism and infant botulism, is unlike any of the other foodborne bacteria. First, *C. botulinum* is an anaerobic bacterium that can live only in the absence of oxygen. Second, the toxins from *C. botulinum* are neurotoxins. They poison the nervous system, causing **paralysis** without the vomiting and diarrhea associated with other foodborne illnesses. Third, toxins that cause adult botulism are released when the bacteria grow in an airless environment outside the body. They can be broken down and made harmless by heat. Finally, botulism is much more likely to be fatal, even in tiny quantities.

Adult botulism outbreaks are usually associated with home canned food, although occasionally commercially canned or vacuum-packed foods are responsible for the disease. *C. botulinum* grows well in non-acidic, oxygen-free environments. If food is canned at too low heat or for too brief a time, the bacterium is not killed. It reproduces inside the can or jar, releasing its deadly neurotoxin. The toxin can be made harmless by heating the contaminated food to boiling for ten minutes. However, even a very small amount of the *C. botulinum* toxin can cause serious illness or death.

Symptoms of adult botulism appear about 18 to 36 hours after the contaminated food is eaten, although there are documented times of onset ranging from four hours to eight days. Initially a person suffering from botulism feels weakness and dizziness followed by double **vision**. Symptoms progress to difficulty speaking and swallowing. Paralysis moves down the body, and when the respiratory muscles are paralyzed, death results from asphyxiation. People who show any signs of botulism poisoning must receive immediate emergency medical care to increase their chance of survival.

Infant botulism is a form of botulism first recognized in 1976. It differs from foodborne botulism in its causes and symptoms. Infant botulism occurs when a child under the age of one year ingests the spores of *C. botulinum*. These spores are found in soil, but a more common source of spores is honey.

The *C. botulinum* spores lodge in the baby’s intestinal tract and begin to grow, producing their neurotoxin.

COMMON PATHOGENS CAUSING FOOD POISONING

<i>Pathogen</i>	<i>Common Host(s)</i>
<i>Campylobacter</i>	Poultry
<i>E.coli</i> 0157:H7	Undercooked, contaminated ground beef
<i>Listeria</i>	Found in a variety of raw foods, such as uncooked meats and vegetables, and in processed foods that become contaminated after processing
<i>Salmonella</i>	Poultry, eggs, meat, and milk
<i>Shigella</i>	This bacterium is transmitted through direct contact with an infected person or from food or water that become contaminated by an infected person
<i>Vibrio</i>	Contaminated seafood

Source: Food Safety and Inspection Service, U.S. Department of Agriculture

(Illustration by Standley Publishing. Courtesy of Gale Group.)

Onset of symptoms is gradual. Initially the baby is constipated, which is followed by poor feeding, lethargy, weakness, drooling, and a distinctive wailing cry. Eventually the baby loses the ability to control its head muscles. From there the paralysis progresses to the rest of the body.

Rotavirus

The clinical characteristics of rotavirus include vomiting and watery diarrhea for three to eight days with abdominal pain and fever also frequently occurring. The incubation period is about two days. Subsequent bouts of rotavirus tend to be less severe than the initial **infection**. Illness can occur when in contact with contaminated food, water, or surfaces. Rotavirus infections are higher in countries with temperate climates (November to April in the United States) with most infections occurring in children under two years old. Adult cases tend to be milder.

Bovine spongiform encephalopathy and Creutzfeldt-Jakob disease

It is extremely unlikely that bovine spongiform encephalopathy will become a foodborne illness in the United States, because the feeding of ruminant by-products to other animals was probably a factor that led to the outbreak in the United Kingdom. Furthermore, the FDA implemented a ban on ruminant feed in 1997 due to evidence that BSE can be transmitted to humans.

Creutzfeldt-Jakob disease has atypical clinical symptoms, including psychiatric or sensory symptoms early in its course, and neurological abnormalities and **dementia** later on. Incidence of CJD in people under 30 years is extremely rare in the US (less than 5 cases per 1 billion per year). In the UK, it primarily affects younger people, with over half of the patients who have died of CJD under 30 years old.

Diagnosis

One important aspect of diagnosing food poisoning is for doctors to determine if a number of people have eaten the same food and show the same symptoms of illness. When a cluster of cases occurs, food poisoning is strongly suspected. The diagnosis is confirmed when the suspected bacterium is found in a **stool culture** or a fecal smear from the person. Other laboratory tests are used to isolate bacteria from a sample of the contaminated food. Botulism is usually diagnosed from its distinctive neurological symptoms, since rapid treatment is essential. Many cases of food poisoning go undiagnosed, since a definite diagnosis is not necessary to effectively treat the symptoms. Because it takes time for symptoms to develop, it is not necessarily the most recent food one has eaten that causes the symptoms.

Treatment

Treatment of most food poisoning, except that caused by *C. botulinum*, focuses on preventing dehydra-

KEY TERMS

Diuretic—Medication that increases the urine output of the body.

Electrolytes—Salts and minerals that produce electrically charged particles (ions) in body fluids. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost all major biochemical reactions in the body.

Lactobacillus acidophilus—This bacterium is found in yogurt and changes the balance of the bacteria in the intestine in a beneficial way.

Platelets—Blood cells that help the blood to clot.

tion by replacing fluids and electrolytes lost through vomiting and diarrhea. Electrolytes are salts and **minerals** that form electrically charged particles (ions) in body fluids. Electrolytes are important because they control body **fluid balance** and are important for all major body reactions. Pharmacists can recommend effective, pleasant-tasting, electrolytically balanced replacement fluids that are available without a prescription. When more fluids are being lost than can be consumed, dehydration may occur. Dehydration is more likely to happen in the very young, the elderly, and people who are taking diuretics. To prevent dehydration, a doctor may give fluids intravenously.

In very serious cases of food poisoning, medications may be given to stop abdominal cramping and vomiting. Anti-diarrheal medications are not usually given. Stopping the diarrhea keeps the toxins in the body longer and may prolong the infection.

People with food poisoning should modify their diet. During the period of active vomiting and diarrhea, they should not try to eat and should drink only clear liquids frequently but in small quantities. Once active symptoms stop, they should eat bland, soft, easily digested foods for two to three days. Such foods include bananas, rice, applesauce, and toast, all of which are easy to digest. Milk products, spicy food, alcohol, and fresh fruit should be avoided for a few days, although babies should continue to breastfeed. These modifications are often all the treatment that is necessary.

Severe bacterial food poisonings are sometimes treated with **antibiotics**. Trimethoprim and sulfamethox-

azole (Septra, Bactrim), ampicillin (Amcill, Polycill) or ciprofloxacin (Ciloxan, Cipro) are most frequently used.

Botulism is treated in a different way from other bacterial food poisonings. Botulism antitoxin is given to adults but not infants if it can be administered within 72 hours after symptoms are first observed. If given later, it provides no benefit.

Both infants and adults require hospitalization, often in the intensive care unit. If the ability to breathe is impaired, patients are put on a mechanical ventilator to assist their breathing and are fed intravenously until the paralysis passes.

Alternative treatment

Alternative practitioners offer the same advice as traditional practitioners concerning diet modification. In addition, they recommend taking charcoal tablets, *Lactobacillus acidophilus*, *Lactobacillus bulgaricus*, and citrus seed extract. An electrolyte replacement fluid can be made at home by adding one teaspoon of salt and four teaspoons of sugar to one quart of water. For food poisoning other than botulism, two homeopathic remedies, either *Arsenicum album* or *Nux vomica*, are strongly recommended.

Prognosis

Most cases of food poisoning (except botulism) clear up on their own within one week without medical assistance. The patient may continue feel tired for a few days after active symptoms stop. So long as the sick person does not become dehydrated, there are few complications. Deaths are rare and usually occur in the very young, the very old, and people whose immune systems are already weakened.

Complications of *Salmonella* food poisoning include arthritis-like symptoms that occur three to four weeks after infection. Although deaths from *Salmonella* are rare, they do occur, mostly in elderly people in nursing homes.

Adults usually recover without medical intervention, but many children need to be hospitalized as the result of *E. coli* food poisoning. *E. coli* toxins may be absorbed into the blood stream where they destroy red blood cells and platelets, which are important in blood clotting. About 5% of victims develop hemolytic-uremic syndrome, which results in sudden kidney failure and makes dialysis necessary. (Dialysis is a medical procedure used to filter the body's waste product when the **kidneys** have failed.)

Botulism is the deadliest of the bacterial foodborne illnesses. With prompt medical care, the death rate is less than 10%.

Health care team roles

Definitive identification of food poisoning is made by a physician, usually with the aid of stool or blood cultures. Nurses, medical technologists, and other health care professionals often aid in taking and analyzing cultures, and in educating patients about preventive measures they can take to avoid food poisoning.

Prevention

Food poisoning is almost entirely preventable by practicing good sanitation and good food handling techniques. These include:

- Keep hot foods hot and cold foods cold.
- Cook meat to the recommended internal temperature. Use a meat thermometer to check. Cook eggs until they are no longer runny.
- Refrigerate leftovers promptly. Do not let food stand at room temperature.
- Avoid contaminating surfaces and other foods with the juices of uncooked meats.
- Wash fruits and vegetables before using.
- Purchase pasteurized dairy products and fruit juices.
- Throw away bulging or leaking cans, or any food that smells spoiled.
- Wash hands well before and during food preparation and after using the bathroom.
- Sanitize food preparation surfaces regularly.

Foot care

Definition

Foot care involves all aspects of preventive and corrective care of the foot and ankle. Physicians specializing in foot care are called podiatrists.

Purpose

During an average lifetime, each person walks about 115,000 miles; and 75% of all people have foot problems at some point in their lives.

Foot problems can arise from wearing ill-fitting shoes, from general wear and tear, as a result of injury, or as a complication of disease. People with **diabetes mellitus** or circulatory diseases are 20 times more likely to have foot problems than the general public.

Podiatrists specialize in treating the foot and ankle. Other doctors who have experience with foot problems are family physicians, orthopedists, sports medicine specialists, and those who care for diabetics. Problems with the feet include foot **pain**, joint inflammation, plantar warts, such fungal infections as athlete's foot, nerve disorders, torn ligaments, broken bones, bacterial infections, and such tissue injuries as frostbite.

Precautions

People with diabetes or circulatory disorders should be alert to even the smallest of foot problems. In this patient population, a break in the skin can lead to possible **infection, gangrene**, and amputation.

Description

Daily foot care for people likely to develop foot problems includes washing the feet in tepid water with mild soap and moisturizing the feet with lanolin-based lotion. Toenails should be cut straight across above the level of the skin after soaking the feet in tepid water. Corns and calluses should not be cut. If they need removal, it should be done under the care of a doctor. If they develop in high-risk patients, athlete's foot and plantar warts should also be treated by a doctor.

Many people with diabetes or circulatory disorders suffer with the problem of cold feet. A problem with cold feet can be helped by not smoking (it constricts the **blood vessels**); not crossing the legs while sitting or sitting in one position too long; wearing warm socks; and avoiding constricting stockings. People with circulatory problems should not use heating pads or hot water bottles on their feet, as even moderate heat can damage the skin if the circulation is impaired.

The patient who is at risk for foot problems should also choose socks that are soft and cushioned. Cotton material is best at wicking moisture away from the feet. Good shoes should be worn whenever the patient is ambulating or out of bed. Flat shoes are preferred, and the fit should allow about 0.75 inch (about 2 cm) between the end of the big toe and the shoe. The patient should not walk barefoot.

A routine part of foot care includes an assessment of the feet for changes or injury. These can include blisters, cuts, redness, scratches, or other breaks in the skin.

Preparation

No special preparation is necessary other than understanding the nature of foot problems.

Aftercare

Foot care is preventative and should be ongoing throughout a person's life.

Complications

There are no complications associated with foot care. The risks are in ignoring the feet and allowing problems to develop.

Results

With regular care, such foot disorders as infections, skin ulcers, and gangrene can be prevented.

Health care team roles

The nurse plays an important role in identifying patients at risk for foot problems and in providing foot care. The patient should be instructed on appropriate foot care and the measures that can be taken to prevent complications.

Foot orthoses

Definition

A foot orthosis is an assistive device used in occupational and **physical therapy**. It is designed to support a person's foot in a way that makes it more functional following disease or injury.

Purpose

Persons with foot and ankle disorders, such as arthritis, ulcers, diabetes, bunions, various forms of tendinitis, and other deformities, can benefit from foot orthoses. Typically, foot orthoses are inlays placed in a client's shoe. The orthosis supports, cushions, and/or pads the foot.

Description

Types of foot orthoses

Most clients with foot problems benefit from mass-produced, prefabricated orthoses. They are relatively common and may absorb shock in the foot or provide added arch under the foot, for example.

Occasionally a prefabricated orthosis is modified in some way to better accommodate a client, and this is referred to as a customized orthosis. These may be molded to better fit a client's foot or have additional padding.

However, some clients with severe foot deformities or disorders may not be able to use a prefabricated orthosis or even a customized orthosis. These clients require custom-molded orthoses that are made from the mold of the client's foot for a perfect, tight fit.

Operation

In order for a client to use a foot orthosis appropriately, he/she must go through a thorough assessment that evaluates the position and range of motion (ROM) of foot and ankle joints in all parts of the foot. Clients should be tested while walking and bearing weight as well as while standing. Clients must be tested for rigidity and flexibility in addition to assessing any foot or ankle **pain**.

Maintenance

Clients who are prescribed footwear need to maintain their orthoses with proper cleaning and repairs when necessary. As the condition of the foot may change or worsen, a previously prescribed orthosis may become ineffective or unnecessary, just as a prescription drug might. Periodic follow-up with a physician, occupational therapist, or appropriate health care professional is necessary to ensure that the foot orthosis remains as functional as possible.

Health care team roles

A variety of health care professionals can help a client determine the most appropriate foot orthosis. Occupational or physical therapy practitioners can provide assessments and evaluations of the effectiveness of foot orthoses. Orthotists and prosthetists, although typically consulted by patients who have lost limbs, also can help in choosing an appropriate orthosis. Pedorthists can evaluate a client in need of an orthosis, provide and fit the shoe, and follow-up the client. However, a prescription for a foot orthosis is necessary.

Foreign bodies

Definition

"Foreign" means "originating elsewhere" or simply "outside the body." Foreign bodies typically become lodged in the eyes, ears, nose, airways, and rectum of human beings.

Description

Both children and adults experience problems caused by foreign objects getting stuck in their bodies. Young children in particular are naturally curious and may intentionally put such shiny objects as coins or button batteries into their mouths. They are also prone to inserting objects in their ears and nostrils. Adults may accidentally swallow a non-food object or inhale a foreign body that gets stuck in the throat or **lungs**. Even if an object like a toothpick successfully passes through the esophagus and into the **stomach**, it can get stuck inside the rectum. Airborne particles can lodge in the eyes of people at any age.

Foreign bodies can be in hollow organs (like swallowed batteries) or in tissues (like bullets). They can be inert or irritating. If they irritate they will cause inflammation and scarring. They can bring **infection** with them or acquire it and protect it from the body's immune defenses. They can obstruct passageways either by their size or by the scarring they cause. Some foreign bodies can be toxic.

Causes and symptoms

Eyes

Dust, dirt, sand, or other airborne material can lodge in the eyes, causing minor irritation and redness. More serious damage can be caused by hard or sharp objects that penetrate the surface and become embedded in the cornea or conjunctivae (the mucous membranes around the inner surface of the eyelids). Swelling, redness, bleeding from the surface **blood vessels**, sensitivity to light, and sudden **vision** problems are all symptoms of foreign matter in the eyes.

Ears and nose

Children will sometimes put objects into their noses, ears, and other openings. Beans, popcorn kernels, raisins, and beads are just a few of the many items that have been found in these bodily cavities. On occasion, insects may also fly into the ears and nose. **Pain, hearing loss,** sounds or a sense of something stuck in the ear are symptoms of foreign bodies in the ears. A smelly, bloody discharge from one nostril is a symptom of a foreign body in the nose.

Airway and stomach

At a certain age children will eat anything. A very partial list of items recovered from young stomachs includes the following: coins, chicken bones, fish bones, beads, rocks, plastic toys, pins, keys, round stones, marbles, nails, rings, batteries, ball bearings, screws, staples, washers, a **heart** pendant, a clothespin spring, and a toy soldier. Some of these items will pass completely through the **digestive system** to be excreted some time later. The progress of metal objects has been successfully followed with a metal detector. Others, like sharp bones, can get stuck and cause problems. Batteries are corrosive and must be removed immediately.

Children eat things and stick things into their bodily openings of their own volition. But they inhale them unwittingly. The most commonly inhaled item is probably a peanut. A crayon and a cockroach have been found in the windpipes (tracheas) of children. These items always cause symptoms (difficulty swallowing and spitting up saliva, for instance) and may elude detection for some time while a child is being treated for **asthma** or recurring **pneumonia**.

Adults are not exempt from unorthodox inedibles. Dental devices are commonly swallowed. Adults with mental illness or subversive motives may swallow such inappropriate objects as toothbrushes.

Rectum

Sometimes a foreign object will successfully pass through the throat and stomach only to get stuck at the juncture between the rectum and the anal canal. Items may also be self-introduced to enhance sexual stimulation and then get stuck. Sudden sharp pain during elimination may signify that an object is lodged in the rectum. Other symptoms vary depending upon the size of the object, its location, how long it has been in place, and whether or not infection has set in.

Diagnosis

The symptoms of foreign bodies are as diverse as the objects and their locations. The most common manifestation of a foreign object anywhere in the body is infection. Even if an object entered in a sterile condition, **bacteria** still seem to find it and are able to hide from the body's defenses there. Blockage of passageways—breathing, digestive or excretory—is another result. Pain is common.

Treatment

Eyes

Small particles like sand may be removable without medical help, but if the object is not visible or cannot be retrieved, prompt emergency treatment is necessary. Trauma to the eyes can lead to loss of vision and should never be ignored. Before attempting any treatment, a person should move to a well-lighted area where the object can be more easily spotted. Hands should be washed, and only clean, preferably sterile, materials should make contact with the eyes. If the particle is small, it can be dislodged by blinking or pulling the upper lid over the lower lid and flushing out the speck. A clean cloth can also be used to pick out the offending particle. Afterwards, the eye should be rinsed with clean, lukewarm water or an ophthalmic wash.

If the foreign object cannot be removed at home, the eye should be lightly covered with sterile gauze to discourage rubbing. A physician will use a strong light and possibly special eyedrops to locate the object. Surgical tweezers can effectively remove many objects. An antibiotic sterile ointment and a patch may be prescribed. If the foreign body has penetrated the deeper layers of the eye, an ophthalmic surgeon will be consulted for emergency treatment.

Ears and nose

A number of ingenious extraction methods have been devised for removing foreign objects from the nose and ears. A bead in a nostril, for example, can often be popped out by blowing into the mouth while holding the other nostril closed. Skilled practitioners have removed peas from the ears by tiny improvised corkscrews. Marbles have been extracted by using cotton swabs and super glue. Tweezers often work well. Insects can be floated out of the ear by pouring warm (not hot) mineral oil, olive oil, or baby oil into the ear canal. Items that are lodged deep in the ear canal are more difficult to remove because of the possibility of damaging the ear drum. These require emergency treatment from a qualified physician.

Airways and stomach

Mechanical obstruction of an airway, which commonly occurs when food gets lodged in the throat, can be treated by applying the **Heimlich maneuver**. If the object is lodged lower in the airway, a bronchoscope (a special instrument to view the airway and remove obstructions) can be inserted. On other occasions, as when an object is blocking the entrance to the stomach, a fiberoptic **endoscope** (an illuminated instrument that views the interior of a body cavity) may be used. A physician typically administers a sedative and anesthetizes the throat. The foreign object will then either be pulled out or pushed into the stomach, depending on whether or not the physician thinks it will pass through the digestive tract on its own. Objects in the digestive tract that are not irritating, sharp or large may be followed as they continue on through. Sterile objects that are causing no symptoms may be left in place. Surgical removal of an offending object is necessary only if it causes symptoms.

Rectum

A rectal retractor can remove objects that a physician can feel during **physical examination**. Surgery may be required for objects deeply lodged within the rectum.

Prognosis

Once foreign objects are removed, persons have no further medical problems. If surgery is required (such as to remove a bullet), permanent damage may be sustained when the object initially enters the body. Once surgical incisions have healed, many persons have no further medical problems. Counseling may be needed to help persons cope with potential after-effects.

Health care team roles

First aid may be provided by trained persons. **Emergency medical technicians** may provide support while transporting people to a hospital or emergency treatment facility. Physicians remove most foreign objects. Surgeons may be needed to remove some objects from the eye (ophthalmologists), ears (otolaryngologists), gastrointestinal system (gastroenterologists), **brain** (neurosurgeons) or body tissues (general surgeons). Radiologists may document progress of an object through the body. Nurses supply supportive care and prevention education to the patient or family. Therapists may be needed to cope with such after-effects as physical impairment, mental distress or simple embarrassment.

KEY TERMS

Bronchoscope—An illuminated instrument that is inserted into the airway to inspect and retrieve objects from the bronchial tubes.

Conjunctivae—Mucous membranes around the inner surface of the eyelid.

Cornea—The rounded, transparent portion of the eye that covers the pupil and iris and lets light into the interior.

Endoscopy—The surgical use of long, thin instruments that have both viewing and operating capabilities.

Heimlich maneuver—An emergency procedure for removing a foreign object lodged in the airway that is preventing the person from breathing. To perform the Heimlich maneuver on a conscious adult, the rescuer stands behind the victim and encircles the choking person's waist. The rescuer makes a fist with one hand and places the other hand on top, positioned below the rib cage and above the waist. The rescuer then applies pressure by a series of upward and inward thrusts to force the foreign object back up the choking person's trachea.

Trachea—Windpipe. The tube that connects the pharynx with the lungs.

Prevention

Using common sense and following safety precautions are the best ways to prevent foreign objects from entering the body. For instance, parents and grandparents should toddler-proof their homes, storing batteries in a locked cabinet and properly disposing of used batteries, so they are not in a location where curious preschoolers can retrieve them from a wastebasket. To minimize the chance of youngsters inhaling food, parents should not allow children to eat while walking or playing. Adults should chew food thoroughly and not talk while chewing. Foods should not be thrown up into the air and caught in an open mouth. Many eye injuries can be prevented by wearing safety glasses while using power tools.

Fractures

Definition

A fracture is a complete or incomplete break in a bone resulting from the application of excessive force. An injury may be classified as a fracture-dislocation when a fracture involves the bony structures of any joint with associated dislocation of the same joint.

Description

Fractures usually result from traumatic injury to a bone, causing the continuity of bone tissues or bony cartilage to be disrupted or broken. Fracture classifications include simple, compound, incomplete, and complete. Simple fractures (more recently termed closed fractures) are not obvious on the surface, as the skin has not been broken and remains intact. Compound fractures (now commonly referred to as open fractures) break the skin, exposing bone and causing additional soft tissue injury and possible **infection**. Single and multiple fractures refer to the number of breaks in the same bone. Fractures are termed complete if the break is completely through the bone, and described as incomplete or "greenstick" if the fracture occurs partly across a bone shaft. This latter type of fracture is often the result of bending or crushing forces applied to a bone.

Fractures are also named by the specific portion of the bone involved and the nature of the break. Identification of a fracture line can further classify fractures. Types include linear, oblique, transverse, longitudinal, and spiral fractures. Fractures can be further subdivided by the positions of bony fragments and are described as comminuted, non-displaced, impacted, overriding, angulated, displaced, avulsed, and segmental.

Fracture lines identification

Linear fractures have a break that runs parallel to the bone's main axis or in the direction of the bone's shaft. For example, a linear fracture of the arm bone could

An x ray can be used to diagnose a fracture, as in this x ray of a fractured humerus bone. (Bates MD/Custom Medical Stock Photo. Reproduced by permission.)

extend the entire length of the bone. Oblique and transverse fractures differ in that an oblique fracture crosses a bone at approximately a 45° angle to the bone's axis. In contrast, a transverse fracture crosses a bone's axis at a 90° angle. A longitudinal fracture is similar to a linear fracture. Its fracture line extends along the shaft but is more irregular in shape and does not run parallel to the bone's axis. Spiral fractures are described as crossing a bone at an oblique angle, creating a spiral pattern. This type of break usually occurs in the long bones of the body such as the upper arm bone (humerus) or the thigh bone (femur).

Bony fragment position identification

Comminuted fractures have two or more fragments broken into small pieces, in addition to the upper and lower halves of a fractured bone. Fragments of bone that maintain their normal alignment following a fracture are described as being non-displaced. An impacted fracture is characterized as a bone fragment forced into or onto another fragment, resulting from a compressive force. Overriding is a term used to describe bony fragments that

overlap and shorten the total length of a bone. Angulated fragments result in pieces of bone being at angles to each other. A displaced bony fragment occurs from disruption of normal bone alignment with deformity of these segments separate from one another. An avulsed fragment occurs when bone fragments are pulled from their normal position by forceful muscle contractions or resistance from ligaments. Segmental fragmented positioning occurs if fractures in two adjacent areas occur, leaving an isolated central segment. An example of segmental alignment occurs when the arm bone fractures in two separate places, with displacement of the middle section of bone.

Causes and symptoms

Individuals with high activity levels appear to have a greater risk for fractures. This group includes children and athletes participating in contact sports. Because of an increase in bone brittleness with aging, elderly persons are also included in this high-risk population. It has been recognized that up to the age of 50, more men suffer from fractures than women due to occupational hazards. However, after the age of 50, more women suffer frac-

tures than men. Specific diseases causing an increased risk for fractures include Paget's disease, rickets, osteogenesis imperfecta, **osteoporosis**, and prolonged disuse of a nonfunctional body part such as after a stroke.

Symptoms of fractures usually begin with **pain** and swelling at the involved site. There may also be a great deal of tenderness in the area near the fracture. The skin in the area may be pale and an obvious deformity may be present. In more severe cases, there may be a loss of pulse below the fracture site (such as in the extremities), accompanied by numbness, tingling, or **paralysis** below the fracture. An open or compound fracture is often accompanied by bleeding or bruising. If a leg is fractured, weakness will usually accompany the injury, causing difficulty with weight bearing.

Diagnosis

Diagnosis begins immediately with an individual's own observation of symptoms. A thorough medical history and physical exam completed by a physician or advanced practice nurse often provides enough information to determine if further testing is necessary. An x ray of the injured area is the most common test used to determine the presence of a bone fracture and its associated displacement. However, it is important to note that not all fractures are apparent on an initial x ray. Rib fractures are often difficult to diagnose and may require several views at different angles to see any fracture lines. If a fracture is open and occurs in conjunction with soft tissue injury, further laboratory studies are often conducted to determine if **blood** loss has occurred.

In the event of exercise-related stress fractures (micro-fractures due to excessive stress), a tuning fork can provide a simple, inexpensive test. The tuning fork is a metal instrument with a stem and two prongs that vibrate when struck. If an individual has increased pain when the tuning fork is placed on a bone, such as the lower leg bone or shinbone, the likelihood of a stress fracture is high. Bone scans are also helpful in detecting stress fractures. In this diagnostic procedure, a radioactive tracer is injected into the blood stream and images are taken of specific areas or the entire skeleton.

Treatment

Fracture treatment depends on the type of fracture, its severity, and the individual's age and general health. The first priority in treating any fracture is to address the entire medical status of an individual. If an open fracture is accompanied by serious soft tissue injury, it may be necessary to control bleeding and the **shock** that can accompany loss of blood.

First aid is the appropriate initial treatment in emergency situations. It includes proper splinting, control of blood loss, and monitoring **vital signs** such as breathing and circulation.

Immobilization

Immobilization of a fracture site can be done internally or externally. The primary goal of immobilization is to maintain the realignment of a bone long enough for healing to start and progress. Immobilization by external fixation uses splints, casts, or braces. This may be the primary and only procedure for fracture treatment. Splinting to immobilize a fracture can be done with or without traction. In emergency situations, splinting is a useful form of fracture management if the injured individual must be moved by someone other than a trained medical professional. Splinting should be done without causing additional pain and without moving the bone segments. In a clinical environment, plaster of Paris casts are used for immobilization. Braces are also useful, as they often allow movement above and below a fracture site. Treatments for stress fractures include rest and decreasing or stopping any activity that causes or increases pain.

Fracture reduction

Fracture reductions are either closed or open. Closed reduction refers to realigning bones without breaking the skin. It is accomplished using manipulation and/or traction and is commonly done with some kind of anesthetic. Open reduction primarily refers to surgery that is performed to realign bones or fragments. Fractures with little or no displacement may not require any form of reduction.

Traction is used to help reposition a broken bone. It works by applying pressure to restore proper alignment. The traction device immobilizes the area and maintains realignment as the bone heals. A fractured bone is immobilized by applying opposing forces at both ends of an injured area, using an equal amount of traction and countertraction. Weights provide the traction pull needed, or the pull is achieved by positioning the individual's body weight. Traction is a form of closed reduction and is sometimes used as an alternative to surgery. Since it restricts movement of an affected limb or body part, it may confine a person to bed rest for an extended period of time.

A person may need open reduction if there is an open, severe, or comminuted fracture. This procedure allows a physician to examine and surgically correct associated soft tissue damage while reducing the fracture and, if necessary, applying internal or external devices. Internal fixation is a surgical procedure that is required

when a fracture cannot be reduced by closed fracture methods. Internal fixation devices include plates, nails, screws, and rods. When healing is complete, the physician may or may not elect to remove these devices.

Alternative treatment

In addition to the importance of **calcium** for strong bones, many alternative treatment approaches advocate mineral supplements to help build and maintain a healthy, resilient skeleton. Some physical therapists use electrostimulation over a fractured site to promote healing. Chinese traditional medicine may be helpful by working to reconnect *chi* through the meridian lines along the line of a fracture. **Homeopathy** can enhance the body's healing process. Two particularly useful homeopathic remedies are arnica (*Arnica montana*) and symphytum (*Symphytum officinalis*). If possible, applying contrast **hydrotherapy** to an extremity (e.g., a hand or foot) of a fractured area can assist healing by enhancing circulation.

Prognosis

Fractures can normally be cured with proper first aid and appropriate aftercare. If determined necessary, the fractured site should be manipulated, realigned, and immobilized as soon as possible. Realignment has been shown to be much more difficult after six hours. Healing time varies from person to person, with the elderly generally needing more time to heal completely. A non-union fracture may result when a fracture does not heal, such as in the case of an elderly person or an individual with medical complications. Recovery is complete when there is no bone motion at the fracture site, and x rays indicate complete healing.

Health care team roles

When treating most fractures, an orthopedic surgeon is the head of the health care team. These physicians have specialized training in bones. They are responsible for reducing, realigning, and immobilizing fractured bones. In the absence of an orthopedic surgeon, a general surgeon or a family practitioner may treat simple, closed fractures. Emergency medical service providers may render immediate first aid to persons with fractures. After fracture reduction and healing have occurred, physical therapists may assist in returning injured body parts to their normal levels of function.

Prevention

Adequate calcium intake is necessary for strong bones and can help decrease the risk of fractures. People

KEY TERMS

Avulsion fracture—A fracture caused by the tearing away of a fragment of bone where a strong ligament or tendon attachment forcibly pulls the fragment away from the bone tissue.

Axis—A line that passes through the center of the body or body part.

Comminuted fracture—A fracture in which there are several breaks in a bone, creating numerous fragments.

Contrast hydrotherapy—A series of hot and cold water applications. A hot compress (as hot as an individual can tolerate) is applied for three minutes followed by an ice cold compress for 30 seconds. These applications are repeated three times each and ending with the cold compress.

Osteogenesis imperfecta—A genetic disorder involving defective development of connective tissues, characterized by brittle and fragile bones that are easily fractured by the slightest trauma.

Osteoporosis—Literally meaning “porous bones,” this condition occurs when bones lose an excessive amount of their protein and mineral content, particularly calcium. Over time, bone mass and strength are reduced leading to increased risk of fractures.

Paget's disease—A common disease of bone of unknown cause, usually affecting middle-aged and elderly people, characterized by excessive bone destruction and unorganized bone repair.

Reduction—The restoration of a body part to its original position after displacement, such as the reduction of a fractured bone by bringing ends or fragments back into original alignment. The use of local or general anesthesia usually accompanies a fracture reduction. If performed by outside manipulation only, the reduction is described as closed; if surgery is necessary, it is described as open.

Rickets—A condition caused by the deficiency of vitamin D, calcium, and usually phosphorus, seen primarily in infancy and childhood, and characterized by abnormal bone formation.

Traction—The process of placing a bone, limb, or group of muscles under tension by applying weights and pulleys. The goal is to realign or immobilize the part or to relieve pressure on that particular area to promote healing and restore function.

who do not get enough calcium in their diets can take a calcium supplement. **Exercise** can help strengthen bones by increasing bone density, thereby decreasing the risk of fractures from **falls**. A University of Southern California study reported that older people who exercised one or more hours per day had approximately half the incidence of hip fractures as those who exercised fewer than 30 minutes per day or not at all.

Fractures can be prevented if safety measures are taken seriously. These measures include using seat belts in cars and encouraging children to wear protective sports gear. Estrogen replacement for women past the age of 50 has been shown to help prevent osteoporosis and the fractures that may result from this condition. In one study, elderly women on estrogen replacement therapy demonstrated a lower risk of hip fractures when compared to similar women not on estrogen replacement therapy.

Fungal culture

Definition

Fungal (mycotic) cultures are microbiology laboratory tests to detect or rule out the presence of **fungi** (plural of fungus) in specimens taken from patients, animals, and the environment. The laboratory uses optimal conditions to grow and identify any fungus present in the specimen while attempting to eliminate or identify contaminants. The specimen is cultured by spreading a small portion of it on various agar media (inoculation). The media are then incubated in a warm, moist environment and examined regularly to detect growth of any organisms. The isolated fungus is identified primarily by its colony morphology and microscopic structures.

Mycology, the study of fungi

Fungi are simple plantlike organisms that do not have roots, stems, or leaves and that live off organic matter such as skin, hair, and vegetation. The group includes mushrooms, yeast, rusts, smuts, molds, and mildews, but only yeast and molds typically cause disease in humans. The basic structural unit of a fungus is either a single yeast cell, or multicellular filamentous hyphae, which are the tubular projections of molds. Molds grow by elongation and branching of hyphae during the vegetative (feeding) stage and produce spores during the reproductive stage. Spores are small reproductive bodies that are capable of sprouting new hyphae. Multiple, loosely intertwined hyphae strands called mycelia are the fluffy, colorful colonies seen as mold growing on rotting fruit. These mycelia are spore producing structures. Yeast primarily reproduce by budding, which is the out-pouching and eventual pinching off of part of the cell. A chain of budding yeast cells adhering together may appear to be like hyphae and are called pseudohyphae. Some fungi, capable of existing in either a yeast or filamentous mold form, depending on the environment, are called dimorphic. The term fungal elements includes any of the structures that may be seen during examination of specimens

or cultures: yeast, budding yeast, hyphae, pseudohyphae, spores, and mycelia.

Fungi differ from higher plants in that they do not contain chlorophyll and thus cannot manufacture their own **carbohydrates**. They must use preformed carbon and nitrogen compounds made by other organisms and are therefore either saprophytic (living on dead or decaying organic matter) or parasitic (living on or within other living organisms). Most fungi trace back to a soil origin. All are obligate aerobes (require oxygen to survive), and tend to thrive in a dark, moist, undisturbed atmosphere. They grow well at room temperature, but some of the pathogenic (disease causing) dimorphic fungi also grow well at body temperature.

Of the more than 50,000 species of fungi, only 100 to 150 species of yeast and molds cause disease in humans. The number routinely seen is much lower. Humans are generally resistant to fungi even when they become accidental hosts by inhaling spores or by having a cut or scrape exposed to a fungus. However, inhalation of spores of some of the dimorphic fungi produces illness ranging from mild cough and **fever** to severe disseminated disease. People with weakened immune systems (immunocompromised) are susceptible to illness from many normally harmless fungi. The characteristics of fungi that make them pathogenic to humans are:

- a small enough spore size to be able to reach the alveoli of the **lungs**
- the ability to grow at body temperature
- the ability of a dimorphic fungus to convert from a mold to a yeast form within the host
- toxin production

Purpose

The purpose of the fungal culture is to attempt to grow and identify any fungus originating from a patient's specimen when the medical staff of a hospital, clinic or doctor's office suspects fungal **infection**. Further, the goal is to determine whether the isolated fungus is clinically significant; that is, the causative agent of the patient's disease. While the physician makes the final decision regarding clinical significance, the laboratory may assist in this process by noting the presence of common contaminants, etc. Since the goal is also to provide information in a timely manner, fungal cultures will usually include smears and stains taken directly from the specimen for microscopic examination. The direct examination attempts to visually detect such fungal elements as hyphae, yeast, or spores.

Precautions

Contraindications

It should be noted that 90% of fungal infections are due to dermatophytes (fungi that infect skin, hair and nails), which do not normally need a fungal culture for diagnosis. A dermatologist can generally make the diagnosis in the office from a KOH preparation (see section on direct examination of specimens) along with the patient's symptoms and site of infection. However, a culture may be needed to prove that a skin condition is not due to nerves, psoriasis, or metabolic imbalances.

Another contraindication for fungal cultures is if the patient has already been treated with antifungal medication. Many patients who see their doctor for the first time with a possible fungal infection have already been treating themselves with such over-the-counter antifungal medication as imidazoles. A fungus may be causing an infection in the patient, yet antifungal agents present within the specimen suppress the growth of the organism in culture. All topical antifungal therapy should be stopped for at least one week prior to culture.

Safety precautions

The medical staff should observe their institution's procedures to protect both themselves and their patients from spread of infectious diseases. The use of such protective barriers as gloves, gowns, aprons, masks or protective eyewear can reduce the risk of exposure of the health care worker to potentially infective materials. All medical staff should take precautions to prevent injuries by needles, scalpels and other sharp instruments during procedures; when cleaning used instruments; and during disposal of used needles. Gloves should be changed after contact with each patient. Hands and other skin surfaces should be washed immediately after gloves are removed. When collecting **blood**, genital, tissue, cerebrospinal and other body fluid specimens universal cautions for the prevention of transmission of bloodborne pathogens should be followed.

Laboratory personnel need to take several precautions when working with fungal cultures. The cultures should never be sniffed. Fungus colonies may release airborne spores that can be inhaled. Processing of specimens and all work with exposed fungus cultures should be performed in a biological safety hood. Spattering of infectious material by careless flaming of wire needles or loops should be avoided. Cultured petri dishes should be sealed with oxygen-permeable tape. Test tubes should have screw-type caps rather than cotton plugs. All contaminated materials must be autoclaved before discarding, and the work area should be disinfected daily.

Description

The fungus culture is a microbiology laboratory test that is part of a comprehensive attempt to determine if any microorganism is causing an infection in a patient. The physician and nursing staff must first suspect the possibility of infection and order the appropriate cultures. The possibilities include testing not only for fungi, but also for aerobic and anaerobic **bacteria**; mycobacteria (also called acid-fast bacteria, AFB, a family of bacteria which includes the **tuberculosis** organism); **viruses**; or parasites. Many fungal infections are clinically similar to mycobacterial infections and so the same specimen is often cultured for both fungi and mycobacteria. Although fungal cultures are usually covered by insurance, they are costly and time-consuming. Cultures should be ordered only when the medical staff is reasonably suspicious of a fungal infection or when the patient is very ill and the culture is a critical part of assessing the illness. The test is also performed in the offices of dermatologists who frequently encounter fungal skin infections. The office staff may report the presence of dermatophytes or yeast, but a reference laboratory is usually required for specific identification.

Direct examination of specimens

The direct examination of specimens is an important first step in processing the specimen for several reasons. Since fungi take days to weeks to grow in culture on agar media, a direct examination result provides a rapid report to the physician, which may allow early treatment to begin. Sometimes easily identifiable morphological characteristics of a fungus may be seen on a direct exam, giving a clue as to the identification of the organism. This information may be helpful not only to the physician but also to the laboratory personnel who can set up additional specialized media to hasten the identification of the fungus. The information may also indicate the need to harvest specimens from other body sites and order serological tests. Direct examinations may also provide evidence of infection even when the fungus culture is negative.

KOH PREPARATION WITH CALCOFLUOR WHITE. The potassium hydroxide (KOH) preparation is used to detect fungal elements in virtually all types of clinical specimens, especially skin, nails, hair, sputum, concentrated urine, and tissue. A 10% to 20% solution of KOH is mixed with the specimen on a slide, a coverslip is placed on top of the preparation and the slide is gently heated. The preparation is then viewed under the 10x (low power) objective of a light **microscope** with fairly low illumination. KOH dissolves keratin and other cellular material but leaves the fungal structures intact and refractile. Hyphae, pseudohyphae, yeast, and spores can be seen. Calcofluor white, a fluorescent dye, may be added

to the KOH preparation to aid in visualizing the fungal elements. Calcofluor white binds to polysaccharides in the cell wall of fungi, and fluoresces either apple-green or blue-white, depending on the combination of filters used in a fluorescent microscope.

INDIA INK PREPARATION AND CRYPTOCOCCAL ANTIGEN TEST. Traditionally, India ink preparations have been used to examine cerebrospinal fluid (CSF) and other clear body fluids for the presence of the encapsulated yeast *Cryptococcus neoformans*. A drop of India ink is mixed with a drop of sediment from a centrifuged specimen and the preparation is examined under the light microscope. Budding yeast in CSF surrounded by a large clear capsule against a black background is presumptive evidence of *C. neoformans* **meningitis**. Since only 50% of these meningitis patients have at least one positive India ink preparation, many laboratories now use the latex agglutination test for cryptococcal antigen in place of the India ink examination. This test detects the capsular polysaccharide antigen of *C. neoformans* in the supernatant of centrifuged CSF and serum.

OTHER DIRECT PREPARATIONS. Stains used in other parts of the laboratory will detect fungal elements. The **gram stain**, which is performed on specimens sent for bacterial culture, will detect most fungi, if present. The acid-fast stain used for the detection of mycobacteria will also detect *Blastomyces dermatitidis*. The Papanicolaou stain, which is used to examine secretions for the presence of malignant cells, also stains fungal elements well. The Wright stain, which is used routinely on peripheral blood smears and bone marrow aspirates, will also detect *Histoplasma capsulatum* and *Cryptococcus neoformans*. Common tissue stains that are excellent for the detection of fungal elements are the periodic acid-Schiff (PAS) stain, the Gomori methenamine-silver nitrate (GMS) stain, and the Mayer mucicarmine stain. Fluorescent antibody stains can be used to detect fungi directly in tissue or fluids and stains for specific organisms are available at the national Centers for Disease Control (CDC) in Atlanta, Georgia. Molecular probes capable of detecting fungi in clinical specimens are promising but not yet commercially available.

Culturing specimens

As the direct examination of the specimen is proceeding, the specimen is set up as a culture without delay. The viability of fungi decreases with time, and contaminant overgrowth may hinder the recovery of the pathogen. When delay cannot be avoided, the specimens, with the exception of blood, CSF, and dermatological (skin, hair, nail) specimens, can be refrigerated for a short time. It is not necessary to concentrate most mycology

specimens except for body fluids over 5 milliliters, such as urine. If such respiratory secretions as sputum are highly viscous, mucolytic agents may be added to liquefy the secretions and facilitate plating on agar media. Tissue samples are ground with a mortar and pestle in a small amount of sterile saline before being inoculated onto media.

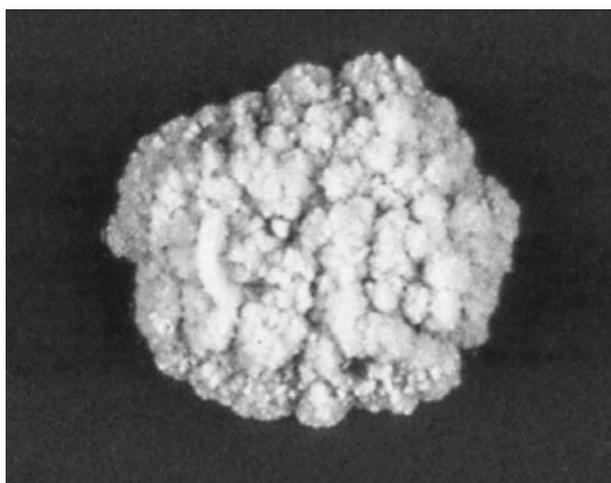

For optimal recovery of fungi, a battery of agar media should be inoculated. Common media for primary fungal isolation include Sabouraud dextrose agar and brain-heart infusion agar, either in petri dishes or screw-top tubes. The media may be enriched with 5% to 10% sheep blood to support the growth of certain fungi. Specimens that are likely to be contaminated with other microorganisms, such as urine or sputum, are set up on agar media containing antimicrobials. Chloramphenicol, streptomycin, or penicillin are incorporated into the agar to inhibit the growth of bacteria, and cycloheximide is used to inhibit the growth of contaminant fungi.

Fungus cultures are incubated at either at 30°C (86°F) or at room temperature (22-25°C or 72-77°F). A temperature of 30°C is recommended because nearly all pathogenic fungi grow better and more rapidly at this temperature. A relative humidity of 40% to 50% is desired to prevent the agar from drying out over time and can be achieved by placing an open pan of water in the incubator. Cultures should be incubated for 30 days and examined at least three times weekly before reporting as negative. Dermatophyte cultures should be incubated six weeks at room temperature.

Identification of positive cultures

The fungi grown in positive cultures are identified by noting their growth rate, colonial morphology, and microscopic structures. Rapid-growing fungi appear in one to three days, intermediate growers take five to nine days to colonize and slow growers take up to four weeks to appear. Colonial morphology traits include color, size, texture, and topography of the colony. Yeast colonies resemble bacterial colonies (moist, rounded, opaque and raised), whereas mold colonies are described variously as wrinkled, heaped, folded, etc. The pigments of both the underside and top of the colony are noted.

The examination of microscopic structures of fungi usually provides definitive identification for molds. Microscopic morphological features that are looked for are the type, size, shape and arrangement of spores and the size and color of hyphae. It is also important to note whether the hyphae have cross walls (septations). Yeast identification may require biochemical tests for fermentation and assimilation of carbohydrates.

Fungus culture topography. (Delmar Publishers, Inc. Reproduced by permission.)

Microscopic observation of molds is done by using several techniques, always prepared in a biological safety hood. Transparent tape preparations are a rapid method for observing the arrangement of spores. The tape is pressed, sticky side down, on the surface of a mold colony and then onto a slide containing a drop of dye-mounting fluid such as lactophenol cotton blue (LPCB). The preparation is then examined under low and high magnification on the microscope for spore type and arrangement. In a wet mount preparation, portions of colonies are teased apart with a dissecting needle, transferred to a drop of LPCB and observed under a coverslip on the microscope. Occasionally, a slide culture is needed to observe spore production. In this procedure, a small cube of agar media is inoculated on four sides with the fungus, placed between two coverslips and incubated five to ten days. When spores are evident, the coverslips are removed and mounted in LPCB and examined under the microscope.

Susceptibility testing

Susceptibility testing of fungal isolates to antifungal agents is generally done only after treatment failure. Testing is done by a reference microbiology laboratory using the minimal inhibitory concentration (MIC) method. Common antifungal agents include amphotericin B, griseofulvin, fluconazole, itraconazole, ketoconazole, miconazole, clotrimazole, flucytosine and nystatin.

Preparation

Specimen collection

The proper collection of appropriate specimens is critical to successful fungus cultures and diagnosis of

mycotic infections. The laboratory should be sent fresh specimens, properly obtained and labeled, of satisfactory volume, and accompanied by pertinent, critical patient information. All specimens for fungus culture should be transported to the microbiology laboratory and processed as soon as possible. Since many pathogenic fungi grow slowly, any delay in processing increases the possibility of overgrowth by rapidly growing contaminants and decreases the probability of isolating the causative agent. Although almost any tissue or body fluid can be submitted for fungal culture, the most common specimens are respiratory tract secretions, hair, skin, nails, tissue, blood, bone marrow, and CSF.

Direct microscopic examination of specimens for fungal elements should always be requested along with fungus culture. Specimens or cultures that need to be sent to a reference laboratory over a long distance should be sent by air-express service. Taped screw-top tubes must be placed in a container, then placed in a second container. The outside label must include a biohazard label.

Specimen types

Respiratory tract secretions including sputum, bronchial washings, and tracheal aspirates are the most common specimen types submitted for fungus cultures, as many fungal infections have a primary focus in the lungs. Patients ideally should provide sputum from a deep cough after rising in the morning. All respiratory specimens should be collected into sterile, leak-proof, screw-top containers.

Hair, skin, and nail scrapings submitted for dermatophyte culture are generally contaminated with bacteria and/or rapidly growing contaminant fungi. Skin and nails should be disinfected with 70% isopropanol before sampling. Skin samples are gently scraped from the outer edge of a surface lesion using a sterile scalpel. Nail specimens may be submitted as either scrapings or cuttings and occasionally as a complete nail. The best nail specimen is crumbly material from the nail bed. A sterile scalpel blade, small curette, or scissors is used to harvest the nail.

A Wood's lamp (ultraviolet radiation from a mercury-vapor source) can be used to detect infected hairs. Hairs infected with such fungi as *Microsporum* species and *Trichophyton schoenleinii* fluoresce when a Wood's lamp is shone on the scalp. Sterile forceps should be used to pluck the hair for culturing. These hair, skin, and nail specimens should be transported to the laboratory in sterile petri dishes, or screw top containers. A potassium hydroxide (KOH) wet mount should be requested. Specimens should not be refrigerated.

Blood cultures are helpful to detect disseminated fungal infections. Blood from patients that are septic (growing organisms in their blood) can harbor a wide variety of fungal pathogens as well as opportunistic saprophytes. Yeast are adequately recovered from any of several automated bacterial **blood culture** systems in use in microbiology laboratories, but filamentous fungi may require specialized techniques for isolation and fungal blood cultures should be specified. A lysis-centrifugation system may be employed which lyses red and white blood cells that may be harboring fungi. After lysis, centrifugation concentrates the organisms before culturing on fungal media.

Cerebrospinal fluid for fungal culture should ideally be of a volume of one to two milliliters or more. The specimen is transported to the lab immediately in a sterile, leak-proof tube. The second or third tubes collected in the lumbar puncture are preferred for any microbiology culture. An India-ink preparation and latex agglutination for cryptococcal antigen test should be requested along with fungal culture.

Other sterile body fluids, deep tissue samples and bone marrow aspirates should be collected by the physician in a sterile manner and transported to the lab in sterile syringes or screw-top tubes. A minimum of 0.5 milliliters of fluid is required, but any size tissue is acceptable. Bone marrow aspirates require sterile anticoagulant.

Urine to be cultured for fungus should be collected by the clean-catch, midstream (CCMS) void method into a sterile screw-top container. First-voided morning urine specimens are preferred, as they are more concentrated. Twenty-four-hour or quantitative urine samples are not acceptable for culturing.

Abscess fluids and wound drainage may be cultured for fungus. Actual tissue from the wound site will greatly increase the likelihood of recovering a fungal pathogen. Urogenital and fecal specimens may occasionally be sent for fungal culture but are generally screened only for yeast. Swabs are acceptable for these cultures, as well as for throats and **wounds**, but the medical staff should be aware that only yeast, no molds, would be isolated.

Aftercare

The care of patients after the collection of a specimen varies with the specimen type. Scrapings of skin or nails, plucking of hair, urine or stool collection and sputum production should involve little or no discomfort or subsequent care. Urogenital and throat swabs may be momentarily uncomfortable. Collection of some respiratory-type specimens such as **bronchoscopy** or bronchial

washes may result in coughing or hoarseness. The patient should be observed for hypoxia (low oxygen), bloody sputum or hemorrhage.

Following the sterile collection of blood for fungal cultures, firm pressure is applied to the draw site for a few minutes, followed by a bandage. Collection of bone marrow aspirates, deep tissue biopsies and sterile body fluids are invasive procedures performed by trained physicians observing sterile procedures. The patient should be monitored afterward to avoid hemorrhage at the site of aspiration or biopsy. Lumbar puncture for the collection of CSF requires special aftercare. The patient should lie prone for four to twelve hours to avoid headaches and the aspiration site is monitored for swelling or bleeding. Any of the invasive procedures may result in some normal aches for one to two days.

Complications

Complications for the patient whose specimen is being sent for fungus culture is dependent on the type of specimen being collected. Drawing of blood cultures can sometimes result in hematoma (bruising) at the draw site and should be done by a well-trained phlebotomist who is familiar with sterile drawing procedures. More invasive procedures such as tissue biopsy, aspiration of bone marrow and other body fluids may be complicated by hemorrhage or infection of the sampling site. Complications for lumbar puncture for CSF collection may include numbness, tingling or **pain** in the legs.

Results

Validity of results

Fungus cultures are fraught with false-positive and false-negative test results and the medical staff must interpret culture results in light of the patient's health status. Any direct microscopic examination may be falsely called negative, giving the physician and patient the early impression that no fungal infection exists. The false-negative direct examination may be due to examiner error through inexperience or lack of thoroughness. The portion of the specimen selected to be examined may have very few organisms, or the organisms may be missed amongst background debris in the smear. Likewise, a direct microscopic examination may be called falsely positive when an examiner misinterprets background artifacts as fungal elements in a preparation. This happens with the widely used KOH preparation and thorough training and experience is essential. A false-positive direct examination may cause antifungal treatment to be initiated unnecessarily.

It is important to be aware that falsely negative fungal cultures may result if the patient has already had anti-

KEY TERMS

Dermatophyte—A fungus that infects only epidermal tissues in which keratin is abundant: hair, skin and nails.

Dimorphic fungus—A fungus capable of existing in both a yeast and mold form, generally as a yeast at body temperature and mold at room temperature. Some dimorphic fungi cause disease in humans.

Fungal elements—Microscopic structures of fungi that may be observed in specimens or from positive cultures: yeast, budding yeast, hyphae, pseudohyphae, spores, mycelium.

Hyphae—Multicellular filaments or tubular projections composing the mycelium of a mold.

Mycelium—A mass of loosely intertwined hyphae extended out from a mold colony.

Mycosis—Any disease caused by a fungal infection.

Opportunistic pathogen—An organism that normally is present in the environment or as part of the normal flora of a host without causing disease, but which causes disease when the host becomes debilitated.

Pseudohyphae—chains of budding yeast that adhere together and appear to look like hyphae during microscopic examination.

Spore—A small, reproductive body of a fungus that is capable of sprouting new hyphae.

Yeast—A single-celled, rounded fungi that usually reproduce by budding.

fungal treatment. Inhibitory agents within the patient's tissues and specimens may suppress the growth of organisms in culture.

False positive cultures result when a fungus contaminates a culture. Certain species of fungi are known to routinely be contaminants of fungal cultures; thus a positive culture report should lead to a discussion between the patient's doctor and the microbiology laboratory or infectious disease specialists, if necessary. Repeating the culture is sometimes indicated.

Mycoses

The fungal diseases, or mycoses, have been categorized as superficial or cutaneous, subcutaneous, and sys-

temic, depending on the tissue or organs involved. The superficial or cutaneous mycoses involve the keratinized tissues of hair, skin, and nails without invasion of deeper tissue. The superficial types are mild, chronic infections of hair and the most superficial layer of the skin. In general they are of little medical consequence except for their cosmetic effect. Included in this group are conditions known as tinea and piedra. The cutaneous mycoses are sometimes referred to as the dermatomycoses, as they are caused by a group of fungi called dermatophytes. These fungi penetrate into epidermal tissue and include the agents of athlete's foot and ringworm. Dermatophytes belong to three genera: *Epidermophyton*, *Microsporum*, and *Trichophyton*.

The subcutaneous mycoses include a diverse group of infections that are characterized by the formation of a lesion at the inoculation site, often the result of injury. Generally, the fungus grows slowly in the subcutaneous tissues at the site, causing gradual spreading of the lesion, but does not disseminate to distant parts of the body. Examples of subcutaneous mycoses include chromoblastomycosis, mycetoma, and sporotrichosis.

The systemic mycoses are those fungal diseases involving the internal organs, often spreading from an initial lung infection. They may become widely disseminated and involve any organ system where they can produce abscesses and granulomas (inflammatory nodules). Prior to effective antifungal therapy, these disseminated mycoses were almost invariably fatal. Traditionally, this group included dimorphic fungi from the genera *Blastomyces*, *Histoplasma*, *Coccidioides* and *Paracoccidioides*, as well as the yeast *Cryptococcus*. Recently, *Penicillium marneffeii* has been added to this group.

Opportunistic pathogens comprise another category of mycosis, which is becoming increasingly common. Opportunistic infections are caused by organisms normally found in the environment, or as part of the normal body flora, which do not cause illness unless the host becomes debilitated. Opportunists cause infection in patients that are immunocompromised, either by underlying disease or such immunosuppressive agents as steroids or cytotoxic drugs. Examples of such opportunists are *Aspergillus* species, which are among the most ubiquitous molds in the human environment. These fungi may inadvertently cause infection in a hospital setting through such portals as dialysis bags, air conditioning ducts and airborne particles associated with construction. Another frequent opportunist is *Candida albicans*, a yeast commonly carried in the mouth, vagina and intestinal tracts of healthy humans. *C. albicans* is the causative agent of oral thrush, vaginal yeast infections and occasionally systemic disease.

In the last two decades there has been a striking increase in the incidence of opportunistic infections, not only because the number of immunocompromised patients, such as **AIDS** patients, is increasing, but also because some modern treatments permit the proliferation and invasion of vital organs by opportunistic molds and yeast. Such things as prolonged use of indwelling catheters, prosthetic **heart** valves, and immunosuppressive drugs for organ transplants have contributed to the increase.

Health care team roles

Members of the health care team play essential roles in the diagnosis of a fungal infection. Doctors and nurses must be aware of when to suspect an infection in general and fungal infections in particular. Signs of any infection include fever, chills, headache, loss of appetite, bad odor, persistent cough, localized pain, burning or bloody urination, **diarrhea**, pus or discharge from a wound or lesion, and elevated white blood cell count. The very young patient (less than one year), the very old, and the debilitated or immunocompromised patient are more susceptible to infection.

Predisposing factors for fungal infection include patients who have received broad-spectrum **antibiotics**, which eradicate the normal bacterial flora and allow fungi to overgrow. Steroid treatment decreases the body's normal protective inflammatory response to invading fungi. Cytotoxic drugs used during **cancer chemotherapy** suppress the **immune system** and make the patient more susceptible to fungi in their environment. Patients who have very low white blood cell counts (less than 1,000 cells per cubic millimeter), or such underlying disorders as **AIDS**, **pneumonia**, diarrhea, leukemia, hepatitis, or transplanted organs are more prone to fungal infections.

Skin conditions that may indicate fungal infection include scaling of skin, blisters of hands or feet, scaling of scalp with broken-off hairs, and discolored toenails or fingernails. Fungus infections of the cornea are more common in farm workers, contact lens wearers, topical steroid users, and those who have corneal injury due to such organic material as a tree branch.

Certain fungal infections are more common in particular areas of the world and the medical staff needs to be aware of what fungi are endemic (constantly present) in their area and also inquire about a patient's travel history. For example, *Histoplasma capsulatum*, the cause of histoplasmosis, is endemic in the Ohio and Mississippi River valleys of the United States.

The medical staff also has a critical role in selecting the appropriate specimen for fungus culture and should be knowledgeable about their institution's requirements

for collecting the specimen properly. See the Preparation section for proper specimen collection.

The mycology section of the microbiology laboratory has the important role of notifying the medical staff promptly of positive direct examination results as well as positive culture results. The cytology and surgical pathology laboratories must work closely with the microbiology laboratory as these former laboratories may detect fungal elements with their tissue stains.

The experienced microbiology technologist's knowledge of common fungal contaminants is invaluable to the doctor. A discussion between the doctor and the lab is often helpful in distinguishing between a contaminant and an opportunistic infection. Fungi that would have once been disregarded as contaminants on a culture are now known to be responsible for serious disease in debilitated hosts.

Fungi

Definition

Fungi are eukaryotic organisms (each containing a membrane-bound nucleus) that develop from reproductive bodies called spores. Fungi may be the cause of any

number of diseases in humans, animals, and plants; fungal infections are called mycoses (singular, mycosis).

Description

Mycology is the branch of science that studies organisms of the kingdom Fungi. Scientists estimate that over 200,000 species of fungus exist in nature. These species include yeasts, moulds, mildews, mushrooms, lichens, and smuts.

There are a number of characteristics that fungi share: they are eukaryotic (containing a nucleus that is bound by a nuclear membrane); they develop from reproductive bodies called spores; their cell walls are composed mostly of chitin, a nitrogen-containing carbohydrate; and they are heterotrophic (they cannot synthesize their own food and therefore absorb food from an external source through their cell walls).

Most fungi obtain their nutrients from dead organic matter and are called saprophytes. Saprophytes play an important ecological role in the decomposition of dead plants, animals, and other organic matter: they release large amounts of carbon dioxide into the atmosphere and recycle nitrogen and other important nutrients for use by plants and other organisms. Other fungi are parasites (obtaining their nutrients from a living host organism in a relationship that usually harms the host) or mutualists (involved in a mutually beneficial relationship with another organism).

Another important characteristic of fungi is that they do not contain chlorophyll. Chlorophyll is a green pigment that enables plants and such other photosynthetic organisms as algae and cyanobacteria to absorb energy from sunlight and use it to synthesize **carbohydrates** (photosynthesis). Because fungi are not reliant on sunlight as an energy source, they can grow in dark or low-light environments and in directions not normally observed in plants.

Morphology

Most fungi may be classified according to two major growth forms: yeasts or molds. Yeasts are round, unicellular (single-celled) organisms that form a vegetative body called a thallus. The thallus may consist of cells in groups or in branched chains called pseudo-hyphae. Examples of yeasts include *Saccharomyces cerevisiae*, used in making bread and alcoholic beverages; and *Candida albicans*, the causative agent of yeast infections.

Molds, on the other hand, are composed of long filaments called hyphae (singular, hypha). Hyphae may be further classified as septate (containing cross walls) or aseptate. A mass of hyphae is called a mycelium.

Oral candidiasis (thrush) in an infant, showing a white coating over the tongue. This infection is caused by a yeast-like fungus, usually *Candida albicans*. (Photograph by Dr. P. Marazzi. Science Source/Photo Researchers. Reproduced by permission.)

Whereas yeast cells each contain a single nucleus, cells in septate hyphae may be uninucleate (containing one nucleus), binucleate (containing two nuclei), or multinucleate (containing many nuclei). An example of a mold is *Penicillium roqueforti*, used to make blue cheese.

Some fungi are dimorphic: they may exist in either yeast or mold form. What form a fungus assumes depends on such environmental factors as the temperature or nutrients present. Some examples of dimorphic fungi include *Histoplasma capsulatum* and *Coccidioides immitis*.

Reproduction

All fungi can reproduce asexually by the production of single-celled structures called spores. The number of chromosomes (structures in the nucleus containing genetic material) remains unchanged when cells duplicate their genetic material and then divide. This is not the ideal state for a fungus and is thus called the imperfect state. (It is often observed in the laboratory when fungi that are normally pathogenic to humans are allowed to reproduce.)

Sexual reproduction can also occur in most fungi and is called the perfect state. In this process, one cell divides to become two haploid cells (each containing a single set of unpaired chromosomes). Two cells can then fuse together to become a diploid cell (containing a full set of chromosomes); that cell can then divide.

Role in human health

Some fungi have been found to be directly or indirectly beneficial to humans, while others are pathogenic

(disease-causing). Still others are pathogenic to plants and animals important in the food chain.

Food manufacturing

Different yeasts in the genus *Saccharomyces* are employed by bakers, brewers, and vintners to make their bread, beer, or wine. For instance, *S. cerevisiae* is commonly used as baker's yeast and in the production of ales. *Candida milleri* is a yeast used in conjunction with an acid-producing **bacteria** to yield sourdough bread.

Various species of mushrooms are cultivated specifically for human consumption. These include *Agaricus bisporus* (accounting for 38% of the world's cultivated mushroom supply), *Lentinus edodes* (shiitake mushrooms), *Volvariella volvacea* (the paddy straw mushroom), and the *Pleurotus* family (oyster mushrooms). Other edible fungi include truffles (fungi of the family *Tuber* that grow in a special subterranean (mycorrhizal) association with certain trees), morels (of the *Morchella* family), and the blue-green mold of the *Penicillium* family that is essential in the production of certain cheeses.

Medicinal and recreational drugs

Discovered in 1929, a metabolite of the fungus *Penicillium notatum* (later to be called penicillin) became the first antibiotic (a substance produced by a microorganism that can selectively treat an infectious disease). Other fungi that are the source of clinically important **antibiotics** include those in the family *Streptomyces*: *S. nodosus* (amphotericin B), *S. erythreus* (erythromycin), *S. fradiae* (neomycin), *S. griseus* (streptomycin), *S. orientalis* (vancomycin), and *S. rimosus* (tetracycline).

Some species of fungi are known as hallucinogens (substances inducing false sensations in the absence of true stimuli) and have been used by many cultures during religious ceremonies (for example, *Amanita muscaria*). *Claviceps purpurea* (the ergot fungus) and fungi of the *Psilocybe* family are also known for their hallucinogenic effects.

Biomedical research

Phycomyces blakesleeanus is a fungus that grows on animal feces in nature. The sporangiophores (the stalks on which spores are produced) of *Phycomyces* have been shown to respond to a variety of stimuli, including light, gravity, wind, and nearby objects. One important finding was that the light sensitivity of the sporangiophore is about the same as the eyes of humans. Furthermore, like humans, the sporangiophore can adapt to a one-billion-fold change in ambient light intensity.

Biologists have recently shown that *Neurospora crassa*, also known as red bread mold, can produce spores at approximately 24-hour intervals (known as a circadian rhythm) when in a constant environment. The fungus is therefore being used as a model organism for investigating circadian rhythms, which occur in many different organisms including humans.

Common disease and disorders

Human mycoses can be classified as superficial, cutaneous, subcutaneous, systemic, or opportunistic.

Superficial and cutaneous mycoses

These fungal infections do not invade underlying muscle or bone and are mostly restricted to the outer layers of the skin, nails, and/or hair. Superficial mycoses involve only the outermost layers of skin and result in a change in hair or skin pigment. For example, tinea nigra, caused by *Exophiala werneckii*, results in black lesions on the skin. *Piedraia hortai*, the causative agent of black piedra, creates hard dark-colored nodules on scalp hair, eyebrows, and/or eyelashes.

Cutaneous mycoses are generally caused by **infection** with a dermatophyte (a skin-infecting fungus). Common families of dermatophytes are *Epidermophyton*, *Microsporum*, and *Trichophyton*. Some of the more commonly seen cutaneous infections include:

- tinea corporis (body, “ringworm”)
- tinea capitis (scalp, eyebrows, eyelashes)
- tinea barbae (beard, “barber’s itch”)
- tinea cruris (groin, “jock itch”)
- tinea inguim (nails)
- tinea pedis (feet, “athlete’s foot”)

Subcutaneous mycoses

In the case of subcutaneous fungal infection, muscle, bone, connective tissue, and/or overlying skin may be involved. Subcutaneous mycoses may begin at the site of a laceration or even a seemingly innocuous scratch or puncture wound; fungi are introduced from soil or plant material. These mycoses, however, typically remain localized rather than spread from the site of infection. Sporotrichosis (caused by *Sporothrix schenckii*) and mycetoma (caused by *Madurella grisea*, among others) are two noted exceptions; sporotrichosis may spread along the **lymphatic system**, and mycetoma to deeper muscle and bone.

KEY TERMS

Cyanobacteria—Photosynthetic bacteria, commonly known as blue-green algae.

Dermatophyte—A fungus that can cause a skin infection.

Hypa—Cellular unit of the fungi; typically a branched and tubular filament.

Lichen—A fungus that grows a symbiotic relationship with algae.

Meningitis—Inflammation of the meninges, the membranes surrounding the brain and spinal cord.

Metabolite—A substance produced by way of a metabolic process.

Morphology—The study of the shape and structure of an organism.

Mutualism—Close relationship of two or more organisms, which typically involves exchange of food or other resources.

Mycorrhiza—Subterranean symbiotic relationship between a fungus and a plant root.

Septum—Wall that separates the cells of a fungal hypha into segments.

Systemic mycoses

Systemic fungal infections usually involve more than one type of body tissue. The **lungs** are often a site of primary infection when airborne spores are inhaled. Often the primary infection is asymptomatic (shows no signs of infection) or resolves quickly. If the fungus spreads to the bloodstream, however, it may disseminate to other organs or systems. The following are the most commonly seen systemic mycoses:

- Blastomycosis, caused by *Blastomyces dermatitidis*; begins as a pulmonary infection but may disseminate to bone and/or skin.
- Coccidioidomycosis, caused by *Coccidioides immitis*; begins as a pulmonary infection (although 60% of infections are asymptomatic) but may disseminate to the **central nervous system**, bone, and/or skin.
- Cryptococcosis, caused by *Cryptococcus neoformans*; begins as a pulmonary infection but may disseminate to the central nervous system to cause meningitis.

- Histoplasmosis, caused by *Histoplasma capsulatum*; begins as a pulmonary infection but may disseminate to the lymph nodes, spleen, and/or **liver**.
- Paracoccidioidomycosis, caused by *Paracoccidioides immitis*; begins as a pulmonary infection but may disseminate to the mucous membranes, lymph nodes, and/or skin.

Opportunistic mycoses

Opportunistic fungi do not normally cause disease in healthy humans, but can cause infection in individuals who are immunocompromised, such as those with acquired immune deficiency syndrome [AIDS] or those who have undergone organ transplantation. Some important opportunistic mycoses include:

- Aspergillosis, a mycosis caused by members of the *Aspergillus* family. Common mechanisms of infection include hypersensitivity (an allergic reaction); local pulmonary infection; opportunistic infection (leading to **pneumonia** and the development of a characteristic “fungal ball”); and systemic infection (leading to abscesses in the **brain**, liver, **kidneys**, skin, or bone).
- Candidiasis. *Candida albicans* is a yeast that causes oropharyngeal candidiasis, also known as thrush. Thrush is an often-seen opportunistic infection in patients with acquired immune deficiency syndrome

(AIDS). *Candida albicans* is also the cause of the majority of cases of vulvovaginitis (yeast infection).

Gait and balance assessment

Definition

Gait or walking is a coordinated action of the neuromuscular and musculoskeletal systems. The coordination of **muscle contraction**, joint movement, and sensory perception allows the human body to move in the environment. Individuals with neuromuscular and/or musculoskeletal involvement may have abnormal or inappropriate muscle activation, joint motion, or sensory perception. The result may be decreased mobility and function, and altered gait. Gait assessment is important to help identify areas of impairment. Once a reason for gait impairment is determined, a treatment plan can be developed. The goals of therapy are to minimize functional loss, restore mobility, and promote safety.

Balance is the ability to sit, stand, or walk safely without postural deviation, falling, or reaching for external items for support. Balance, like gait, is a coordinated response of the neuromuscular and musculoskeletal systems, as well as **vision** and sensory perception. Vestibular and cortico-cerebellar levels in the **brain** are also involved in maintaining stability. Balance assessment is used to evaluate the patient's ability to maintain appropriate posture during functional activities. It is usually evaluated statically and dynamically.

Purpose

The goal of gait assessment is to evaluate walking in an effort to isolate dysfunction. Areas of impairment may include muscle weakness, loss of joint range, incoordination, or poor postural control.

During balance assessment, a patient's stability during activities is evaluated to identify areas of impairment, the reason for impairment, and the effect on function.

Both gait and balance evaluations are useful in identifying areas of impairment so that safe and proficient function and mobility can be restored.

Precautions

During gait and balance assessment, individuals with impairment are at risk for further injury, especially from **falls**. Clinicians who evaluate patients with suspected gait and balance deficits must provide close supervision and ensure that the testing areas are safe.

Description

Gait can be analyzed with a variety of techniques, involving a range of difficulty. One basic method is simply watching the patient walk and interact in the environment, noting any deviations or instability. More advanced techniques use motion analysis, force platform data, and **electromyography** in an effort to gain a global representation of joint motions, joint forces, and electrical activity of muscles during walking.

Balance is very complex and requires many systems to work at optimum levels. A problem or injury affecting strength, joint motion, vision, sensory perception, or vestibular apparatus may lead to functional impairment. Balance needs to be evaluated both statically and dynamically, and if a deficit is present, further testing is indicated.

Preparation

In a simple gait analysis, the patient is observed during standing (static testing) and walking (dynamic testing). Initially, the patient is examined in the standing position to evaluate posture as well as bone and soft tissue symmetry. The clinician evaluates the foot and ankle during standing to assess any deviation in the rear foot and forefoot. The patient is then asked to walk across the floor while the clinician evaluates the gait cycle. The clinician assesses joint range of motion, speed, and quality

KEY TERMS

Berg balance scale—An assessment tool used to evaluate stability during functional activities. The patient is scored on 14 different tasks.

Cortico-cerebellar—Pertaining to the cerebellum and the cerebral cortex of the brain.

Dynamic—Movement such as walking that is due to muscles contracting.

Electromyography—An evaluation tool that detects electrical activity of muscles.

Force platform—A large plate, usually mounted in the floor, that records forces when an individual stands or walks on it.

Forefoot—The front portion of the foot from the ankle.

Functional reach test—A test that evaluates stability when reaching out beyond an individual's base of support. In this test the patient stands and tries to reach out with one hand as far as possible without losing balance. The reach is recorded in inches.

Get-up-and-go test—Evaluates balance during a functional activity. The test is scored based on the patient's ability to get up from a chair, walk forward about 10 feet (3 m), return to the chair and sit down. The test may be timed to monitor progress.

Motion analysis—Use of an instrumented system to record whole body and joint movement for later analysis.

Musculoskeletal system—Pertaining to the muscle and skeletal systems.

Neuromuscular—Pertaining to the nervous and muscle systems.

Normative—A group that is free from dysfunction compared to a group that has dysfunction. For example, in groups with and without knee osteoarthritis, the group without the osteoarthritis is the normative group.

Proprioception—The ability to sense movement and position of the body.

Rear foot—The back portion of the foot that includes the ankle and heel.

Sensory perception—The ability to perceive touch, pressure, pain, and joint position in the limbs and trunk.

Static—Without movement, i.e. standing still, with or without muscle contraction.

Tinetti balance test—A battery of tests to assess balance and identify individuals at risk for falling.

Vestibular—Pertaining to the apparatus in the inner ear that senses orientation and movement of the body in space.

of gait, and synchrony of all upper and lower extremity joints. The patient should be evaluated walking barefoot as well as while wearing normal walking shoes. The clinician should observe walking from the back, front, and side. In more complex gait assessments, videography is used to record patient movement and joint motion, and force plates and electromyography provide additional information. Unfortunately, the equipment used in complex analyses is expensive and thus cost-prohibitive to the average clinician. However, there are gait laboratories that have equipment specializing in instrumented gait analysis.

Various tests are used for balance assessment. Certain tests are specific to visual, cerebellar, muscular, or proprioceptive areas. Sensory integration tests and the Romberg test are used to try to isolate involvement of vision, sensation, and cerebellar integrity. Other tests commonly used are the Berg balance scale, the get-up-

and-go test, the functional reach test, and the Tinetti balance tests. These tests provide quantitative data that allow the clinician to compare individual results with a normative group and document progress over time.

Aftercare

The treatment of an individual with a gait abnormality may include stretching, strengthening, joint mobilization, splinting or bracing, education, or a change in footwear. The treatment of an individual with a balance deficit may include stretching, strengthening, postural awareness exercises, various weight-shifting exercises, and increasing environmental stimuli in an effort to retrain proprioception. Treatment is individualized according to a patient's problem. For example, strengthening exercises are recommended for an identified muscle weakness.

Complications

A major concern is safety during a gait or balance assessment. If impaired balance or gait abnormalities increase the likelihood of falling, appropriate measures need to be taken, such as clear and safe pathways, adequate lighting, and good guarding techniques by staff members.

Results

Gait or balance assessments are usually recommended for a decline in function, self-reported loss of balance, or unexplained falls. The patient may be fearful of falling, and restoring confidence often needs to be addressed. Ideally, areas of impairment are identified during the assessment so that appropriate treatments can be directed at the problem.

Health care team roles

Nursing and other allied health professionals in hospitals, outpatient clinics, diagnostic centers, skilled nursing facilities, and assisted living facilities need to be aware of their patients' gait, posture, and general mobility. When a patient is using an assistive device inappropriately, or gait and balance appear to have changed, it is the health care provider's role to address the problem to minimize the risk of falls. A request for further evaluation, such as a gait or balance assessment, may be an appropriate next step.

Mark Damian Rossi, Ph.D, P.T., C.S.C.S.

one's center of gravity (COG) over the base of support (BOS) in static or dynamic tasks and environments.

Description

Any number of factors may contribute to gait and balance problems. Postural control, the task that involves controlling one's position in space, involves maintaining a relationship among the body, the task at hand, and the given environment. Difficulty in maintaining an appropriate relationship may occur due to:

- impaired sensory processes (visual, vestibular, somatosensory)
- inadequate neuromuscular responses (signaling of **brain** to/from muscle)
- musculoskeletal problems (impaired range of motion, strength, flexibility)
- decreased cognition (inability to anticipate or adapt to postural needs)

Due to the wide variety of factors, many individuals can be affected with gait and balance problems at some point in their lives. Inability of peripheral sensory receptors to gain information about the environment results in the inability to use that information for postural control. This type of loss may occur in people who have visual, vestibular, or somatosensory deficits not based in the **central nervous system** (CNS). Examples include, but are not limited to, diabetic retinopathy, **cataracts**, **glaucoma**, temporal bone fracture, acoustic neuroma, Ménière's disease, **spinal cord injury**, peripheral neuropathy, and amputation.

The CNS is responsible for integrating the environmental information that is supplied through peripheral sensory receptors; this is called sensory processing. Motor planning, on the other hand, is an individual's ability to plan movement to accomplish a task. Individuals who have experienced injury to the CNS in the form of a stroke, brain trauma, or disease process like **multiple sclerosis**, Parkinson's or cerebellar ataxia, may exhibit gait and balance problems due to difficulty with sensory processing and/or motor planning.

Musculoskeletal problems, whether orthopedic or neurologic in origin, can contribute to balance and gait difficulties because certain levels of mobility and strength are required to execute movements within functional parameters. Automatic postural strategies, such as an ankle or hip strategy, operate to keep the body over the center of gravity when a disturbance to balance is presented. The larger the disturbance is, the more intense the response. If there is inadequate range of motion at the

Gait and balance problems

Definition

Gait and balance problems exist when a disease process, trauma, or aging result in the inability to control

A balance machine is used in the assessment of balance problems. (Photograph by Will & Deni McIntyre. *Science Source/Photo Researchers. Reproduced by permission.*)

ankle, or weakness in hip musculature, these strategies cannot be adequately used.

Impaired cognition is an important contributor to balance and gait problems. Poor attention, decreased judgment and slow processing can increase risk of loss of balance. Without awareness of environmental hazards and necessary safety precautions, patients who have had a stroke or brain trauma have an increased propensity to fall.

Causes and symptoms

Cerebellar lesions

Cerebellar lesions are one cause of disturbed balance. Depending upon the area affected, the disturbance may be slight or severe. The cerebellum also contains proprioceptive feedback loops, in addition to receiving input from the **spinal cord**. When these areas are affected, the postural changes that take place affect balance. It

is very common to find gait problems in conjunction with cerebellar lesions; in one study, 60% of patients with cerebellar problems displayed ataxic gait, which resembles intoxicated gait.

Basal ganglia dysfunction

The basal ganglia are three nuclei at the base of the cerebral cortex. It appears that the basal ganglia play a large role in preparing an individual for motion. This may include preparing the cortex, setting postural **reflexes**, and organizing sensory input. When there is dysfunction in this area, such as in Parkinson's or Huntington's disease, disturbances in central sensory processing, along with rigidity and akinesia (inability to move), contribute to postural instability and gait difficulties.

Hemiplegia

Hemiplegia (**paralysis** of one side of the body) as a result of a **cerebrovascular accident**, or stroke, is also a common cause of balance and gait difficulties. Loss of trunk control results in the inability to maintain weight evenly over the pelvis. In the early stages of recovery, along with upper extremity dysfunction, lower extremity positioning in standing may be marked by pelvic depression, hip and knee flexion (decreasing the angle of the joints), and ankle plantarflexion on the affected side. Later, extensor patterns (increasing the angle of the joints) become more available, and the pelvis may be elevated, with the knee hyperextended and ankle plantarflexed. Sensory loss may manifest itself in many ways, from loss of discrimination and localization to complete neglect of the affected side. All of these factors contribute to balance and gait problems due to inadequate sensory processing, musculoskeletal tightness or weakness, and/or cognitive deficits.

Vestibular hypofunction

While problems with central processing of vestibular input can create balance and gait difficulties in individuals with CNS problems, peripheral vestibular hypofunction (the under-functioning of inner ear structures associated with balance) also is a common contributor to balance deficits. Peripheral vestibular hypofunction may result from temporal bone fracture, acoustic neuroma, ototoxicity (damage to the eighth cranial nerve due to aminoglycoside **antibiotics**), or unknown causes. One or both sides may be damaged, resulting in dizziness and vertigo that lead to decreased balance.

Although these are some of the main pathologies that are known to cause balance and gait problems, any disease process or trauma resulting in impairments of sensory processing, neuromuscular response, muscu-

loskeletal function, or cognition can result in balance and gait disturbances. Due to changes that take place in the proprioceptive (self-awareness of movement) and vestibular systems, even normal aging has an effect on balance and gait.

Diagnosis

The pathologies that underlie gait and balance problems are diagnosed by physicians using a variety of methods, including signs and symptoms, diagnosis of exclusion, imaging, etc. Discussion of specific diagnostic criteria for each disease process that could contribute to a balance disorder is beyond the scope of this entry.

A **physical therapy** diagnosis of decreased balance or abnormal gait is made based on a thorough examination that includes a patient history and systems review. In addition, tests and measures may be used to assess any or all of the following possible contributors to balance and gait disturbances: aerobic endurance, cognitive status, cranial and peripheral nerve integrity, assistive devices, muscle strength, range of motion, posture, reflexes, sensory integrity, and functional abilities. Balance, gait, and locomotion may be tested in a variety of ways, which usually include observation or video analysis of quiet standing, active standing, or functional activities. In some clinical tests such as the Clinical Test for Sensory Interaction on Balance, the physical therapist will purposefully manipulate the environment to change one component of sensory feedback (e.g., the patient stands on foam to challenge the somatosensory system). In some cases, the physical therapist manipulates the individual (e.g., the Hallpike-Dix maneuver). Other tests include a variety of functional skills that must be completed. A large number of balance tests exist; the key is choosing the right one. It is important to understand the purpose of a test before using it and to match that purpose with the impairments and goals of the patient or client being tested. For example, a test that measures stability in quiet standing may be appropriate for a patient who is recovering from a stroke, but not so appropriate for an athlete training to return to professional sports.

Treatment

Medical and surgical management of pathologies underlying balance and gait disturbances includes, but is not limited to, the following:

- levo-dihydroxy-phenylalanine (L-dopa) and/or amantadine for Parkinson's disease
- surgery to alter connectivity in the basal ganglia in Parkinson's
- dopamine antagonists in Huntington's chorea

- anti-spasticity medication (diazepam, baclofen, dantrolene) for patients who have had a stroke, **head injury** or other neurological insult
- particle repositioning maneuvers for benign paroxysmal positional vertigo (dizziness)
- surgery for Ménière's disease or acoustic neuroma (a tumor in the auditory canal)

These interventions can help to decrease the contributors to balance and gait disorders such as dyskinesia (impaired ability to move voluntarily), rigidity, hypertonicity (diminished muscle tone), or vertigo. Balance and gait, however, often must be retrained using physical therapy. Successful treatment intervention based on theories of motor learning addresses the interactions of the individual, task and environment. In the individual, it is important to recognize what impairments contribute to difficulties, and whether or not they can be realistically corrected or if compensation will be necessary. The patient must be evaluated for cognitive ability to relearn balance skills, and for the level he or she is at in learning a skill (acquisition, refinement, or retention/transfer). In evaluating a task, the clinician must determine what is predominantly required—mobility, stability or both—and the timing, force and duration needed. The environment also must be analyzed and manipulated to best aid the patient in preparing for function in the real world.

Treatments may involve the manipulation of sensory input while performing a task. This may be done for any of the three systems responsible for providing sensory feedback. For example, to encourage use of vestibular input, visual and somatosensory information may be challenged. Visual input is challenged by taking it away (e.g., eyes closed) or by destabilization (e.g., involving head and eye movements in the task). Unstable surfaces (e.g., rocker board or rough terrain) or compliant surfaces (e.g., foam) help to challenge somatosensory input. Vestibular input may be manipulated by changing the position of the vestibular organ (e.g., neck extension or repeated head movements).

Other physical therapy treatment for balance and gait focuses on the patient's ability to control his or her COG over the BOS. Exercises related to functional activities are performed and progressed according to patient ability. Initially, treatment may begin with practicing the ability to establish static balance in a position with a wide BOS, such as sitting and using hands for support. Eventually, the BOS is narrowed and/or destabilized to train automatic, anticipatory and voluntary postural responses. This type of progression can take place in sitting, standing, walking, etc., with or without the addition of such concurrent tasks as putting on a shoe while sitting or reading signs on a wall while walking. Specific bal-

KEY TERMS

Ankle strategy—An automatic posture response in which the body moves as a unit over the feet to control postural sway.

Base of support—The location on a body or object where most of the weight is supported.

Center of gravity—The center of weight in a body or object.

Hip strategy—An automatic posture response in which control comes from the pelvis and trunk.

Posturography—The study of posture and its effects on health.

Somatosensory system—The components of the central and peripheral nervous systems that process information about the muscles, pain, temperature, pressure and joint position.

Vestibular system—Interaction among the inner ear structures associated with balance and position sense, and the central nervous system.

Visual system—Components that transmit information from the retina to the brain.

ance training on a force plate designed to provide visual feedback about a patient's COG has not been shown to be convincingly more effective than conventional physical therapy in adults with hemiplegia. This may be due to the fact that weight shifting on a force plate may not carry over to such higher-level tasks as walking.

Prognosis

Prognosis depends on the cause of pathology, level of impairment, and such other factors as comorbidity. The basal ganglia disorders are progressive; therefore, while medical and physical therapy management may be effective in slowing the decline of function and training compensatory strategies, the overall prognosis is fair at best. Cerebellar lesions or cerebral stroke may allow for slight to significant return to function, depending upon the extent of the damage to the brain tissues. In a study on gait recovery following stroke, prognostic indicators included the ability to weight shift immediately post-stroke; and later in recovery, affected knee extension strength. In true orthopedic cases with no neurological involvement, recovery may be less complicated if it depends purely on restoration of range of motion or strength to a musculoskeletal structure.

Health care team roles

Upon diagnosis of pathology by a physician and referral of an individual to physical therapy, the physical therapist is responsible for examination, evaluation, diagnosis, prognosis, and intervention.

Examination

The examination includes a patient history and systems review of cardiovascular, pulmonary, integumentary, musculoskeletal, neuromuscular and/or cognitive status. Physical therapists also use a wide variety of tests and measures to determine extent of impairment and functional limitations. Some of the more common balance tests used include: Romberg, Functional Reach, Clinical Test for Sensory Interaction on Balance, Berg Balance Scale, Get Up and Go, Tinetti Performance Oriented Assessments of Balance and Gait, Fugl-Meyer Sensorimotor Assessment of Balance Performance, Functional Obstacle Course, and posturography. These tests assess tasks ranging from quiet and active standing to the ability to maneuver an obstacle course of different floor surfaces, obstacles and stairs.

Evaluation, diagnosis and prognosis

The therapist must use his or her clinical judgment and expertise to establish a physical therapy diagnosis and prognosis, including the plan of care. The diagnosis indicates the primary dysfunction(s) toward which intervention will be directed. The prognosis and plan of care must encompass many factors such as current level of function, comorbidity, familial and social considerations and overall health.

Intervention

Intervention includes treatment of any impairments that hinder function, as described in the treatment section above. In addition, **patient education** is of utmost importance. Education may include information regarding: the prognosis and plan of care, specific exercises to perform outside of therapy sessions, fall and injury prevention, compensatory strategies, assistive or adaptive device recommendations and usage, and social/community resources.

Prevention

Gait and balance problems, as discussed earlier, are usually impairments resulting from a pathological process. In some cases, such as in Parkinson's or multiple sclerosis, intentional prevention of pathology is difficult because its causes are not completely understood. Some causes, however, may be modified. For example,

high cholesterol levels contribute to risk of thrombi. Some medications may cause peripheral vestibular damage or dizziness. Reduced range of motion, decreased strength, and inactivity in the elderly can lead to balance and gait problems. Safety education, environmental adaptations, strengthening, flexibility and balance exercises, **gait training**, good shoes, orthotics, and assistive devices are all key factors in prevention of **falls** due to balance and gait problems.

Gait training

Definition

Gait training refers to helping a patient relearn to walk safely and efficiently. Gait training is usually done by rehabilitation specialists who evaluate the abnormalities in the person's gait and employ such treatments as strengthening and balance training to improve stability and body perception as these pertain to the patient's environment. Gait training often incorporates the use of such assistive devices as parallel bars, walkers or canes to promote safe and proficient ambulation. In order to walk again without assistance, the patient will need mental attentiveness and adequate sensation, coordinated with adequate musculoskeletal functioning and motor control.

Purpose

A person's gait is a pattern of stepping or walking that is specific to that individual. Gait training is needed to help a specific patient gain proficient and safe ambulation within and outside the home with or without an assistive device. Patients usually require gait training if there is some lower trunk or lower limb dysfunction. This dysfunction is often associated with neurological or orthopedic impairment. Complications that may require gait training include:

- muscle weakness
- deformity
- spasticity (the presence of abnormal involuntary muscular contractions)
- loss of sensation due to injury or disease that results in inaccurate sensory information and unsafe or inefficient motion
- **pain** in the weight-bearing joints of the lower extremities, which causes distortion of normal gait

These complications may result from injury to or amputation of the lower extremities; surgery; **osteoarthritis** or other disorders of the weight-bearing joints; **muscular dystrophy**; muscle atrophy due to long periods of inactivity or bed rest; lesions of the **brain** or **spinal cord**; or changes in perception and other body functions that are part of the aging process.

Normal gait

In order to understand gait training, the reader may find a descriptive outline of normal human gait helpful. Human gait is measured from heel strike to heel strike, also known as the gait cycle or "one stride." The gait cycle has two phases, the stance (about 60% of the cycle)

KEY TERMS

Ataxia—Loss of muscular coordination.

Cadence—The rhythm of a person's walk.

Double stance—The point in the gait cycle at which both feet are touching the ground. It is also sometimes called double support time.

Gait—A person's habitual pattern of walking or stepping.

Gait cycle—A unit of measurement used in evaluation of gait abnormalities. The gait cycle consists of two phases, stance and swing, and is measured from heel strike to heel strike (the length of one stride).

Gait velocity—The speed of a person's walk.

Muscular dystrophy—An inherited disease characterized by progressive wasting of the muscles.

Osteoarthritis—A degenerative joint disease that causes inflammation and pain in the peripheral and spinal joints.

Spasticity—A condition marked by sudden abnormal involuntary muscle contractions, with associated hyperactivity of deep tendon reflexes. It may be associated with rigidity.

and the swing (about 40%). The point at which the body's weight is transferred from one foot to the other, when both feet are touching the ground, is called double stance or double support time. The speed of a person's walk is called the gait velocity, and the rhythm of their walk is called the cadence. Cadence is usually related to the length of the person's leg and their overall height; short people typically take smaller steps at a more rapid cadence while taller people take larger steps at a slower cadence.

Deviations in gait

Deviations from normal gait can occur in any portion of the lower extremity. Common abnormalities include:

- Ankle/foot. Deviations of stance include foot slap and foot flat. Deviations of swing include toe drag (foot drop).
- Knee. Abnormalities of stance include hyperextension of the knee. Abnormalities of swing include limited flexion of the knee.

- Hip. Deviations of swing include circumduction and "hip hiking."
- Trunk. Deviations of stance include lateral lean (Trendelenberg gait), backward lean (gluteus maximus gait), and forward lean.
- Other. Ataxia (loss of muscular coordination) and antalgia (limping from pain).

Deviations can occur together as a group of compensations for one impairment. For example, a patient's gait may show foot drop as well as hip hiking.

Precautions

Before gait training the clinician must review all **medical records** and examine any pathologies or impairments that may affect the patient's ability to walk. Furthermore, through the rehabilitation evaluation, the clinician should have an understanding of the patient's present abilities and prior level of function. Once gait training begins, the clinician must choose the appropriate assistive device that will provide optimal stability and still allow the patient mobility.

The therapist should use a gait belt or similar device to help support the patient if he or she loses balance. Gait training should be done in a safe environment with few visual distractions, and with the patient wearing appropriate footwear. Some rehabilitation specialists have designed mechanical gait trainers with parachute harness systems that allow patients to practice their gait without overstraining the therapist.

Preparation

Patient assessment

In determining the patient's readiness for gait training, the therapist will evaluate the patient's physical abilities (weight-bearing, strength, stability, coordination and balance) and his or her mental and emotional readiness for gait training. Routine evaluation of elderly patients who are beginning to develop gait problems may be done by a primary care physician, but assessment of complex disorders usually requires a gait specialist. A simple evaluation of a patient's gait can be performed in a straight hallway without pictures or other objects that may distract the eye. The examiner will need a stopwatch for timing and a T-square to measure the length of the patient's stride. Advanced evaluation of gait kinetics, however, requires a laboratory with computer and video technology.

Assistive devices

Patients with gait problems caused by pain in the lower extremities; decreased ability to bear weight; or

loss of strength, balance, endurance, or coordination may use a range of assistive devices as part of their gait training. The physical therapist will take into account the patient's prognosis, home or institutional environment, capacity for standing, and the demands of the device itself in selecting an appropriate assistive device.

The most stable assistive device is a set of parallel bars, followed in descending order of stability by walkers, crutches, single crutches, bilateral canes, and single canes. In terms of the demands that assistive devices place on the patient's coordination, parallel bars are the least demanding, followed in ascending order by walkers, single canes, bilateral canes, axillary (under the armpit) crutches, and forearm crutches.

Choosing a device and gait pattern

The therapist must consider not only the type of assistive device most appropriate to the patient's needs, but also the gait pattern (pattern of the patient's movement) that will be most helpful. For example, a walker can be used with either a swinging or a stepping-through-and-rolling motion. Crutches can be used with either a reciprocating (uses both lower extremities) or nonreciprocating (favors the weight-bearing lower extremity). A so-called four-point gait will be used with a cane or single crutch. In this pattern the crutch or cane advances forward first, followed by the opposite lower extremity, then the other limb, all in a reciprocal pattern. In a three-point gait, one lower extremity is full weight-bearing and the other is non-weight-bearing. An example of a three-point gait would be a patient with bilateral crutches, with one limb lifted and one in contact with the ground. A two-point gait is a pattern in which the patient's assistive device is a cane or single crutch that moves simultaneously with the opposite lower limb. The progression of various gait patterns from use of assistive devices to full independence depends on the type of impairment as well as the patient's mental and physical abilities; it also depends to some extent on the experience of the clinician.

Once selected, the assistive device is fitted to accommodate the patient's height and weight. The cost varies: while a standard cane costs about \$25 and a quad cane about \$50, crutches cost between \$65 and \$110, with walkers costing between \$80 and \$150. Most health insurance policies, however, cover assistive devices.

Patient education

After the assistive device has been selected and fitted to the patient, the therapist demonstrates the appropriate gait pattern, including weight-bearing; shows the patient how to check the assistive device for safety and points of wear; teaches the patient how to move from a

sitting to a standing position; helps the patient practice the gait pattern; and shows the patient how to move from a standing to a sitting position.

The next stage in training involves learning the gait pattern on different types of surface. The patient must know how to use the assistive device on uneven surfaces, curbs, and stairs as well as level surfaces. In stair gait training, the patient is taught a basic rule regarding the affected and unaffected sides of his or her body: "Up with the good, down with the bad; the device stays below."

Aftercare

Aftercare for gait training includes helping patients cope with the various disadvantages of assistive devices. Crutches and walkers, for example, are difficult to use in small or crowded areas. In addition, walkers offer little or no protection from backward **falls**. The use of axillary crutches may place too much pressure on the patient's underarm area. Quad canes are hard to use on stairs and may be unstable on some surfaces, since the patient must have all four cane legs down on the floor or pavement with hand pressure centered over the legs.

Results

The results of gait training vary according to the cause of the patient's gait abnormalities, his or her overall health and mental attitude, and the prognosis. Some patients may be able to walk again without assistive devices, while others may make only limited progress. The importance of encouraging physical activity, however, cannot be overemphasized. Even modest amounts of **exercise** help to prevent muscle atrophy, benefit the **cardiovascular system**, and may lessen the pain of osteoarthritis. In addition, most gait training patients find that a greater degree of physical independence is good for their spirits as well as their bodies.

Health care team roles

In addition to the roles of physicians and rehabilitation specialists in patient assessment and gait training, nurses and other allied health professionals should monitor the walking patterns of their patients and any use or misuse of assistive devices. Gerontologists should routinely assess elderly patients for changes in gait velocity, cadence, step length, or other indications of fears of falling. Furthermore, nurses and other allied health professionals should monitor all patients for changes in ambulation in an effort to maximize their safety.

Gallbladder

Definition

The gallbladder, an organ of the gastrointestinal system involved in the storage and concentration of bile, is shaped like a deflated balloon or pear, and lies on the surface of the right lobe of the **liver**.

Description

The gallbladder is pear-shaped and generally about 3–4 in (7.6–10.2 cm) in length. It consists of three parts. The fundus is the closed, bottom portion of the gallbladder that borders the liver. The body is the largest section of the gallbladder. In adults, the gallbladder can hold between 0.67 and 1.69 fl oz (20–50 ml) of bile. The neck of the gallbladder is much narrower than the body and empties into the cystic duct.

A close-up view of an inflamed gallbladder. (Custom Medical Stock Photo. Reproduced by permission.)

Function

The gallbladder acts like a storage tank for bile (a bitter, greenish yellow liquid composed in part of cholesterol, bile salts, and bile pigment). Bile is made in the liver and travels through the hepatic duct to be stored and concentrated in the gallbladder until the body needs it to help break down ingested **fats**. When the gallbladder receives a signal from cholecystokinin (a hormone) in the **small intestine**, it contracts and releases bile into the common bile duct, where it travels to the small intestine to help digest fats.

Role in human health

While the body can function normally without a gallbladder, this accessory organ of digestion is important to the proper digestion of fats.

Common diseases and disorders

One of the most common disorders of the gallbladder occurs when cholesterol mixes with bile and **calcium**, forming gallstones. Gallstones occur most frequently in middle-aged women, but they can also occur in people suffering from **obesity**, diabetes, hyperthyroidism, or any other disease that results in increased levels of cholesterol. When the stones stay in the body of the gallbladder they generally cause no **pain** or other symptoms. However, if a stone travels out into the neck of the gallbladder or into one of the bile ducts, nausea, vomiting, and severe pain follow. The patient may also become jaundiced. Gallstones usually have to be removed surgically. In severe cases, the entire gallbladder must be removed.

Other diseases can also cause obstruction of the neck of the gallbladder, causing symptoms like those of gall-

KEY TERMS

Adenocarcinoma—Any one of a large group of cancerous, epithelial cell tumors of the glands.

Biliary tree—Also referred to as biliary tract, it includes all of the parts associated with the passage of bile, beginning at the liver and ending at the opening of the bile duct into the small intestine.

Cholecystitis—Acute or chronic inflammation of the gallbladder.

Cholecystokinin—The hormone manufactured in the lining of the small intestine that signals the gallbladder to release bile.

Cystic duct—The duct that allows passage of bile from the gallbladder to the common bile duct.

stones. **Crohn's disease**, **pancreatitis** (inflammation of the **pancreas**), echinococcosis (infestation of the **digestive system** by tapeworms), and ascariasis (infestation of the digestive system by parasitic nematode worms) can all produce swellings that obstruct the gallbladder's neck.

Cholecystitis, or inflammation of the gallbladder, causes sharp, severe pain in the upper right portion of the abdomen. Cholecystitis causes **fever**, nausea, and vomiting; and, if left untreated, can be life-threatening.

Cancer that invades any portion of the biliary tree can interrupt or prevent the normal flow of bile and result in multiple complications. Two of the most common malignancies that occur in the biliary tract involve adenocarcinoma of the gallbladder itself or of the bile ducts that carry bile from the gallbladder.

Gallbladder ultrasound *see* **Abdominal ultrasound**

Gallbladder x rays

Definition

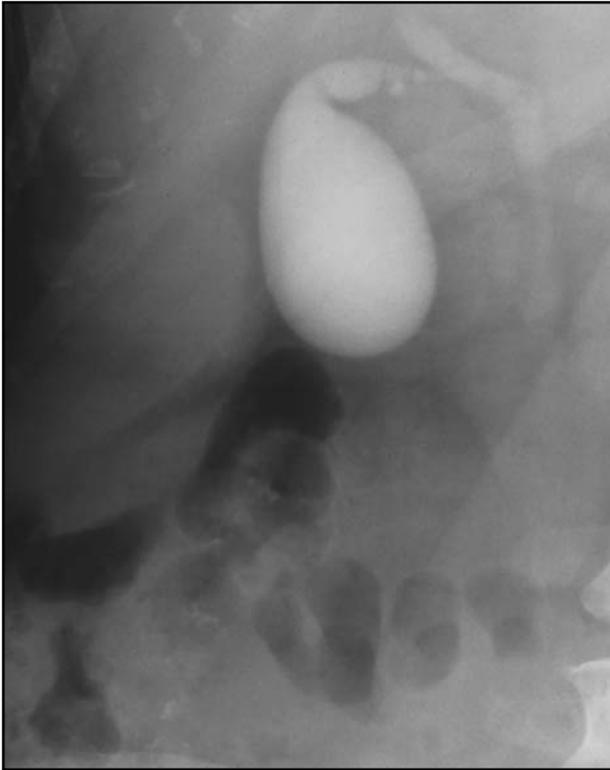

Gallbladder x rays are diagnostic studies of the gallbladder (GB), a small pear-shaped sac that stores bile and is located under the **liver**. The study involves taking tablets containing iodine compounds a day before the x ray. The tablets are absorbed by the intestine, excreted by the liver and then concentrated in the gallbladder. In some clinics and hospitals the tablets are taken over a two day period, in hope of a better visualization of the gallbladder. This is known as a double-dose oral cholecystogram. This test was once the standard for diagnosing diseases of the GB; however, in recent years it is not often requested due to the advances in diagnostic ultrasound.

Purpose

This test, also known as an oral cholecystogram or OCG, is usually ordered to help physicians diagnose disorders of the gallbladder, such as gallstones, inflammation, and tumors. The test is usually ordered when a gallbladder ultrasound has proved non-diagnostic. It is used in the investigation of patients complaining of upper abdominal **pain** after eating a fatty meal. Obese women over forty with a diet high in fat and low in fiber are at risk for gallstones. This test also measures gallbladder function, since the failure of the organ to visualize can signify a non-functioning or diseased gallbladder. The gallbladder may also not visualize if the bilirubin level is over four, and the study should not be performed under these circumstances. A CT scan, MRI (**magnetic resonance imaging**), or an ERCP (endoscopic retrograde cholangio-pancreatography) would be done instead.

Precautions

The physician must be notified if the patient is pregnant or allergic to iodine. Patients with a history of severe

An x-ray image showing a healthy gallbladder outlined as a sac-like opaque mass. (Science Source/Photo Researchers. Reproduced by permission.)

kidney damage have an increased risk of side effects from this procedure. Ultrasound is commonly used instead of the x-ray examination when gallstones are suspected. Some people experience side effects from the contrast material (iodine tablets), especially **diarrhea**. During preparation for the test, patients should not use any **laxatives**. Diabetics should discuss the need for any adjustment in medication with their physician.

Description

The exam is performed in the radiology department. The iodine tablets are purchased at a pharmacy or supplied by the hospital. The night before the test, patients swallow six tablets (one at a time) with plenty of water. If a double-dose OCG is requested, this will be done over a two day period.

The patient will be asked to put on a hospital gown. The x-ray technologist will take a preliminary or scout film to see if the gallbladder is well visualized. The patient is placed prone with the right side slightly raised to prevent superimposition of the spine. The first film should show all of the right side of the abdomen, from the lateral side of the spine down to the iliac crest (top of

the pelvis). Tall thin patients will need to be turned more since the gallbladder tends to lie lower and closer to the spine than in shorter, heavier patients. If the gallbladder is well seen on the first film, the x-ray technologist or radiologist will take another film coned-down and centered directly on the gallbladder. At least one more film in an upright or a lateral decubitus position will be done, since gallstones tend to sink downward or float in the gallbladder, as compared to a tumor or polyp, which remains in the same position. The gallbladder can displace to a considerably lower position when the patient is upright, so the radiography technologist must take into account the bodily habitus (size and shape) of each individual patient.

The radiologist will review the x-rays and then take a series of coned-down (spot) films of the gallbladder with a **fluoroscope** (a special apparatus that projects the image onto a video monitor to be seen immediately). The radiologist may ask for another film to be taken 30 minutes after a fatty meal. The patient will be given a glass of egg nog or in some instances buttered toast and coffee or tea with cream. This meal will cause the gallbladder to contract and release bile, so the gallbladder should diminish in size on the post-fatty meal film (PFM). Delayed films may be taken if this doesn't occur. The exam usually takes one hour to complete and may be done in a hospital or a clinic that is certified to take x rays.

Preparation

The day before the test, patients are instructed to eat a normal breakfast and lunch and a light fat-free dinner (no fried or fatty foods, cream, milk, or butter). The night before, six Telepaque pills (iodine tablets) are taken one at a time, five minutes apart, with a large glass of water. Only water or juice is permitted until midnight. After midnight no food or liquids are allowed until after the exam. In some instances the clinic or hospital may prefer that a double-dose OCG be routinely done. This involves taking the Telepaque tablets over a two-day period. The pills may be taken two at a time with each fat-free meal or all at once, depending on the routine requested by the radiology department.

Aftercare

No special care is required after the study.

Complications

There is a small chance of an allergic reaction to the contrast material. In addition, there is a low level of radiation exposure. X rays are monitored and regulated to provide the minimum amount of radiation exposure

needed to produce the image. Most experts feel that the risk is low compared with the benefits. Pregnant women and children are more sensitive to the risks of x rays, and the risk versus the benefits should be discussed with the treating physician. In some cases diarrhea or vomiting may occur. The x-ray technologist should be informed, since the gallbladder might not be well visualized.

Results

A normal OCG will show a normal gallbladder. The gallbladder should visualize, and be free of any solid structures, such as stones, polyps, or tumors. It should empty freely with no obstruction after the PFM (post-fatty meal).

Abnormal results may show gallstones, tumors, or cholesterol polyps (a tumor growing from the lining that is usually non-cancerous). Typically stones will “float” or move around as the patient changes position, whereas tumors will stay in the same place.

Health care team roles

The radiography technologist works closely with the nurses (if the patient is hospitalized) to make sure the patient is given the Telepaque tablets and follows a fat-free diet. Any diarrhea or vomiting must be noted and the radiology department advised. The x-ray technologist must also be aware of the bilirubin level, which could indicate liver disease and a non-functioning gallbladder. In the case of a high bilirubin level the exam would not be done. All x-ray technologists must be certified and registered with the American Society of Radiologic Technologists or an equivalent association, depending on where the exam is being done.

Patient education

Patients must understand the importance of taking the contrast tablets and following a fat-free diet. All women of child-bearing age should be aware of the dangers of x rays to a fetus, and will be protected as much as possible without obstructing the image of the gallbladder.

BOOKS

- Levenson, Deborah E. and Hans Fromm. “Oral Cholecystogram.” In *Hepatology: A Textbook of Liver Disease*, edited by David Zakim and Thomas D. Boyer et al. Philadelphia: W.B. Saunders Company. 1996, p.1883.
- Zeaman, Robert K. “Oral Cholecystography.” In *Bockus Gastroenterology*, edited by William S. Haubrich et al. Philadelphia: W.B. Saunders Company. 1995, pp. 208-211.

KEY TERMS

Bile—A yellow-green liquid produced by the liver, which is released through the bile ducts into the small intestines to help digest fat.

Bilirubin—A reddish-yellow pigment formed from the destruction of red blood cells, and metabolized by the liver. Levels of bilirubin in the blood increase in patients with liver disease or blockage of the bile ducts.

Body habitus—The size and shape of a person’s body.

ERCP—An endoscopic retrograde cholangio-pancreatography. A flexible telescope is placed through the nose or mouth into the stomach, upper intestine and then the common bile duct to visualize the GB and pancreas. This is done when there is poor visualization of the gallbladder on an ultrasound examination, CT scan or OCG.

Ultrasound—A noninvasive procedure based on changes in sound waves of a frequency that cannot be heard, but respond to changes in tissue composition. Patients must be fasting for at least six hours but no contrast material is given. There is no radiation used in an ultrasound exam, so it is the exam of choice for the diagnosis of stones in the gallbladder, but is less accurate in diagnosing stones in the bile ducts. Gallstones as small as 2 mm can be identified.

Gallium scan of the body

Definition

A gallium scan of the body is a diagnostic imaging test that utilizes a radionuclide, Ga67, to detect areas of **infection** and inflammation, or to detect certain types of tumors.

Purpose

In cases where patients have a suspected infection or inflammation, a gallium scan is useful to establish the site of origin, particularly with bone or orthopedic infections, and with such diseases as sarcoidosis. Patients with a chronic infection accompanied with a **fever** of unknown origin are also candidates for a gallium scan. Gallium is also used to localize primary tumors and locate metastases; to diagnose Hodgkin's and other lymphomas; and to determine the stage of a lymphoma. Gallium scans are also performed to follow up patients who have received therapeutic treatment, to demonstrate the regression, progression, or recurrence of disease.

Precautions

Ga67 is radioactive; therefore, patients who are pregnant are cautioned against having this test unless the benefits outweigh the risks. Women who are breastfeeding will need to stop breastfeeding for a specified period of time, usually for several weeks, depending on the dose.

Description

The patient is required to come to the testing facility, usually a hospital nuclear medicine department or outpatient radiology facility, to receive an intravenous injection of the Ga67. After the injection, the patient must return anywhere from six hours to ten days later for the images, depending on the disease or condition being evaluated. The study itself takes approximately one hour, unless a more detailed SPECT (single photon emission computed tomography) is performed, which requires more time. The patient lies on an imaging table while a gamma camera obtains the necessary data to produce an image. In most cases, the camera is moved across the patient's body, or, in the case of a SPECT study, the camera will circle around the body. The camera does not give off radiation, but instead detects the radiation from any areas where the gallium has accumulated. Images are obtained, posteriorly, anteriorly, and sometimes laterally. The camera may occasionally touch the patient but will not cause any discomfort.

KEY TERMS

Gallium—An element whose radioactive form, Ga 67, is used for gallium scans.

Sarcoidosis—A chronic, progressive disease of unknown etiology that can affect almost any organ or tissue.

Preparation

No special preparation is necessary, although some patients may be required to have light or clear meals within a day or less of the procedure. Some patients may need to take **laxatives** or an enema prior to the scan, to eliminate any residual gallium from the bowel.

Aftercare

There is no particular aftercare required.

Complications

There are no complications. There is a minimal risk of exposure to radiation from the Ga67, but the exposure from one gallium scan is generally less than exposure from many common x-ray procedures.

Results

It is normal for the gallium to accumulate in the **liver**, spleen, bones, and large bowel. An abnormal concentration of gallium in areas other than those where it normally concentrates may indicate the presence of disease. Abnormal concentrations may be due to inflammation, infection, or presence of a tumor. Further investigation with ultrasound or CT is usually necessary to confirm the suspicions of abnormal findings, or to distinguish between a malignant and a benign tumor.

Health care team roles

The injection and scan are performed by a nuclear medicine technologist, who is specially trained to handle radioactive materials and to operate the equipment used for this study. The technologist will obtain any pertinent medical history and explain the test to the patient. The technologist processes the data obtained during the scan. A doctor who is a radiologist or nuclear medicine specialist interprets the images and may make recommendations for follow-up tests or for further diagnostic procedures. If the patient is hospitalized during the time in

which the gallium scan is performed, the nursing staff may be needed to administer the enema and, if indicated, to oversee that the patient received a specified diet. The patient receives the results of this test from their personal physician or the doctor who ordered the test.

Gangrene

Definition

Gangrene is the death of tissue caused by the lack of **blood** supply.

Description

The severity of gangrene is wide-ranging. It can affect a minuscule skin area or a finger or toe, or even an entire limb such as an arm, a foot, or a leg. Gangrene is usually classified into two categories, dry gangrene and wet gangrene.

Dry gangrene

Dry gangrene occurs when a portion of bodily tissue dies because its blood supply has been decreased or completely cut off. This type of gangrene will not spread to other healthy tissue, and **infection** is not present. It is usually a slow process, with the affected area gradually becoming cold, discolored, and eventually totally black. Shrinkage and withering away of the affected tissue occurs as the tissue dies.

Wet gangrene

Dry and wet gangrene are two terms often applied to different phases of the same death of tissue. Wet gangrene (also called moist gangrene) occurs when dry gangrene becomes infected, often due to injury, and the infection causes the tissue to die.

In the United States, approximately 50% of moist gangrene cases are the result of a severe traumatic injury; 40% occur following surgery. Car and industrial accidents, crush injuries, and gunshot **wounds** are the most common traumatic causes. Because of prompt surgical management of wounds with the removal of dead tissue, the incidence of gangrene from trauma has significantly diminished. Surgeries involving the bile ducts or intestine are the most frequent procedures causing gangrene. Approximately two-thirds of cases affect the extremities, and the remaining one-third involve the abdominal wall.

One particularly dangerous type of wet gangrene is termed gas gangrene, or myonecrosis. This particular type is caused by the infection of injured tissue or surgical wounds from the *Clostridium* species of **bacteria**, an especially virulent pathogen. In anaerobic conditions, that is, conditions in which oxygen levels are low, *Clostridium* can rapidly produce poisonous substances called toxins that cause tissue to die. Four of the *Clostridium* toxins, Alpha, Beta, Epsilon, and Iota, are capable of causing death.

Gas gangrene differs from other wet gangrenes because it is more involved with muscle than skin tissue. Not only do the toxins manufactured by *Clostridium* cause the death of tissue, but they also destroy blood cells, constrict **blood vessels**, thus decreasing circulation, and damage blood vessels so that they leak. Fortunately, in peacetime, and with improvements in medical care, gas gangrene is not a frequently occurring phenomenon. (It occurs in only between one and three thousand people in the United States each year.) However, in the past, in wartime, gas gangrene has killed literally millions.

Causes and symptoms

Dry gangrene

Some of the most common causes of dry gangrene include:

- arterial obstruction, or occlusion of an artery, caused by arteriosclerosis, **diabetes mellitus**, **AIDS** or blood clot
- severe blunt trauma to a part of the body causing damage and therefore obstruction of an artery

A close-up of gangrene in the toes of a diabetic patient.

(Photo Researchers, Inc. Reproduced by permission.)

- frostbite, which occurs when tissue becomes so cold that it is literally deprived of blood and therefore oxygen, and dies
- diseases that affect the blood vessels, and especially the arteries, such as Buerger's disease or Raynaud's disease
- traumatic occurrences such as crushing injuries, **fractures**, **burns**, and even injections given into skin or muscle

Wet gangrene

Causative organisms for wet gangrene infection include:

- *Streptococcus*
- *Staphylococcus*

A serious but rare form of infection with Group A *Streptococcus* can impede blood flow and, if untreated, can progress to gangrene caused by chemical reaction. This type of gangrene is more commonly called necrotizing fasciitis, or infection of the skin and tissues directly beneath the skin.

Gas gangrene, the most serious form of wet gangrene, often is caused by *Clostridium* bacteria, which are normal inhabitants of the gastrointestinal, respiratory, and female genital tracts. They often infect thigh amputation wounds, especially in those individuals who have lost control of their bowel function (incontinence). Gangrene, incontinence, and debility are often combined in patients with diabetes, and it is in the amputation stumps of diabetic patients that gas gangrene often occurs.

Areas of either dry or moist gangrene are initially characterized by a red line on the skin that marks the border of the affected tissues. The onset of dry gangrene is normally characterized by dull, aching **pain** at the site. The skin usually develops an abnormal, unhealthy-

appearing pallor and is cold to the touch. As tissues begin to die, dry gangrene may continue to cause some pain; but it may go unnoticed, especially in the elderly or in those individuals with diminished sensation to the affected area. As more tissue dies, its color changes to brown, and finally purplish-black. This dead tissue will gradually separate from the healthy tissue and fall off.

Gas gangrene has a dramatically sudden, rapid onset. It is frequently first noticed as a marked swelling and either a pallid or brownish-red colored area surrounding the wound site. The borders of the infected site can expand literally within minutes. Symptoms of gas gangrene include:

- edema, or swelling, at the injury site that expands quickly
- pain in the area surrounding the skin injury
- *crepitus*, a bubbly, crackling sound often heard upon palpation
- pallor at the injury site, then increasingly dusky discoloration
- low-grade to moderate temperature elevation
- tachycardia, or increased **heart** rate
- diaphoresis, or clammy, sweaty skin
- formation of blisters filled with rust-colored fluid
- wound drainage, foul-smelling and rusty or bloody in appearance
- in severe cases, **shock** (Symptoms of shock include generalized pallor, hypotension, rapid pulse, and cold hands and feet.)

Diagnosis

A diagnosis of gangrene is based on a combination of the patient history, a **physical examination**, and the results of blood and other laboratory tests. A physician will look for a history of recent trauma, surgery, **cancer**, or chronic disease. Blood tests will be used to determine whether infection is present and determine the extent to which an infection has spread.

A sample of drainage from a wound, possibly obtained through surgical exploration, may be cultured with oxygen (aerobic) and without oxygen (anaerobic) to identify the microorganism causing the infection and to aid in determining which antibiotic will be most effective. A gangrenous sample will contain few if any white blood cells and, when stained (with **Gram stain**) and examined under the **microscope**, will show the presence of purple (Gram-positive) rod-shaped bacteria.

X ray studies and more sophisticated imaging techniques, such as computed tomography scans (CT) or **magnetic resonance imaging** (MRI), may be helpful in making a diagnosis, since gas accumulation and muscle death (myonecrosis) may be visible. These techniques, however, are not sufficient alone to provide an accurate diagnosis of gangrene.

Precise diagnosis of gas gangrene often requires surgical exploration of the wound. During such a procedure, the exposed muscle may appear pale, beefy-red, or in the most advanced stages, black. If infected, the muscle will fail to contract with stimulation, and the cut surface will not bleed.

Treatment

Gas gangrene is a potentially lethal condition requiring immediate action. It is recommended that anyone having any or all of the symptoms of gas gangrene contact a health provider immediately. Generally, once a diagnosis of gas gangrene is made, infected, gangrenous tissue must be removed surgically. To assure its complete removal, it is often necessary to remove all tissue surrounding the infection or even to amputate a portion of the body. Aggressive use of **antibiotics**, usually intravenously to start, is also begun as soon as possible. Pain medication will also usually be necessary.

Areas of dry gangrene that remain free from infection (aseptic) in the extremities are most often left to wither and fall off. Treatments applied to the wound externally (topically) are generally not effective without adequate blood supply to support wound healing. Assessment by a vascular surgeon, along with x rays to determine blood supply and circulation to the effected area, can help determine whether surgical intervention would be beneficial.

Once the causative organism has been identified, moist gangrene requires the prompt initiation of intravenous, intramuscular, and/or topical broad-spectrum antibiotic therapy. In addition, the infected tissue must be removed surgically (debridement), and amputation of the affected extremity may be necessary. Pain medications (**analgesics**) are prescribed to control discomfort. Intravenous fluids and, occasionally, blood transfusions are indicated to counteract shock and replenish red blood cells and electrolytes. Adequate hydration and **nutrition** are vital to wound healing.

Although still controversial, some cases of gangrene are treated by administering oxygen under pressure greater than that of the atmosphere (hyperbaric) to the patient in a specially designed chamber. The theory behind using hyperbaric oxygen is that more oxygen will

dissolve in the patient's bloodstream, and therefore more oxygen will be delivered to the gangrenous areas. By providing optimal oxygenation, the body's ability to fight off the bacterial infection is believed to be improved, and there is a direct toxic effect on the bacteria that thrive in an oxygen-free environment. Some studies have shown that the use of hyperbaric oxygen produces marked pain relief, reduces the number of amputations required, and reduces the extent of surgical debridement required. Patients receiving hyperbaric oxygen treatments must be monitored closely for evidence of oxygen toxicity. Symptoms of this toxicity include slow heart rate; profuse sweating; ringing in the ears; shortness of breath; nausea and vomiting; twitching of the lips, cheeks, eyelids, nose; and convulsions.

The emotional needs of the patient suffering from gangrene are also a large component of treatment. The individual with gangrene should be offered moral support, along with an opportunity to share questions and concerns about changes in body image. In addition, particularly in cases where amputation is required, physical, vocational, and rehabilitation therapy will also be required.

Prognosis

Except in cases where the infection has been allowed to spread through the blood stream, as in the case of severe gas gangrene, prognosis for survival is generally favorable. Anaerobic wound infection can progress quickly from initial injury to gas gangrene and the spread of the infection to the blood stream within one to two days. Between 20 and 25% of gas gangrene victims do not survive. If recognized and treated early, however, approximately 80% of patients survive, and only 15 to 20% require any form of amputation. Unfortunately, the individual with dry gangrene most often has multiple other health problems that complicate recovery, and it is usually these health problems that can prove fatal.

Health care team roles

- In most cases, gangrene is discovered while the patient is still in a healthcare facility following trauma, surgery, or treatment of serious medical conditions. A diagnosis of gangrene is generally made by a primary care physician or surgeon.
- Both registered nurses (RNs) and licensed practical nurses (LPNs) must complete a prescribed course in nursing and pass a state examination. RNs typically have a degree in nursing. Both RNs and LPNs care for patients afflicted by gangrene both in general hospitals,

KEY TERMS

Aerobic—A type of organism that grows and thrives only in environments containing oxygen.

Anaerobic—A type of organism that grows and thrives in an oxygen-free environment.

Arteriosclerosis—Build-up of fatty plaques within the arteries that can lead to the obstruction of blood flow.

Aseptic—Without contamination with bacteria or other microorganisms.

Crepitus—A crackling sound.

Gram stain—A staining procedure used to visualize and classify bacteria. The Gram stain procedure allows the identification of purple (Gram-positive) organisms and red (Gram-negative) organisms.

Hyperbaric oxygen—Medical treatment in which oxygen is administered in specially designed chambers under pressures greater than that of the atmosphere in order to treat specific medical conditions.

Incontinence—A condition characterized by the inability to control urination or bowel functions.

Myonecrosis—The destruction or death of muscle tissue.

Sepsis—The spreading of an infection in the bloodstream.

Thrombosis—The formation of a blood clot in a vein or artery that may obstruct local blood flow; or may dislodge, travel downstream, and obstruct blood flow at a remote location.

homes, or other healthcare facilities. Good nursing care and observation are primary requirements. These will include taking **vital signs**, monitoring surgical wounds or injuries for signs and symptoms of infection, providing aseptic (germ-free) treatment to wounds and injuries, collecting specimens of wound drainage to be tested, and making all efforts necessary to keep the patient as comfortable as possible. Education about the underlying cause of the gangrene (diabetes, infection, etc.) is an important aspect of caring for these patients.

- Clinical laboratory scientists have specialized training and must pass a state examination. They do the necessary tests on wound drainage specimens to determine the organism involved in the infection.

- Radiologic technologists have specialized training and must pass a state examination. They take X rays and other tests to visualize and monitor the course of the gangrene.
- Physical therapists must complete a prescribed course and pass a state examination in order to be licensed. Typically they have a degree. Physical therapists work with patients that have sustained an amputation because of gangrene to maintain and maximize mobility in walking, wheelchair use, and transferring (from wheelchair to toilet or from standing to sitting, for example). The physical therapist advises on such mobility aids as wheelchairs, braces, and canes.
- Social workers have a degree in social work. A social worker may help coordinate services and ease the transition out of the hospital back into the home or extended care facility, if necessary. Social workers may help counsel the patient and the family during the difficult rehabilitation period.
- Occupational therapists must complete a prescribed course and pass a state examination in order to be licensed. Typically they have a degree. They help people disabled after an amputation or loss of function caused by gangrene to relearn necessary functions needed to carry out normal activities of daily living such as bathing, dressing, and preparing meals.

All healthcare team members need to be aware that the person with gangrene, and possibly an amputation, and the family members who may care at home for the person will need to learn an entirely new set of skills and adaptations. Both the patient and family often experience **stress, anxiety**, and depression. Both may need teaching regarding both physical and mental symptoms that often follow gangrene or amputation, and the family may need to be taught how to deliver necessary care. For the patient with gangrene, finding other individuals or a support group composed of people that have had similar illness or injury can be one of the most important steps in the rehabilitation process.

Prevention

Patients with diabetes or severe arteriosclerosis need to take particular care of their hands and feet because of the risk of infection associated with even a minor injury. Education about proper **foot care** is vital. Diminished blood flow as a result of narrowed vessels will not lessen the body's defenses against invading bacteria. Measures taken towards the reestablishment of circulation are recommended whenever possible. Any abrasion, break in the skin, or infected tissue should be cared for immedi-

ately. Any dying or infected skin must be removed promptly to prevent the spread of bacteria.

Penetrating abdominal wounds should be surgically explored and drained, any tears in the intestinal walls closed, and antibiotic treatment begun early. Patients undergoing elective intestinal surgery should receive preventive antibiotic therapy. Use of antibiotics prior to and directly following surgery has been shown to significantly reduce the rate of infection from 20-30% to between 4 and 8%.

Gas embolism

Definition

Gas embolism, also called air embolism or arterial gas embolism, is the presence of gas bubbles in the bloodstream that obstruct circulation.

Description

Gas embolism may occur with decompression from increased pressure. It typically occurs in ascending divers who have been breathing compressed air. If a diver does not fully exhale upon ascent, the air in the **lungs** expands as the pressure decreases, overinflating the lungs and forcing bubbles of gas (emboli) into the bloodstream. When gas emboli reach the arteries to the **brain**, the **blood** blockage causes unconsciousness. Gas embolism is second only to drowning as a cause of death among divers.

In rare cases, gas embolism may also result from trauma or medical procedures, such as catheterization

and open **heart** surgery, that allow air into the circulatory system.

Sometimes, the term "the bends" is used to describe any manifestation of **decompression sickness**, including gas embolism. Specifically, the bends refers to a condition caused by dissolved nitrogen leaving the tissues too quickly on ascent during a dive. It is manifested by **pain**, often in the limbs and joints.

Causes and symptoms

Gas embolism occurs independently of diving depth. It may occur in as little as 6 ft (2 m) of water if the swimmer has access to a source of air and takes even one breath underwater. Gas embolism is frequently caused when divers hold their breath during ascent. It may also result from an airway obstruction or other condition that prevents a diver from fully exhaling.

The primary sign of gas embolism is immediate loss of consciousness, which may or may not be accompanied by convulsions.

Diagnosis

Any unconscious diver should be assumed to be the victim of gas embolism, regardless of whether consciousness was lost during or promptly after ascent. A doctor may also find pockets of air in the victim's chest around the lungs and, occasionally, a collapsed lung from overinflation and rupture. Coughing up blood or a bloody froth around the mouth are visible signs of lung injury.

Treatment

Prompt recompression treatment in a hyperbaric (high-pressure) chamber is necessary to deflate the gas bubbles in the bloodstream, dissolve the gases into the blood, and restore adequate oxygenated blood flow to the brain and other organs. Transport to a suitable recompression chamber should take precedence over nonessential procedures.

Recompression by returning the diver to deeper water will not work, and should not be attempted. The patient should be kept lying down and given oxygen while being transported for recompression treatment.

Before the diver receives recompression treatment, other lifesaving efforts may be necessary. If the diver is not breathing, artificial respiration (also called mouth-to-mouth resuscitation or rescue breathing) should be administered. In the absence of a pulse, **cardiopulmonary resuscitation (CPR)** must be performed.

KEY TERMS

Compressed air—Air that is held under pressure in a tank to be breathed underwater by divers.

Compression—An increase in pressure from the surrounding water that occurs with increasing diving depth.

Decompression—A decrease in pressure from the surrounding water that occurs with decreasing diving depth.

Emboli—Plural of embolus. An embolus is an object that blocks the blood flow in a blood vessel, as in a gas bubble, a blood clot, a fat globule, a mass of bacteria, or other foreign body.

Hyperbaric chamber—A sealed compartment in which patients are exposed to controlled pressures up to three times normal atmospheric pressure. Hyperbaric treatment may be used to regulate blood gases, reduce gas emboli, and provide higher levels of oxygen more quickly in cases of severe gas poisoning.

Recompression—Restoring the elevated pressure of the diving environment to treat gas embolism by decreasing bubble size.

Prognosis

The prognosis is dependent upon the promptness of recompression treatment and the extent of the damage caused by oxygen deprivation. Gas embolism may cause a stroke.

Health care team roles

A gas embolism is an emergency situation. Any unconscious diver should be assumed to be the victim of gas embolism. Maintaining air supply is the most crucial step, and artificial respiration or CPR should be administered as needed. Fluids should be administered, either orally if the patient is conscious, or intravenously.

Prevention

All divers should receive adequate training in the use of compressed air and a complete evaluation of fitness for diving. People with a medical history of lung cysts or spontaneous collapsed lung (pneumothorax), and those with active **asthma** or other lung disease, must not dive, for they would be at extreme risk for gas embolism. Patients with such conditions as **alcoholism** and drug

abuse are also discouraged from diving. Individuals with certain other medical conditions, such as diabetes, may be able to dive safely with careful training and supervision.

Gas exchange

Definition

Gas exchange is the process by which oxygen is transferred from the atmosphere to bodily tissues for use in **metabolism**; and the gas produced by metabolism, carbon dioxide, is transferred from tissues to the atmosphere.

Description and function

Overview of gas exchange

The process of gas exchange has several steps. The following is a summary of the steps:

- ventilation (breathing)
- interchange of CO₂ and O₂ between air in the lungs' alveoli and **blood** in lung capillaries by diffusion
- transport of CO₂ and O₂ through the bloodstream

- interchange of CO₂ and O₂ between blood in lung capillaries and alveolar air by diffusion
- use of O₂ and production of CO₂ by cells through metabolism

Ventilation

The transfer of oxygen from the atmosphere to the tissues starts with the inspiration of air into the **lungs**. The lungs consist mainly of tiny air-containing alveolar sacs. The alveoli are small hollow sacs connecting to the larger terminal bronchioles of the airways. The air adjacent to the surfaces of the alveolar wall are lined by a single cell layer of flat epithelial cells called type I alveolar cells. In between these type I cells are thicker and more rounded type II alveolar cells, which produce a detergent-like fluid. In the alveolar walls, the fluid and connective tissue fills the interstitial space and is interspersed with capillaries. In some places the interstitial space is nonexistent, and the epithelial **cell membranes** are in direct contact with the capillaries. The blood in the capillaries is separated from the air molecules by a single layer of flat epithelial cells. The surface area in a single alveolus, because of the undulating terrain of type I and II epithelial cells, is roughly the size of a medium-sized room. There are around 300 million alveoli in the adult male. Therefore, there is a large amount of surface area placing air and the blood stream in close proximity. This trait is needed for gas exchange to easily occur. The **respiratory system** also needs a continual supply of fresh air. This air is supplied to the lungs through the nose and mouth, trachea, and bronchi. Ventilation is the interchange of air between the atmosphere and the alveoli by bulk flow. Bulk flow is the movement of air from a region of high pressure to one of low pressure.

The physics of gas exchange

In order to understand why oxygen and carbon dioxide are able to diffuse from their respective areas of high concentration, Dalton's Law must first be presented. It states that in a mixture of gases, the pressure exerted by each gas is independent of the pressure exerted by the others. It is why carbon dioxide can move out of the bloodstream while oxygen is diffusing into the blood stream. The concentration of oxygen (O₂) will not affect the activity of carbon dioxide (CO₂).

Henry's law explains why CO₂ can move from the blood stream into the airspace of the lung, and O₂ can move from that airspace into the bloodstream. It states that the amount of gas dissolved will be directly proportional to the partial pressure of the gas with which the liquid is in equilibrium. At equilibrium, the partial pressures of the gas molecules in liquid and gaseous phases must be identical. Elemental gas can move from air into or out of a liquid where there is a pressure difference.

Interchange

During inspiration, the partial pressure of oxygen (PO₂) in the lung (105 mmHg) is higher than that in the arteries of the alveoli (40 mmHg). This pressure difference allows O₂ to transfer into the blood stream. The partial pressure of carbon dioxide (PCO₂) in the lung (40 mmHg) is less than the arterial partial pressure of the alveoli (46 mmHg). This pressure difference allows carbon dioxide to diffuse into the lung and eventually into the atmosphere. The ventilation of the lungs allows for the continual renewal of imbalance and need for breathing and metabolism to continue.

Transport

The circulatory system continually supplies blood in need of oxygenation and the ventilation of CO₂ to the lungs. It arrives in the lungs with a PO₂ of 40 mmHg and a CO₂ of 46 mmHg and leaves the lungs with a PO₂ of 100 mmHg and a CO₂ of 40 mmHg. From the lungs, the oxygenated blood travels through the pulmonary veins to the left side of the **heart** and into the systemic arteries. The blood eventually flows to the tissue capillaries where another pressure difference occurs.

Use and transport

At the capillaries the PO₂ is 100 mmHg and the PCO₂ is 40 mmHg. In the tissues the PO₂ is less than 40 mmHg and the PCO₂ is greater than 46 mmHg. The O₂ in the capillaries diffuses into the tissue and the CO₂ produced by metabolism comes into the capillaries. Deoxygenated blood travels from the tissues to the right side of the heart via the systemic veins and then returns to the lungs for more O₂ through the pulmonary arteries, where the process begins again.

Hemoglobin

Each liter of oxygenated blood normally contains 200 ml of pure gaseous O₂ at atmospheric pressure (760 mmHg). It exists in the blood stream dissolved in the plasma and erythrocyte water or combined with hemoglobin molecules in the erythrocytes.

Oxygen is relatively insoluble in water and only 3 ml will be dissolved in one liter of blood at the arterial partial pressure of 100 mmHg. It is consistent with Henry's law because the amount of O₂ dissolved in the blood is directly proportional to the partial pressure of the blood. This leaves another 197 ml of O₂ in need of a way to be dissolved in the blood stream.

The hemoglobin molecule is a protein with four subunits. Each subunit is made up of a heme (a molecular group) with a polypeptide attached. Heme contains one

KEY TERMS

Chemoreceptor—A type of cell activated by a change in its chemical balance that results in a nerve impulse.

Metabolism—The sum of physical and chemical changes in the tissue including anabolism, catabolism, energy production and synthesis of molecules.

Ventilation—Movement of gases into and out of the lungs; tidal exchange between the lungs and the atmosphere.

atom of **Iron** (Fe) to which one O₂ molecule can bind. This means that every hemoglobin molecule can bind four O₂ molecules. The four polypeptides in hemoglobin are called globin. With O₂ attached to the molecule, it is known as oxyhemoglobin (HbO₂) and without it is known as deoxyhemoglobin (Hb). The bonding of O₂ to hemoglobin allows a full 200 ml of O₂ to dissolve completely in the blood. In reference to Dalton's law it allows for a greater difference in the concentration of O₂ between the O₂ in the lung and the bloodstream, and the blood. The O₂ tied up by the hemoglobin cannot be considered when looking at concentration differences. Conversely the concentration difference between the tissues and the capillaries at the tissue level causes the O₂ to dissociate from the hemoglobin, leaving the O₂ free to diffuse into tissue and the hemoglobin free to bond to the carbon dioxide leaving the tissue. By tying up carbon dioxide with hemoglobin, even more CO₂ can be carried to the lungs by the blood.

CO₂ is far more soluble in water than O₂. Only ten percent of the carbon dioxide that enters the blood is dissolved in water. Thirty percent of the carbon dioxide bonds with hemoglobin to form carbaminohemoglobin. Sixty percent of the carbon dioxide is converted to bicarbonate.

Deoxyhemoglobin serves as a buffer in the bloodstream as well. It has an affinity for acidic hydrogen atoms left in the bloodstream by the formation of bicarbonate. This allows the blood to maintain a pH of around 7.4 and explains why even venous blood maintains this pH.

Regulation of gas exchange

The exchange of gases in the body will occur with the respective differences of partial pressure between the blood and tissues, and the lung and alveoli. Respiratory rate must be controlled in order to suit the O₂ needs of the

body and ensure a balanced supply of O₂ to the tissues. Respiratory rate is controlled by the peripheral chemoreceptors located high in the neck, where the common carotid arteries split, as well as on the arch of the aorta. They are called carotid bodies and aortic bodies respectively. These chemoreceptors are stimulated by the minor elevation of PCO₂ levels, causing an increase in ventilation. Chemoreceptor response to the PCO₂ level in the blood is the primary and most immediate indicator of gas deficiency and surplus in the blood stream. Elevated levels of PCO₂ normally cause an increase in breathing, and lower levels normally cause a decrease. This response system allows for a balance of gases available for use in metabolism.

Conversely, a decrease in arterial PO₂ levels and an increase in blood acidity do not affect a minimal increase in ventilation stimulated by chemoreceptors until PO₂ goes below 60 mmHg. Oxygen transport at the tissues will not be reduced until the blood PO₂ reaches 60 mmHg. Thus, the chemoreceptors are not triggered for lack of PO₂ in normal circumstances. If there is lung disease, or in high altitudes, these receptors can be stimulated and will affect an increase in the respiratory rate.

Role in human health

Gas exchange provides a needed fuel (O₂) for metabolism to occur and a means to expel the gaseous byproduct (CO₂) of metabolism from the body. Without gas exchange the body would not function. The hindrance of gas exchange by disease, disorder, or chemicals can slow body functions and even cause death.

Common diseases and disorders

The interference of gas exchange occurs when the function of a number of different organs and tissues is impaired. The most common form of impairment to gas exchange is hypoxia, which is the lack of oxygen in the tissues. Hypoxia can be caused by hypoventilation, diffusion impairment, shunt, and or ventilation-perfusion (the rate of ventilation relative to CO₂ production) inequality.

Hypoventilation is the reduced alveolar ventilation in comparison to the metabolic CO₂ production in which the PCO₂ levels increase above normal. It is caused by disease in the lung, abnormalities in the thoracic cage, or deficits in the respiratory control pathway from the medulla to the chemoreceptors.

Diffusion impairment occurs when there is a decrease in the surface area or thickening of the alveolar membranes. Diseases or disorders in the lung can cause this impairment.

Asthma is an intermittent disease characterized by a chronic inflammation of the airway, which causes smooth **muscle contraction** in the airway.

Chronic obstructive pulmonary disease (COPD) refers to **emphysema**, chronic bronchitis or a combination of the two. Cigarette smoking is a major cause of this and the following diseases associated to COPD. Chronic bronchitis is characterized by excessive mucus production in the bronchi and chronic inflammatory changes in the small airways. Emphysema is a major cause of hypoxia and is characterized by the destruction of the alveolar walls, and the atrophy and collapse of the lower airways. **Pneumonia** is normally caused by bacterial or viral **infection**. The alveolar spaces fill with mucus, inflammatory cells, and fibrin.

Other disorders that impact gas exchange are hyperventilation, in which ventilation is increased relative to the metabolic CO₂ production, and in which the PCO₂ drops below normal levels; and the effects of high altitude (called altitude sickness), in which the lack of O₂ in the atmosphere causes the body to compensate for that deficiency.

Gas gangrene see **Gangrene**

Gas laws

Definition

The gas laws are mathematical formulations of the interrelationships among the four variables that describe the behavior of a gas sample: its volume (V), pressure

(P), temperature (T), and the amount (n) of gas present (see Gases, properties of).

The **properties of gases** were already being studied and described as early as the seventeenth century. Unlike solids, which have a fixed shape and volume, and liquids, which have a fixed volume but can change shape according to the container, gases assume both the shape and the volume of their container. The volume of space occupied by a sample of gas depends on the number of gas molecules present and the sample's pressure and temperature.

Simple gas laws

Boyle's law: volume is inversely proportional to pressure

Boyle's law, formulated by English scientist Robert Boyle in 1662, states that the pressure of a fixed amount of gas at a constant temperature is inversely proportional to its volume. In other words, when a sample of gas is allowed to expand to occupy a larger volume, its pressure decreases; and when it is compressed into a smaller volume, its pressure increases. Mathematically, this inverse relationship may be formulated:

$$P_1V_1 = P_2V_2$$

or

$$V = \text{constant} \div P$$

In continental Europe, this gas law is known as the law of Mariotte, after Edme Mariotte, who published the results of his studies of the properties of gases a few years later than Boyle.

The working of a syringe can be used to illustrate Boyle's law. When the plunger of a syringe is drawn back, the volume of the air inside the syringe barrel is increased and the pressure decreased relative to the exterior of the syringe, and fluid is pulled into the syringe. When the plunger is depressed, the volume is decreased, the pressure increased, and fluid is forced out.

Charles's law: volume is directly proportional to temperature

Charles's law, which was formulated by French physicist Jacques Charles in 1787, states that the volume of a sample of gas kept at constant pressure is directly proportional to the temperature; or, more simply stated, a gas sample will expand upon heating and contract when cooled. This may be formulated mathematically as:

$$V_1 \div T_1 = V_2 \div T_2$$

or

$$V = \text{constant} \times T$$

Charles's law states that the temperature and volume of a gas are directly related under constant pressure conditions. This demonstration shows the volume of air in the balloons decreasing (balloons shrinking) when they are held in a flask of liquid nitrogen (cooled), and re-expanding when the air in the balloons is allowed to warm to room temperature. (Photograph by Charles D. Winters. Science Source/Photo Researchers. Reproduced by permission.)

A hot air balloon demonstrates the principle of Charles's law. When the balloon is fired, the air is heated and expands to fill the balloon.

Gay-Lussac's law: pressure is directly proportional to temperature

This gas law, published in 1802 by Frenchman Joseph Louis Gay-Lussac, describes the relationship between the gas's pressure and temperature. At constant volume, the pressure of a gas sample is directly proportional to its temperature. In other words, a sample of gas exerts more pressure on its surrounding container when hot than when cold. The mathematical formulation of this law is

$$P_1 \div T_1 = P_2 \div T_2$$

or

$$P = \text{constant} \times T$$

Avogadro's law: volume is directly proportional to amount

In the early nineteenth century, the Italian Count Amadeo Avogadro hypothesized that different gases of

equal volume at a given temperature and pressure contain equal numbers of gas molecules. Alternatively, samples of two different gases containing the same number of molecules will occupy equal volumes. Avogadro's law mathematically formulated is:

$$V_1 \div n_1 = V_2 \div T_2$$

or

$$V = \text{constant} \times n.$$

At standard temperature and pressure (STP), one mole of any gas occupies 22.4 L.

As an example of the law of Avogadro, consider that, during respiration, the amount of air in the **lungs** is alternately increased and decreased by the movement of the diaphragm that causes the volume of the lungs to be alternately increased and decreased.

It should be noted that all gaseous substances behave alike according to these laws. Also, in each of the formulations above, the proportionality constant has a different meaning and is expressed in different units. Moreover, in calculations, temperature must be expressed in terms of the Kelvin, or absolute, temperature scale.

Ideal gas law

The ideal gas law, first derived in 1834 by Emil Clapeyron, compiles the simple gas laws into a single expression with a single constant, called the ideal gas law:

$$PV = nRT$$

The single constant R is called the universal gas constant. The value of the constant depends on the units used to express pressure and volume. The standard units for measuring volume, pressure, amount, and temperature are, respectively, the liter (L), the atmosphere (atm), the mole (mol), and Kelvin (K), giving rise to the value $R = 0.082$ liter atm mol⁻¹ K⁻¹.

All of the relationships established by the simple gas laws are preserved in the expression of the ideal gas law:

- The volume of a gas is inversely proportional to its pressure.
- The volume of a gas is directly proportional to its temperature.
- The pressure of a gas is directly proportional to its temperature.
- The volume of a gas is directly proportional to the amount of gas present.

An ideal, or perfect, gas is a hypothetical gas that obeys the gas laws in terms of its pressure, volume, and temperature behavior. Such a gas would have to be composed of molecules that do not interact with one another.

Real gases are not always accurately described by the ideal gas equation. Under ordinary conditions, however, the observed behavior of a real gas is only negligibly different from that predicted for an ideal gas.

Dalton's law of partial pressures

The simple and ideal gas laws describe the behavior of pure gaseous substances. Mixtures of gases also behave like ideal gases, provided the different components do not undergo a reaction, or interact in some other way. This concept—that each individual gas in a mixture expands to exert its partial pressure as if the other gas components were not present—was developed by John Dalton in 1801 and is known as Dalton's law of partial pressures.

Given that the pressure of a gas is directly related to the number of moles of gas present, and that all gases behave alike, it follows that the total pressure exerted by a mixture of gases is equal to the sum of the pressures of each of the components of the gas mixture. The pressure exerted by a component gas in a mixture is referred to as the partial pressure of that gas. Thus, for a mixture of gases, A, B,...,

$$P_{\text{tot}} = P_A + P_B + \dots$$

Each component gas experiences the same temperature and volume conditions as all other components. Application of the ideal gas equation to each pressure term allows formulation of a useful term known as the mole fraction (X) of a gas. The mole fraction is defined as the ratio of the number of moles of one component to the total number of moles of gas in the mixture, which is equal to the ratio of the partial pressure to the total pressure ($X_A = n_A \div n_{\text{tot}} = P_A \div P_{\text{tot}}$).

$$V = n_A RT$$

Gay-Lussac's law of combining volumes

In 1808, Gay-Lussac, in collaboration with Alexander von Humbolt, studied the reactions of gases. They determined that, at a given temperature and pressure for the reactions involving gaseous substances, the volumes of the reactant and product gases are in ratios of small whole numbers. For example, two volumes of hydrogen gas react with one volume of oxygen gas to form two volumes of water vapor.

KEY TERMS

Celsius (centigrade) and Kelvin temperature scales—On the Celsius scale, the temperature at which water freezes is defined as zero degrees and the temperature at which water boils is defined as 100°. The Kelvin scale is the official temperature scale of the International System of Units (SI), the units preferred by most international scientific agencies. The Kelvin scale is based on the Celsius scale, with zero defined as the temperature at which molecular motion ceases, equal to -273.15°C .

Gas—One of the three physical states in which matter can exist; gaseous matter conforms to the shape and volume of its container.

Mole—An amount of substance containing a number of atoms or molecules equal to Avogadro's constant, 6.022×10^{23} .

Pressure—The force or weight per unit area exerted by matter on its surroundings. For calculations involving gas properties, pressure is usually measured in atmospheres (atm); other units of pressure include lb/in.², bar, torr, and mm mercury.

Standard conditions of temperature and pressure (STP)—For gases, standard conditions are 0°C and 1 atm.

Volume—The three dimensional space occupied by a substance, measured in liters (l).

Gases, properties of

Definition

The fundamental physical properties of a gas are related to its temperature, pressure, and volume. These properties can be described and predicted by a set of equations known as the **gas laws**. While these laws were originally based on mathematical interpretations for an ideal or perfect gas, modern atomic and kinetic theory of gases has led to a modified expression that more accurately reflects the properties of real gases.

Description

Current understanding of gas properties came as a result of study of the interaction between volume, pressure, and temperature. Robert Boyle was the first to describe the relationship between the volume and pressure of a gas. In 1660 he learned that if an enclosed amount of a gas is compressed to half its original volume while the temperature is kept constant, the pressure will double. He expressed this mathematically as $PV = \text{constant}$, where P stands for pressure, V stands for volume, and the value of the constant depends on the temperature and the amount of gas present. This expression is known as Boyle's law.

The second fundamental property of gases was defined by Jacques Charles in 1787. He found that the temperature and volume of a gas are directly related. Charles observed that a number of gases expanded equally as heat was applied and the pressure was kept constant.

Charles's ideas were expanded upon in research by others in the field, most notably Joseph Gay-Lussac, who also studied the thermal expansion of gases. The volume/temperature relationship is known as Charles's law.

The third property of gases was described by Gay-Lussac who, in addition to his work with volume and temperature, researched the connection between pressure and temperature. In 1802, he formulated an additional law. These three laws can be combined into one generalized equation that expresses the interrelation between pressure, temperature and volume. This equation, called the ideal gas law, is written as $PV = nRT$.

While the ideal gas law works very well in predicting gas properties at normal conditions, it does not accurately represent what happens under extreme conditions. Neither does it account for the fact that real gases can undergo phase change to a liquid form. Modern atomic theory helps explain these discrepancies. It describes molecules as having a certain freedom of motion in space. Molecules in a solid material are arranged in a reg-

ular lattice such that their freedom is restricted to small vibrations about lattice sites. Gas molecules, on the other hand, have no macroscopic spatial order, and they can move about their containers at random. The motion of these particles can be described by the branch of physics known as classical mechanics. The study of this particulate motion is known as the kinetic theory of gases. It states that the volume of a gas is defined by the position distribution of its molecules. In other words, the volume represents the available amount of space in which a molecule can move. The temperature of the gas is proportional to the average kinetic energy of the molecules, or to the square of the average velocity of the molecules. The pressure of a gas, which can be measured with gauges placed on the container walls, is a function of the particle momentum, which is the product of the mass of the particles and their speed.

Function

The human body requires certain gases to function. Oxygen and carbon dioxide are respiratory gases that move between the **blood** and air through the **lungs**. Respiratory gases are exchanged between the body and the environment through the mechanisms of convection and diffusion.

Convection is also called mass flow. Convection moves the air from the air in the environment into the lungs. Convection also moves the blood between the body tissues and the lungs. Diffusion moves the oxygen and carbon dioxide across membranes and transports gases between air and blood in the lungs and between blood and respiratory tissues in the body.

Role in human health

The gases in the human body that are most significant are oxygen and carbon dioxide. If the gases are not exchanged in the proper quantities and adequately transported through the body, then both minor and major health problems can result.

Common diseases and disorders

Many common diseases or disorders can affect the adequate exchange of gases throughout the human body. These diseases or ailments can range from severe respiratory diseases, such as **emphysema**, to the **common cold**. Both lung disease and **heart** disease can lead to abnormalities in the composition of **blood gases**. Following is a list of just a few of the diseases or disorders that can cause abnormalities in the exchange of gases in the human body.

KEY TERMS

Ideal gas law—The mathematical expression that predicts the behavior of a “perfect” gas.

Kinetic theory of gases—The physical principles that describe how gas molecules interact.

- emphysema
- chronic obstructive pulmonary disease
- congestive heart failure
- pneumonia

Gastric analysis

Definition

Gastric analysis consists of a series of tests used to analyze the contents of the **stomach**. The complete series involves:

- collecting residual gastric fluid from a fasting patient
- collecting basal secretions every 15 minutes for four hours
- intramuscular administration of a drug that stimulates gastric acid output
- collecting stomach secretions every 15 minutes for 90 minutes

The appearance, **blood**, bile, pH, volume, millimoles of H⁺ per liter, millimoles of H⁺ per volume, and

millimoles of H⁺ per hour of each specimen is then evaluated.

Purpose

A gastric analysis is performed to evaluate gastric function by measuring the contents of a fasting patient’s stomach for acidity, appearance, and volume. The basal gastric secretion test is indicated for patients with obscure gastric **pain**, loss of appetite, and weight loss. It is also utilized for suspected peptic ulcer, severe **gastritis**, and Zollinger-Ellison (Z-E) syndrome.

The gastric acid stimulation test is indicated when abnormalities are found during the basal secretion test. These abnormalities can be caused by a number of disorders, including duodenal ulcer, pernicious anemia, and gastric **cancer**. While this test will detect abnormalities, x rays and other studies are necessary to obtain a definitive diagnosis.

Precautions

Because both the basal acid output test and the gastric acid stimulation test require gastric intubation through the mouth or nasal passage, neither test is recommended for patients with esophageal problems, aortic aneurysm, severe gastric hemorrhage, or congestive **heart failure**. The gastric acid output test is also not recommended in patients who are sensitive to pentagastrin (the drug used to stimulate gastric acid output).

Description

This test, whether performed for basal gastric acid secretion, gastric acid stimulation, or both, requires gastric intubation by mouth or through the nasal passage.

Basal gastric acid secretion

The patient should be fasting overnight (12 hours) prior to intubation. After allowing approximately 10 to 15 minutes for the patient to adjust to the presence of the tube, and with the patient in a sitting position, specimens are obtained every 15 minutes for a period of 90 minutes. The first two specimens are examined visibly for blood and volume but are discarded to eliminate gastric contents that might be affected by the stress of the intubation process. The patient is allowed no liquids during the test, and saliva must be ejected to avoid diluting the stomach contents.

The final four specimens collected during the test constitute the *basal acid output*. Each sample is titrated to pH 3.5 using 0.1 N sodium hydroxide. The millimoles of hydrogen ion in each sample are calculated from the

KEY TERMS

Achlorhydria—An abnormal condition in which hydrochloric acid is absent from the secretions of the gastric glands in the stomach.

Intubation—Insertion of a tube into a body canal or hollow organ, as into the stomach.

Pernicious anemia—One of the main types of anemia, caused by inadequate absorption of vitamin B₁₂. Symptoms include tingling in the hands, legs, and feet, spastic movements, weight loss, confusion, depression, and decreased intellectual function.

Subcutaneously—Under the skin.

Zollinger-Ellison syndrome—A rare condition characterized by severe and recurrent peptic ulcers in the stomach, duodenum, and upper small intestine, caused by a tumor or tumors, usually found in the pancreas. The tumor secretes the hormone gastrin, which stimulates the stomach and duodenum to produce large quantities of acid, leading to ulceration. Most often cancerous, the tumor must be removed surgically; otherwise total surgical removal of the stomach is necessary.

amount of base used to neutralize the stomach acid of each. The results of the closest three samples are averaged and multiplied by four to give the millimoles of free hydrogen ions per hour. If analysis suggests abnormally low gastric secretion, the maximum acid output test is performed immediately afterward.

Gastric acid stimulation test

After the basal samples have been collected, the tube remains in place for the gastric acid stimulation test. Pentagastrin, or a similar drug that stimulates gastric acid output, is injected subcutaneously. After 15 minutes, a specimen is collected every 15 minutes for one hour. These specimens are called the post-stimulation specimens. As is the case with the basal gastric secretion test, the patient can have no liquids during this test, and their saliva must be ejected to avoid diluting the stomach contents. The maximal acid output (MAO) is determined by titrating each of the four specimens and averaging the results. The average is used to determine the millimoles of hydrogen ion produced per hour. Alternatively, the peak acid output (PAO) is determined by titrating each specimen and using the average hydrogen ion concentra-

tion of the highest two to calculate the acid produced in millimoles per hour.

Analyses and calculations

The appearance, blood, bile, pH, volume, millimoles of H⁺ per liter, millimoles of H⁺ per volume, and millimoles of free H⁺ per hour of each specimen are then evaluated. In addition, the basal acid output (BAO) is computed, as is the maximal acid output (MOA) or peak acid output (PAO). BAO is calculated by averaging the output of the three closest samples. MAO is calculated as the average of the four specimens. PAO is calculated by taking the mean of the two highest post-stimulation values.

Preparation

The patient should be fasting (nothing to eat or drink after the evening meal) on the day prior to the test, but may have water up to one hour before the test. **Antacids**, anticholinergics, cholinergics, alcohol, H₂-receptor antagonists (Tagamet, Pepcid, Acid, Zantac), reserpine, adrenergic blockers, and adrenocorticosteroids should be withheld for one to three days before the test, as the physician requests. If pentagastrin is to be administered for the gastric acid secretion test, medical supervision should be maintained, as possible side effects may occur.

Additionally, because such external factors as the sight or odor of food, as well as psychological stress, can stimulate gastric secretion, accurate testing requires that the patient be relaxed and isolated from all sources of sensory stimulation.

Aftercare

Such complications as nausea, vomiting, and abdominal distention or pain are possible following removal of the gastric tube. If the patient has a **sore throat**, soothing lozenges may be given. The patient may also resume the usual diet and any medications that were withheld for the test(s).

Complications

There is a slight risk that the gastric tube may be inserted improperly, entering the trachea instead of the esophagus. If this happens, the patient may experience difficulty breathing or a coughing spell until the tube is properly inserted. Also, because the tube can be difficult to swallow, if a patient has an overactive gag reflex, there may be a transient rise in **blood pressure** due to **anxiety**. Other complications may include bleeding, dysrhyth-

mias, esophageal perforation, laryngospasm and decreased mean pO₂ (a measure of blood oxygen levels).

Results

Reference values for the basal acid output test and gastric acid stimulation test vary by laboratory, but are usually within the following ranges:

- Fasting volume: 20-100 mL.
- Fasting pH: less than 2.0.
- BAO for men: 0 to 5 mmol/hour.
- BAO for women: 0 to 4 mmol/hour.
- MAO for men: 5 to 26 mmol/hour.
- MAO for women: 7 to 15 mmol/hour.

An abnormal basal acid output is considered non-specific and must be evaluated in conjunction with the results of a gastric acid stimulation test. However, elevated secretion may suggest different types of ulcers; and markedly elevated results may be suggestive of Zollinger-Ellison syndrome. Depressed secretion may indicate a gastric cancer, while complete absence of secretion (achlorhydria) may suggest pernicious anemia.

Elevated gastric secretion levels in the gastric acid stimulation test may be indicative of duodenal ulcer; highest levels of secretion suggest Zollinger-Ellison syndrome, a gastrin-secreting tumor.

Measurement of plasma gastrin by radioimmunoassay is often performed when the gastric acid level is abnormal. Frankly elevated serum gastrin levels occur in pernicious anemia and atrophic gastritis, which are both associated with low gastric acid output; and in Zollinger-Ellison syndrome, which is associated with high gastric acid output. Gastrin levels are not elevated in persons with duodenal ulcers and are normal or slightly increased in persons with gastric ulcers.

Health care team roles

A physician orders the gastric analysis and interprets the results. The testing physician must obtain an accurate patient history, especially to determine if the patient is taking any drugs that can affect the test result and to learn about any recent illness, trauma, or symptoms that could be related to gastric function. The procedure should be explained to the patient by the unit nurse, who should be aware of the degree of seriousness of the patient's condition. Gastric analysis is performed by clinical laboratory scientists/medical technologists or by clinical laboratory technicians/medical laboratory technicians.

Gastrin test see **Gastric analysis**

Gastritis

Definition

Gastritis commonly refers to inflammation of the lining of the **stomach**, but the term is often used to encompass a variety of symptoms resulting from stomach lining inflammation, as well as symptoms of burning or discomfort. True gastritis comes in several forms and is diagnosed using a combination of tests. In the 1990s scientists discovered that the main cause of true gastritis is **infection** from a bacterium called *Helicobacter pylori* (*H. pylori*).

Description

Gastritis should not be confused with common symptoms of upper abdominal discomfort. Gastritis has been associated with resulting ulcers, particularly peptic ulcers. In some cases, chronic gastritis can lead to more serious complications.

Nonerosive Helicobacter pylori (H. pylori) gastritis

The main cause of true gastritis is *H. pylori* infection. *H. pylori* is indicated in an average of 90% of persons with chronic gastritis. This form of nonerosive gastritis is the result of infection with the *H. pylori* bacterium, a microorganism whose outer layer is resistant to the normal effects of stomach acid in breaking down **bacteria**. This resistance means that the bacterium may rest in the stomach for long periods of times, even years, and eventually cause

symptoms of gastritis or ulcers when other factors are introduced, such as the ingestion of nonsteroidal antiinflammatory drugs (NSAIDs). It also seems to be activated in people with a genetic predisposition. Study of the role of *H. pylori* in development of gastritis and peptic ulcers has disproved the former belief that **stress** led to most stomach and duodenal ulcers. This understanding has resulted in improved treatment and reduction of stomach ulcers. *H. pylori* is most likely transmitted between humans, although the specific routes of transmission were still under study in 2001. Studies are also underway to determine the role of *H. pylori* and resulting chronic gastritis in the development of gastric **cancer**.

Erosive and hemorrhagic gastritis

After *H. pylori*, the second most common cause of chronic gastritis is the use of NSAIDs. These commonly used **pain** killers, including aspirin, fenoprofen, ibuprofen, and naproxen—among others—can lead to gastritis and peptic ulcers. Other forms of erosive gastritis are those due to ingestion of alcohol and corrosive agents, or due to such trauma as ingestion of **foreign bodies**.

Other forms of gastritis

Clinicians differ on the classification of the less common and specific forms of gastritis, particularly since there is so much overlap with *H. pylori* in development of chronic gastritis and complications of gastritis. Other types of gastritis that may be diagnosed include:

- Acute stress gastritis. This is the most serious form of gastritis and usually occurs in persons who are critically ill, such as those in intensive care. Stress erosions may develop suddenly as a result of severe trauma or stress to the stomach lining.
- Atrophic gastritis. This is the result of chronic gastritis that is leading to atrophy (a decrease in size and wasting away) of the gastric lining. Gastric atrophy is the final stage of chronic gastritis and may be a precursor of gastric cancer.
- Superficial gastritis. This is a term often used to describe the initial stages of chronic gastritis.
- Uncommon forms of gastritis. These are nonspecific forms of gastritis that include granulomatous, eosinophilic, and lymphocytic gastritis.

Causes and symptoms

Nonerosive H. pylori gastritis

H. pylori gastritis is caused by infection from the *H. pylori* bacterium. It is believed that most infection occurs in childhood. The route of its transmission was still under

study in 2001 and clinicians assume there may be more than one route for the bacterium to enter a body. Its prevalence and distribution differ in nations around the world. The presence of *H. pylori* has been detected in between 86% and 99% of persons with chronic superficial gastritis. However, physicians are still learning about the link between *H. pylori* and chronic gastritis and peptic ulcers, since many persons with *H. pylori* infection do not develop symptoms of gastritis or peptic ulcers. *H. pylori* is also seen in approximately 90% to 100% of people with duodenal ulcers.

Symptoms of *H. pylori* gastritis include abdominal pain and reduced acid secretion in the stomach. However, the majority of people with *H. pylori* infection suffer no symptoms, even though the infection may lead to ulcers and resulting problems. Ulcer symptoms include dull, gnawing pain, often two to three hours after meals, and pain in the middle of the night when the stomach is empty.

Erosive and hemorrhagic gastritis

The most common cause of this form of gastritis is use of NSAIDs. Other causes may be **alcoholism**, or stress from surgery or critical illness. The role of NSAIDs in development of gastritis and peptic ulcers depends upon the dosage level. Although even low doses of aspirin or other NSAIDs may cause some gastric upset, such low doses generally will not lead to gastritis. However, as many as 10%–30% of persons on higher and more frequent doses of NSAIDs, such as those with chronic arthritis, may develop gastric ulcers. As of 2001, studies were underway to determine the role of *H. pylori* in gastritis and ulcers among persons using NSAIDs.

Individuals with erosive gastritis may also experience no symptoms. When symptoms do occur, they may include anorexia nervosa, gastric pain, nausea, and vomiting.

Other forms of gastritis

Less common forms of gastritis may result from a number of generalized diseases, or from complications of chronic gastritis. Any number of mechanisms may cause various less common forms of gastritis that may differ slightly in their presentation, symptoms, and clinical signs. However, they all have in common inflammation of the gastric mucosa.

Diagnosis

Nonerosive H. pylorigastritis

H. pylori gastritis is easily diagnosed through the use of the urea breath test. This test detects the active pres-

ence of *H. pylori* infection. Other serological tests, which may be readily available in a physician's office, may be used to detect *H. pylori* infection. Newly developed versions offer rapid diagnosis. The choice of test will depend upon cost, availability, and the physician's experience, since nearly all of the available tests have an accuracy rate of 90% or better. Endoscopy, or the examination of the stomach area using a hollow tube inserted through the mouth, may be ordered to confirm diagnosis. A biopsy of the gastric lining may also be ordered.

Erosive or hemorrhagic gastritis

The patient's clinical history may be particularly important in the diagnosis of this type of gastritis, since its cause is most often the result of chronic use of NSAIDs, alcohol, or other erosive substances.

Other forms of gastritis

Gastritis that has developed to the stage of duodenal or gastric ulcers usually requires endoscopy for diagnosis. The endoscopy allows a physician to perform a biopsy for possible malignancy and for *H. pylori*. Sometimes, an upper gastrointestinal x-ray study with barium is ordered. Some diseases, such as Zollinger-Ellison syndrome, an ulcerative disease of the upper gastrointestinal tract, may show large mucosal folds in the stomach and duodenum on radiographs or in endoscopy. Other tests check for changes in gastric function.

Treatment

H. pylori gastritis

The discovery of *H. pylori*'s role in development of gastritis and ulcers has led to improved treatment of chronic gastritis. In particular, relapse rates for duodenal and gastric ulcers have been reduced with successful treatment of *H. pylori* infections. Since the infection can be treated with **antibiotics**, the bacterium can be completely eliminated up to 90% of the time.

Although *H. pylori* can be successfully treated, the treatment can be inconvenient, and relies heavily on the patient's compliance. As of 2001 studies were underway to identify the best treatment method based on simplicity, personal cooperation, and results. No single antibiotic had been found at that time that would eliminate *H. pylori*, so a combination of antibiotics is prescribed to treat the infection.

DUAL THERAPY. Dual therapy involves the use of an antibiotic and a proton pump inhibitor. Proton pump inhibitors are medications that help reduce stomach acid by halting the mechanism that pumps acid into the stomach. This combination also helps promote healing of

ulcers or inflammation. Dual therapy has not been proven to be as effective as triple therapy, but may be ordered for some people who are unable to consistently comply with the use of a larger number of medications, and who will therefore more likely follow the two-week course of therapy.

TRIPLE THERAPY. As of 2001, triple therapy was the preferred treatment for persons with *H. pylori* gastritis. It is estimated that triple therapy successfully treats between 80% and 95% of *H. pylori* cases. This treatment regimen usually involves a two-week course of three drugs. An antibiotic such as amoxicillin or tetracycline, and a second antibiotic such as clarithromycin or metronidazole, are used in combination with bismuth subsalicylate, a substance found in the over-the-counter medication Pepto-Bismol, that helps protect the lining of the stomach from acid. Physicians are experimenting with various combinations of drugs and times of treatment to balance side effects with effectiveness. Side effects of triple therapy are not serious, but may cause enough discomfort that people are not inclined to follow the treatment regimen.

OTHER TREATMENT THERAPIES. Scientists have experimented with quadruple therapy, which adds an antisecretory drug—one that suppresses gastric secretion—to the standard triple therapy protocol. One study showed this therapy to be effective with only a one-week course of treatment in more than 90% of patients. Short-course therapy was attempted with triple therapy involving antibiotics and a proton pump inhibitor, and seemed effective in eliminating *H. pylori* in one week for more than 90% of patients. The goal is to develop the most effective therapy combination that can work in a treatment period of one week or less.

MEASURING *H. PYLORI* TREATMENT EFFECTIVENESS. In order to ensure that *H. pylori* has been eradicated from the gastrointestinal tract, physicians will test persons following treatment. The breath test is, once again, the preferred method.

Treatment of erosive gastritis

Since few people with this form of gastritis show symptoms, treatment may depend upon severity of symptoms. When symptoms do occur, patients may be treated with therapy similar to that for *H. pylori*, especially since some studies have demonstrated a link between *H. pylori* and NSAIDs in causing gastric ulcers. Avoidance of NSAIDs will most likely be prescribed.

Other forms of gastritis

Specific treatment will depend upon the cause and type of gastritis. These may include prednisone or antibi-

KEY TERMS

Duodenal—Refers to the duodenum, or the first part of the small intestine.

Gastric—Relating to the stomach.

Mucosa—The mucous membrane, or the thin layer of tissue that lines many body cavities and passages.

Ulcer—A break in the skin or mucous membrane. It can fester and create exudate like a sore.

otics. Critically ill persons at high risk for bleeding may be treated with preventive drugs to reduce risk of acute stress gastritis. If stress gastritis does occur, the patient is treated with a constant infusion of a drug to stop bleeding. Sometimes surgery is recommended, but must be weighed against the possibility of surgical complications or death. Once torrential bleeding occurs in acute stress gastritis, mortality rates can exceed 60%.

Alternative treatment

Alternative forms of treatment for gastritis and ulcers should be used cautiously and in conjunction with conventional medical care, particularly now that scientists have confirmed the role of *H. pylori* in gastritis and ulcers. Such alternative treatments as diet, nutritional supplements, herbal medicine, and Ayurvedic medicine can help address gastritis symptoms. It is believed that **zinc**, **vitamin A**, and beta-carotene aid in the stomach lining's ability to repair and regenerate itself. Herbs thought to stimulate the **immune system** and reduce inflammation include echinacea (*Echinacea* spp.) and goldenseal (*Hydrastis canadensis*). Ayurvedic medicine involves **meditation**. There are also certain herbs and nutritional supplements aimed at helping to treat ulcers.

Prognosis

The discovery of *H. pylori* has improved the prognosis for persons with gastritis and ulcers. Since treatment exists with the potential to eradicate the infection, recurrence is much less common. As of 2001, people requiring treatment for *H. pylori* were those at high risk because of such factors as NSAIDs use, or those with ulcers and other complicating factors or symptoms. Research will continue into the most effective treatment of *H. pylori*, especially in light of the bacterium's resistance to certain antibiotics. Regular treatment of persons with gastric and duodenal ulcers has been recommended, since *H. pylori* plays such a consistently high role in development of ulcers. It is believed that *H. pylori* also

plays a role in the eventual development of serious gastritis complications and cancer. Detection and treatment of *H. pylori* infection may help reduce occurrence of these diseases. The prognosis for persons with acute stress gastritis is less encouraging, with a 60% or higher mortality rate among those experiencing heavy bleeding.

Health care team roles

A family physician or internist usually makes a diagnosis of gastritis, prescribes treatment, and provides follow-up testing to ascertain the effectiveness of the prescribed treatment regimen. Surgeons occasionally remove a portion of stomach when gastritis is caused by factors other than *H. pylori* or by cancer. Nurses play an important role in **patient education**, particularly in relation to medication, diet, prevention, compliance with treatment, and treatment side effects.

Prevention

The widespread detection and treatment of *H. pylori* as a preventive measure in gastritis has been discussed but not resolved. Until more is known about the routes by which *H. pylori* is spread, specific prevention recommendations cannot be made. Erosive gastritis from NSAIDs can be prevented by discontinuing the use of these drugs. In 1998 an education campaign was launched to educate people, particularly an aging population of arthritis sufferers, about the risk of ulcers from NSAIDs and alternative drugs. As of 2001 the success of this campaign had not been evaluated.

Gastroesophageal reflux scan

Definition

Gastroesophageal reflux disease (GERD) is one of the most common gastrointestinal problems among children or adults. It is defined as the movement of solid or liquid contents from the **stomach** into the esophagus. Gastrointestinal reflux imaging encompasses methods used to visualize and diagnose GERD.

Purpose

The purpose of gastroesophageal reflux scanning is to visualize the interior of the upper stomach and lower esophagus. Such inspections assist in making an accurate diagnosis and in planning appropriate treatment.

Precautions

For all tests used to evaluate GERD, persons must not have other medical complications such as high **blood pressure**, **asthma**, or esophageal varices. They should not be experiencing other acute medical conditions.

Description

A brief description of gastroesophageal reflux disease assists in understanding the scanning methods used. Gastroesophageal reflux disease is the term used to describe the symptoms and damage caused by the back-flow (reflux) of the contents of the stomach into the esophagus. Stomach contents are usually acidic. Because of their acidity, they have the potential to cause chemical **burns** in unprotected tissues such as those lining the esophagus.

Gastrointestinal reflux is common in the American population. Approximately one adult in three reports experiencing some occasional reflux, commonly referred to as heartburn. Approximately 10% of these persons experience reflux on a daily basis. Most persons have very mild disease. Occasionally, persons experience

burning as a result of reflux. This is described as reflux esophagitis when it occurs in the esophagus.

There are several causes of gastroesophageal reflux. These include the following:

- **Incompetent lower esophageal sphincter.** When the muscular sphincter that is the boundary of the esophagus and stomach relaxes, reflux can occur. This is the most common cause for gastroesophageal reflux. Reflux usually occurs when persons bend, lift a weight, or strain. Persons with esophageal strictures or Barrett's esophagus are more likely to experience gastroesophageal reflux than are others.
- **Acidic irritation.** Gastric contents are acidic, with a pH less than 3.9. Such acid is very caustic to the lining of the esophagus. Repeated exposure to acidic gastric contents leads to scarring. If the exposure is sufficiently severe or prolonged, strictures can develop. Occasionally, pancreatic enzymes or bile reflux into the stomach and lower esophagus. These contents are extremely acidic (with a pH less than 2.0).
- **Abnormal esophageal clearance.** Acid reflux is washed away by saliva that is swallowed over the course of a day. During the night, swallowing is decreased. This results in a longer contact time between acidic stomach contents and the esophagus. The net result is a chemical injury. Sjögren's syndrome, radiation to the oral cavity, and some medications (anticholinergics) also decrease the flow of saliva and can result in chemical injury. Saliva also contains bicarbonate, which neutralizes some acid content. This, too, is diminished at night, contributing to nocturnal exposure and irritation over a period of time. Other medical conditions such as Raynaud's disease and scleroderma are often associated with abnormal esophageal clearance. Hiatal hernia is present in more than 90% of persons with erosive disease.
- **Delayed gastric emptying.** When gastric outflow is obstructed or gastric motility is impaired, gastric contents do not leave the stomach in a timely manner. This enhances the opportunity for gastric reflux.

Heartburn associated with gastroesophageal reflux occurs 30 to 60 minutes after eating. It also occurs when a person reclines. Most persons who experience gastroesophageal reflux can obtain relief with baking soda (Alka-Seltzer) or antacid tablets. This pattern is often sufficient for diagnostic purposes. Under these conditions, **physical examination** and laboratory findings are usually within normal limits.

Persons with complicated GERD, or those who do not respond to the usual remedies (baking soda or antacid tablets), require special examinations. There are several

imaging methods used in the diagnosis of GERD. Details concerning each of the procedures follow.

Upper endoscopy

Upper endoscopy is the standard procedure for diagnosis, determination of the degree of tissue damage, and documentation of GERD. Between half and three-quarters of all persons with GERD will display abnormalities in their esophageal mucosa. The abnormalities include erosion, tissue fragility, and erythema. Upper endoscopy is also used to document esophageal strictures and Barrett's esophagus. Approximately half of all persons who undergo endoscopy have normal findings. Endoscopy is indicated for persons who have such symptoms as hematemesis, **iron deficiency anemia**, guaiac-positive stools, or **dysphagia**.

An **endoscope** is passed through the oral cavity into the esophagus. The mucosal lining of the esophagus, the gastroesophageal junction, and the lining of the upper portion of the stomach are visualized directly. Biopsy specimens can be obtained at the same time.

Ambulatory esophageal pH monitoring

This test provides information concerning the frequency and duration of acid reflux. It can also provide information related to the timing of episodes of reflux. It is the standard procedure for documenting abnormal acid reflux. However, it is not needed for most persons with GERD as they can be adequately diagnosed on the basis of history or by using upper endoscopy.

In this test, a tiny catheter (about 2 millimeters) with two electrodes is passed through the nose and throat. One electrode is positioned about 5 cm above the esophageal sphincter. The other electrode is positioned just below the esophageal sphincter. Data on pH are obtained every four seconds for 24 hours. Persons tested are instructed to keep a diary recording symptoms. Special emphasis is placed on coughing episodes, meal times, time of lying down for sleep, and time of rising in the morning. The electrodes are removed after 24 hours. The patients' diaries are reviewed.

Barium esophagography

A water solution containing barium is slowly swallowed. X-rays are taken during swallowing and are analyzed for signs of reflux, inflammation, dysmotility, strictures, and other abnormalities. This test can diagnose, or provide important information about, a number of disorders involving esophageal function, including craniopharyngeal achalasia (a swallowing disorder of the throat); decreased or reverse peristalsis; and hiatal hernia.

Esophageal manometry

When surgery is anticipated, esophageal manometry is useful. It provides data about esophageal peristalsis and minimum esophageal sphincter closing pressure.

Esophageal manometry measures the pressure within the esophagus. It can be used to evaluate the action of muscle waves in the main portion of the esophagus, as well as the muscular sphincter at the end of the esophagus. A thin soft tube is passed through the nose, or occasionally the mouth. Upon swallowing, the tip of the tube enters the esophagus and is positioned at the desired location. The patient then swallows air or water while a technician records the pressure at the tip of the tube.

Preparation

Upper endoscopy

Prior to the test, persons are instructed not to eat or drink for six hours. A mild sedative is usually given to calm persons who are about to be tested.

Ambulatory esophageal pH monitoring

No special preparations are needed. A short-acting anesthetic spray is sometimes used to relieve any discomfort associated with placing the electrodes.

Barium esophagography

Prior to the test, persons are instructed not to eat or drink for six hours.

Esophageal manometry

Persons are asked not to eat or drink for the eight hours prior to the test. Prior to the test, persons are instructed not to eat or drink for six hours. An anesthetic spray is often used to reduce the irritation experienced when the manometry tube is passed through the nose and oral cavity.

Aftercare

Upper endoscopy

After the test, persons must be driven home due to lingering effects of the sedative.

Ambulatory esophageal pH monitoring

There are no special steps to be taken after the electrodes have been removed.

Barium esophagography

There are no special instructions after the test.

KEY TERMS

Barrett's esophagus—An abnormal condition of the (usually) lower esophagus in which normal mucous cells are replaced by changed cells. The condition is often a prelude to cancer.

Dysphagia—Difficulty in swallowing.

Erythema—Redness.

Esophageal varices—Varicose veins at the lower-most portion of the esophagus. These are easily injured. Bleeding from esophageal varices is often difficult to stop.

Esophagus—The tube that connects the mouth to the stomach.

Hematemesis—Vomit that contains blood, usually seen as black specks in the vomitus.

pH—A measure of acidity; technically, a measure of hydrogen ion concentration.

Raynaud's disease—A disease of the arteries in hands or feet.

Reflux—Backflow, also called regurgitation.

Sjögren's syndrome—An autoimmune disorder characterized by dryness of the eyes, nose, mouth, and other areas covered by mucous membranes.

Sphincter—A physiologic valve comprised of muscle.

Esophageal manometry

There are no special instructions after the test.

Complications

Upper endoscopy

Patients may feel as if they are choking as the endoscope proceeds down the throat. Actual choking is uncommon due to sedation.

Ambulatory esophageal pH monitoring

There are no common complications.

Barium esophagography

Constipation after the test is an infrequent complication. This is routinely treated by administration of a laxative.

Esophageal manometry

Complications are very rare.

Results

Upper endoscopy

Endoscopy documents the condition of mucosa in the lower esophagus and upper stomach, evaluating the extent of GERD progression.

Ambulatory esophageal pH monitoring

Measurements of pH are used to evaluate the degree of GERD.

Barium esophagography

Barium esophagography can detect many abnormalities, including reflux.

Esophageal manometry

This documents the ability of the esophageal sphincter to close and keep stomach contents from refluxing.

Health care team roles

A family physician, pediatrician, internist, or cardiologist usually makes the initial diagnosis of GERD. A gastroenterologist usually performs the tests required for diagnosis. A radiology technologist performs the barium esophagography and a radiologist interprets it.

Gene therapy

Definition

Gene therapy is a rapidly growing field of medicine in which genes are introduced into the body to treat diseases. Genomics is the DNA which is found in an organism's total set of genes and is passed on to the offspring as information necessary for survival. Genetics is the study of the patterns of inheritance of specific traits. Genes control heredity and provide the basic biological code for determining a cell's specific functions. Gene therapy seeks to provide genes that correct or supplant the disease-controlling functions of cells that are not performing in a normal manner.

Somatic gene therapy introduces therapeutic genes at the tissue or cellular level to treat a specific individual. Germ-line gene therapy inserts genes into reproductive cells or possibly into embryos to correct genetic abnormalities that could be passed on to future generations. Initially conceived as an approach for treating inherited diseases such as **cystic fibrosis** and Huntington's disease, the scope of potential gene therapies has grown to include treatments for **cancer**, arthritis, and infectious diseases.

Description

The history of gene therapy

In the early 1970s, scientists proposed "gene surgery" for treating inherited diseases caused by abnormally functioning genes. The idea was to take out the disease-causing gene and surgically implant a gene that functioned correctly. Although sound in theory, and after some advances in science, this technique has not yet been successful.

However, in 1983, a group of scientists from Baylor College of Medicine in Houston, Texas, proposed that gene therapy could one day be a viable approach for treating Lesch-Nyhan disease, a rare neurological disorder. The scientists conducted experiments in which an enzyme-producing gene (a specific type of protein) for correcting the disease was injected into a group of cells for replication. The scientists theorized the cells could then be injected into people with Lesch-Nyhan disease, thus correcting the genetic abnormality that caused the disease.

As the science of genetics advanced throughout the 1980s, gene therapy grew in the estimation of medical scientists as a promising approach to treatments for specific diseases. One of the major reasons for the growth of gene therapy was the increasing body of knowledge

available to assist in identifying the specific genetic malfunctions that caused inherited diseases. Interest grew as further studies of DNA and chromosomes (where genes reside) showed that specific genetic abnormalities in one or more genes occurred in successive generations of certain family members who experienced diseases like intestinal cancer, manic-depression (**bipolar disorder**), **Alzheimer's disease**, **heart** disease, diabetes, and many more. Although genes may not be the only cause of the disease in all cases, they may make certain individuals more susceptible to developing a particular condition due to such environmental influences as smoking, pollution, and **stress**. In fact, some scientists theorize that all diseases may have a genetic component.

The biological basis of gene therapy

Gene therapy has grown out of the science of genetics or how heredity functions. Scientists know that life begins in a cell, the basic building block of all multicellular organisms. Humans, for instance, are made up of trillions of cells, each performing a specific function. Within each cell's nucleus (the center part of a cell that regulates its chemical functions) are pairs of chromosomes. These threadlike structures are made up of deoxyribonucleic acid (DNA), which carries the blueprint of life in the form of codes, or genes, that determine dominant or recessive inherited characteristics.

A DNA molecule looks like two ladders with one of the sides taken off both and then twisted around each other—a formation known as the double helix. The rungs of these ladders meet (resulting in a spiral staircase-like structure) and are called base pairs. Base pairs are made up of nitrogen-containing molecules and arranged in specific sequences. Millions of these base pairs, or sequences, constitute a single gene, specifically defined as a segment of the chromosome and DNA that contains certain hereditary information. The gene, or combination of genes formed by these base pairs, ultimately directs an organism's growth and characteristics through the production of certain chemicals—primarily **proteins** that carry out most of the body's chemical functions and biological reactions.

Scientists have long known that alterations in the genes present within cells may cause such inherited diseases as cystic fibrosis, sickle-cell disease, and **hemophilia**. Similarly, errors in entire chromosomes may cause such conditions as **Down syndrome** or Turner syndrome. As the study of genetics advanced, however, scientists learned that altered genetic sequences may also make people more susceptible to such diseases as atherosclerosis, cancer, and **schizophrenia**. These diseases have a genetic component, but are also influenced by

such environmental factors as diet and lifestyle. The objective of gene therapy is to treat diseases by introducing functional genes into the body to alter the cells involved in the disease process, either by replacing missing genes or by providing copies of functioning genes to replace nonfunctioning ones. The inserted genes may be naturally occurring genes that produce the desired effect or may be engineered (or altered) genes.

Scientists have known how to manipulate a gene's structure in the laboratory since the early 1970s through a process called gene splicing. The process involves removing a fragment of DNA containing a specific desired genetic sequence and then inserting it into the DNA of another gene. The resultant product is called recombinant DNA, and the process is called **genetic engineering**. This technique is used in preparing some new therapies (monoclonal antibodies, **blood** component replacements for hemophilia, antiinflammatory therapy for collagen diseases).

There are two types of gene therapy. Germ-line gene therapy introduces genes into reproductive cells (sperm and eggs) to participate in germination. Some scientists hope that it may eventually be possible to insert genes into embryos in hopes of correcting genetic abnormalities that can then be passed on to future generations. Most of the current work in applied gene therapy, however, has been in the realm of somatic therapy. In this type of gene therapy, therapeutic genes are inserted into tissue or cells to produce a naturally occurring protein or substance that is lacking or not functioning correctly in an individual.

Viral vectors

In both types of therapy, scientists need a mechanism to transport either an entire gene or a recombinant DNA to a cell's nucleus, where the chromosomes and DNA reside. In essence, vectors are molecular delivery trucks. One of the first and most widely used vectors to be developed were **viruses**, because they invade cells as part of their natural **infection** process. Viruses have the potential to be excellent vectors because they have a specific relationship with a host in that they colonize certain cell types and tissues in specific organs. As a result, vectors are chosen according to their attraction to certain cells and areas of the body.

One of the first classes of vectors used were retroviruses. Because these viruses are easily cloned (artificially reproduced) in the laboratory, scientists have studied them extensively and learned a great deal about their biologic action. They have also learned how to remove the genetic information that governs viral replication, thus reducing the chances of infection from the host vector.

Retroviruses work best in actively dividing cells, but most cells in a human body are relatively stable and do not often divide. As a result, these cells are used primarily for *ex vivo* (outside the body) manipulation. First, the cells are removed from a person's body, and the vector, or virus carrying the gene, is inserted into them. Next, the cells are placed into a nutrient culture where they grow and replicate. Once enough cells are gathered, they are returned to the body, usually by injection into the blood stream. Theoretically, as long as these cells survive, they will provide the desired therapy.

Another class of viruses, called adenoviruses, may also prove to be good gene vectors. These viruses effectively infect non-dividing cells in the body, where the desired gene product is then expressed naturally. In addition to being a more efficient approach to the problem of gene transportation, these viruses, which are known to cause respiratory infections, are more easily purified and stabilized than are retroviruses. The result is less likelihood of unintended viral infection. However, these viruses live for several days in the body, and there is some concern about the possibility of infecting other people with the viruses through sneezing or coughing. Other viral vectors include **influenza** viruses, Sindbis virus, and a herpesvirus that infects nerve cells.

Scientists have also studied nonviral vectors. These vectors rely on the natural biologic process in which cells take up (or gather) macromolecules. One approach is to use liposomes, globules of fat produced by the body and taken up by cells. Scientists are also investigating the introduction of raw recombinant DNA by injecting it into the bloodstream or placing it on microscopic beads of gold injected into the skin using air pressure. Another possible vector under development is based on dendrimer molecules. A class of polymers (naturally occurring or artificial substances that have a high molecular weight and are formed by smaller molecules of the same or similar substances) is constructed in a laboratory by combining these smaller molecules. They have been used in manufacturing styrofoam, polyethylene cartons, and Plexiglas. In the laboratory, dendrimers have shown the ability to transport genetic material into human cells. They can also be designed to form an affinity for particular **cell membranes** by attaching to certain sugars and protein groups. Much additional research must be conducted before dendrimers can be used on a routine basis.

Viewpoints

On September 14, 1990, a four-year old girl who had a genetic disorder that prevented her body from producing a crucial enzyme became the first person to undergo gene therapy in the United States. Because her body

could not produce adenosine deaminase (ADA), she had a weakened **immune system**, making her extremely susceptible to severe, life-threatening infections. W. French Anderson and colleagues at the National Institutes of Health's Clinical Center in Bethesda, Maryland, took white blood cells (which are crucial to proper immune system functioning) from the girl, inserted ADA-producing genes into them, and then transfused the cells back into the girl. Although the young girl continued to show an increased ability to produce ADA, debate arose as to whether the improvement resulted from the gene therapy or from an additional drug treatment she received.

Although gene therapy testing in humans has advanced rapidly, many questions surround its use. For example, some scientists are concerned that the therapeutic genes themselves may cause disease. Others fear that germ-line gene therapy may be used to control human development in ways not connected with disease, such as intelligence or physical appearance.

Nevertheless, a new era of gene therapy began as more and more scientists sought to conduct clinical trial (testing in humans) research in this area. In that same year, gene therapy was tested on persons with melanoma (skin cancer). The goal was to help them produce antibodies (disease fighting substances in the immune system) to battle the cancer.

The relative success of these experiments prompted a growing number of attempts at gene therapies designed to perform a variety of functions in the body. For example, a gene therapy for cystic fibrosis aims to supply a gene that alters cells, enabling people with cystic fibrosis to produce a specific protein to battle the disease. Another approach was used for people with **brain** cancer, in which the inserted gene was designed to make the cancer cells more likely to respond to drug treatment. A third gene therapeutic approach for people experiencing artery blockage, which can lead to strokes, induces the growth of new **blood vessels** (collateral circulation) near clogged arteries, thus ensuring relatively normal blood circulation.

As of 2001, there are a host of new gene-therapy agents in clinical trials. In the United States, both nucleic acid-based (*in vivo*) treatments and cell-based (*ex vivo*) treatments are being investigated. Nucleic acid-based gene therapy uses vectors (such as viruses) to deliver modified genes to target cells. Cell-based gene therapy requires removal of cells from a person, genetically altering the cells and then reintroducing them into the body of the person being treated. Presently, gene therapies for the following diseases are being studied: cystic fibrosis (using adenoviral vector), HIV infection (cell-based), **malignant melanoma** (cell-based), Duchenne **muscular**

dystrophy (cell-based), hemophilia B (cell-based), kidney cancer (cell-based), Gaucher disease (retroviral vector), **breast cancer** (retroviral vector), and **lung cancer** (retroviral vector). When a cell or individual is treated using gene therapy and successful incorporation of engineered genes has occurred, the cell or individual is said to be transgenic.

The medical establishment's contribution to transgenic research has been supported by increased government funding. In 1991, the U.S. government provided \$58 million for gene therapy research, with increases in funding of \$15-40 million dollars a year over the following four years. With fierce competition over the promise of societal benefits in addition to huge profits, large pharmaceutical corporations have moved to the forefront of transgenic research. In an effort to be first in developing new therapies, and armed with billions of dollars of research funds, such corporations are making impressive progress toward making gene therapy a viable reality in the treatment of once elusive diseases.

The Human Genome Project

Although great strides have been made in gene therapy in a relatively short time, its potential usefulness has been limited by lack of scientific data concerning the multitude of functions that genes control in the human body. For instance, it is now known that much genetic material is contained in non-coding regions. That is, they merely store information that may be used at different times in a cell's life cycle. Some of these large portions of the genome are involved in control and regulation of gene expression. Each individual cell in the body carries thousands of genes that have coding for proteins. Some experts estimate this number to be 150,000 genes. For gene therapy to advance to its full potential, scientists must discover the biologic role for each of these individual genes and identify the location on the DNA helix for each of the base pairs that comprise them.

To address this issue, the National Institutes of Health initiated the Human Genome Project in 1990. Led by Dr. James Watson (one of the co-discoverers of the chemical makeup of DNA) the project's 15-year goal is to map the entire human genome (a combination of the words gene and chromosome). A genome map would clearly identify the location of all genes as well as the more than three billion base pairs that comprise them. With a precise knowledge of gene locations and functions, scientists may one day be able to conquer or control diseases that have plagued humanity for centuries.

Scientists participating in the Human Genome Project have identified an average of one new gene a day, but many expect this rate of discovery to increase. In

February of 2001, scientists published a rough draft of the complete human genome. With fewer than the anticipated number of genes found, between 30,000 and 40,000, the consequences of this announcement are potentially profound. Scientists caution, however, that the initial publication is only a draft of the human genome, and much more work is still ahead for the completion of the project. By the year 2005, their goal is to determine the exact location of all the genes on human DNA and the exact sequence of the base pairs that make them up. Some of the genes identified through this project include a gene that predisposes people to **obesity**; one associated with programmed cell death (apoptosis); a gene that guides HIV viral reproduction; and the genes of inherited disorders like Huntington's disease, amyotrophic lateral sclerosis (Lou Gehrig's disease), and some colon and breast cancers. As the human genome is completed, more information will be available for gene therapy research and implementation.

Professional implications

Diseases targeted for treatment by gene therapy

The potential scope of gene therapy is enormous. More than 4,200 diseases have been identified as resulting directly from non-functioning or abnormal genes, and countless others that may be partially influenced by a person's genetic makeup. Initial research has concentrated on developing gene therapies for diseases whose genetic origins have been established and for other diseases that can be cured or ameliorated by substances genes produce.

The following are examples of potential gene therapies. People with cystic fibrosis lack a gene needed to produce a salt-regulating protein. This protein regulates the flow of chloride into epithelial cells, (the cells that line the inner and outer skin layers) that cover the air passages of the nose and **lungs**. Without this regulation, people with cystic fibrosis have a buildup of thick mucus in their lungs. In turn, this mucus makes these patients prone to lung infections and respiratory problems, and usually leads to death within the first 29 years of life. A gene therapy technique to correct this abnormality might employ an adenovirus to transfer a normal copy of what scientists call the cystic fibrosis transmembrane conductance regulator (CTRF) gene. The gene is introduced into a person by spraying it into the nose or lungs.

Familial hypercholesterolemia (FH) is also an inherited disease, resulting in the inability to process cholesterol properly, which leads to high levels of artery-clogging fat in the bloodstream of even the youngest family members. Persons with FH often suffer heart attacks and strokes because of blocked arteries. A gene therapy

approach used to address FH is much more intricate than most gene therapies because it involves partial surgical removal of persons' livers (*ex vivo* transgene therapy). Corrected copies of a gene that acts to reduce cholesterol build-up are inserted into the **liver** sections, which are then transplanted back into the people.

Gene therapy has also been tested on persons with acquired immune deficiency syndrome (**AIDS**). AIDS is caused by the human **immunodeficiency** virus (HIV), which weakens the body's immune system to the point that people with the condition are unable to fight off such diseases as **pneumonia** and cancer. In one approach, genes that produce specific HIV proteins have been altered to stimulate immune system functioning without causing the negative effects that a complete HIV molecule has on the immune system. These genes are then injected in a person's blood stream. Another approach to treating AIDS is to insert, via white blood cells, genes that have been genetically engineered to produce a receptor that would attract HIV and reduce its chances of replicating. As of 2001, these approaches are experimental and have not been approved for treatment.

Several cancers also have the potential to be treated with gene therapy. A therapy tested for melanoma, a progressive, aggressive skin cancer, would introduce a gene with an anticancer protein called tumor necrosis factor (TNF) into test tube samples of a person's own cancer cells, which are then reintroduced into the person's body. In brain cancer, the approach is to insert a specific gene that increases the cancer cells' susceptibility to a common drug used in fighting the disease.

Gaucher disease is an inherited disease caused by a mutant gene that inhibits the production of an enzyme called glucocerebrosidase. Persons with Gaucher disease have enlarged livers (hepatomegaly) and spleens (splenomegaly). Clinical gene therapy trials will focus on inserting the gene for producing the missing enzyme.

Gene therapy is also being considered as an approach to solving a problem associated with a surgical procedure known as balloon **angioplasty**. In this procedure, a stent (a piece of tubular material resembling a straw) is used to open the clogged artery. However, in a "fail-safe" response to the trauma of the stent insertion, the body initiates a natural healing process that produces too many cells in the artery and results in restenosis or reclosing of the artery. The gene therapy approach to preventing this unwanted side effect is to cover the outside surfaces of an inserted stent with a soluble gel containing vectors for genes that may reduce an overactive healing response.

The future of gene therapy

Gene therapy seems elegantly simple in its concept: supply the human body with a gene that can correct a biologic malfunction causing a disease. However, there are many obstacles and some distinct questions concerning the viability of gene therapy. For example, viral vectors must be carefully controlled lest they infect a person with a viral disease. Some vectors, like retroviruses, can also enter normally functioning cells and interfere with natural biologic processes, possibly leading to other diseases. Other viral vectors, such as adenoviruses, are often recognized and destroyed by the immune system so their therapeutic effects are short-lived. Maintaining gene expression so that it performs its role properly after vector delivery is difficult. As a result, some therapies need to be repeated often to provide long-lasting benefits.

One of the most pressing issues, however, is gene regulation. Genes work in concert to regulate their functioning. In other words, several genes may play a part in turning other genes on and off. For example, certain genes work together to stimulate **cell division** and growth; but if these are not regulated, the inserted genes could cause tumor formation and cancer. Another difficulty is learning how to make the gene go into action only when needed. For the best and safest therapeutic effort, a specific gene should turn on, for example, when certain levels of a protein or enzyme are low and must be replaced. But the gene should also remain dormant when not needed to ensure that it does not oversupply a substance and disturb the body's delicate chemical balance.

One approach to gene regulation is to attach other genes that detect certain biologic activities and then react as a type of automatic off-and-on switch, regulating the activity of other genes according to biologic cues. Although still in the rudimentary stages, researchers are making progress in inhibiting some gene functioning by using a synthetic DNA to block gene transcriptions (the copying of genetic information). This approach may have applications for gene therapy.

The ethics of gene therapy

While gene therapy holds promise as a revolutionary approach for treating disease, ethical concerns over its use and ramifications have been expressed by scientists and lay people alike. For example, since much needs to be learned about how these genes actually work and their long-term effects, is it ethical to test these therapies on humans, in whom they could have a disastrous result? As with most clinical trials concerning new therapies, including many drugs, the people participating in these studies have usually not responded to more established

KEY TERMS

Cells—The smallest living units of the body that carry a full complement of the DNA, and which group together to form tissues and help the body perform specific functions.

Chromosome—Threadlike structures in a cell that carry most of the genetic material in the form of DNA and genes.

Clinical trial—The testing of a drug or some other type of therapy in a specific human population.

Clone—A cell or organism derived through asexual (without sex) reproduction, and which contains the identical genetic information of the parent cell or organism.

DNA (deoxyribonucleic acid)—The specific molecules that comprise chromosomes and genes.

Embryo—The earliest stage of development of the zygote before the human or animal is considered a fetus (which is usually the point at which the embryo takes on the basic physical form of its species). Embryos are formed *in vivo* (*in utero*) or *in vitro* (in a laboratory) in preparation for implantation.

Enzyme—A type of molecule made by cells that, when released, facilitates chemical reactions in the body.

Eugenics—A social movement in which the population of a society, country, or the world is to be improved by selective mating, controlling the passage of hereditary information.

Gene—A specific biologic component found in the cell nucleus that carries the instructions for the formation of an organism and its specific traits, such as eye or hair color.

Gene transcription—The process by which genetic information is copied from DNA to RNA, resulting in a specific protein formation.

Genetic engineering—The manipulation of genetic material to produce specific results in an organism.

Genetics—The study of hereditary traits passed on through genes.

Genome—The total set of genes carried by an individual or cell.

Genomics—The DNA which is found in the organism's total set of genes carried by an individual or cell and is passed on to offspring as information necessary for survival.

Germ-line gene therapy—The introduction of genes (natural or engineered) into reproductive cells or embryos to correct inherited genetic abnormalities that can cause disease by replication.

Liposome—Fat organelle made up of layers of lipids.

Macromolecule—A large molecule composed of thousands of atoms.

Nitrogen—An element that is a component of the base pairs in DNA.

Nucleus—The central part of a cell that contains most of its genetic material, including chromosomes and DNA.

Protein—Macromolecule made up of long sequences of amino acids. Proteins comprise the dry weight of most cells and are involved in structures, hormones, and enzymes in muscle contraction, immunological response, and many other functions essential to life.

Somatic gene therapy—The introduction of genes into tissue or cells to treat a genetic-related disease in an individual.

Vector—Something used to transport genetic information to a cell.

therapies and are often so ill that the novel therapy is their only hope for long-term survival.

Another questionable outgrowth of gene therapy is that scientists could potentially manipulate genes to control traits in human offspring that are not related to health. For example, perhaps a gene could be inserted to ensure that a child would not be bald, a seemingly harmless goal. However, what if genetic manipulation were

used to alter skin color, prevent homosexuality, or ensure good looks? If a gene is found that can enhance intelligence of children who are not yet born, will all members of society have access to the technology, or will it be so expensive that only the elite can afford it?

The Human Genome Project, which plays such an integral role for the future of gene therapy, also has social repercussions. If individual genetic codes can be deter-

mined, will such information be used against people? For example, will someone more susceptible to a disease have to pay higher insurance premiums or be denied health insurance altogether? Will employers discriminate between two potential employees, one with a healthy genome and the other with genetic abnormalities?

Some of these concerns can be traced back to the eugenics movement that was popular in the first half of the twentieth century. This genetic philosophy was a societal movement that encouraged people with so-called positive traits to reproduce while those with less desirable traits were sanctioned from having children. Eugenics was used to pass strict immigration laws in the United States, barring less suitable people from entering the country lest they reduce the quality of the country's collective gene pool. Probably the most notorious example of eugenics in action was the rise of Nazism in Germany, which fostered the Eugenic Sterilization Law of 1933. The law required sterilization for those with certain disabilities and even for some persons who were simply deemed to be unattractive. To ensure that this novel science is not abused, many governments have established organizations specifically for overseeing the development of gene therapy. In the United States, the Food and Drug Administration and the National Institutes of Health require scientists to take a precise series of steps and meet stringent requirements before approving clinical trials.

In fact, gene therapy has been immersed in more controversy and is surrounded by more scrutiny from both the health care and ethics communities than most other technologies (except, perhaps, for cloning) that have the potential to substantially change society. Despite the health and ethical questions surrounding gene therapy, the field will continue to grow and is likely to change medicine more quickly than any previous medical advancement.

Genetic counseling

Definition

Genetic counseling is a communication process by which personal genetic risk information is translated into practical information for families. Genetic counselors are health care professionals with specialized training and experience in the areas of medical genetics and counseling. Genetic counselors are able to assist individuals and families by:

- Helping people to understand information about birth defects or genetic disorders. This includes explaining patterns of inheritance, recurrence risks, natural history of diseases, and **genetic testing** options.
- Providing nondirective supportive counseling regarding emotional issues related to a diagnosis or testing options.
- Helping individuals and families make decisions with which they are comfortable, based on their personal ethical and religious standards.
- Connecting individuals and families with appropriate resources, such as support groups or specific types of medical clinics, locally and nationally.

Purpose

There are several purposes or aspects to be addressed within the scope of genetic counseling. These include obtaining a pedigree; tracing ethnicity; exploring issues of consanguinity; and documenting exposures to toxins, diseases, or environmental agents during **pregnancy**.

Pedigree

In all types of genetic counseling, an important aspect of the counseling process is information gathering about family and medical history. Information gathering is performed by drawing a chart called a pedigree. A pedigree is made of symbols and lines that represent a family history. To accurately assess the risk of inherited diseases, information about three generations of the fam-

ily, including health status and cause of death, is usually needed. If a family history is complicated, information from more distant relatives may be helpful, and **medical records** may be requested for any family members who have had a genetic disorder. Thorough examination of a family history may enable a counselor to calculate the probability of occurrence of genetic disorders in the future.

Ethnicity

In obtaining a family history, a genetic counselor asks about a person's ethnicity or ancestral origin. There are some ethnic groups that have a higher chance of being carriers of some genetic diseases or abnormalities. For instance, the chance that an African American is a carrier of a gene for **sickle cell disease** is one in 10. People of Jewish or central European ancestry are likely to be carriers of several conditions, including Tay-Sachs disease, Canavan's disease and **cystic fibrosis**. People of Mediterranean ancestry are likely to be carriers of a type of anemia called thalassemia. Genetic counselors discuss inheritance patterns of these diseases, carrier risks, and genetic screening or testing options.

Consanguinity

Another question a genetic counselor asks in obtaining a family history is whether the couple are related to one another by **blood**. The practice of marrying or having children with relatives is infrequent in the United States, but is more common in some countries. When two people are related by blood, there is an increased chance for their children to be affected with conditions that are inherited in a recessive pattern. In recessive inheritance, each parent of a child affected with a disease carries a single gene for a disease. The child gets two copies, one from each parent, and is affected. People who have a common ancestor are more likely than unrelated people to be carriers of genes for the same recessively inherited disorders. Depending on family history and ethnic background, blood tests can be offered to couples to get more information about the chance of these conditions occurring.

Exposures during pregnancy

During prenatal genetic counseling, the counselor will ask about pregnancy history. If a woman has taken medications or has had exposure to a potentially harmful substance from the environment such as a chemical, toxin, or radiation, the genetic counselor can discuss the possibility of adverse effects. Ultrasound is often a useful tool to look for some effects of exposure.

Precautions

There are no physical precautions that are needed before genetic counseling. However, persons who will receive the results of genetic tests should be prepared mentally and emotionally for the possibility of unpleasant information. This includes discussing if they want to know the results of genetic testing and what choices they may have to make based on the information supplied.

Description

Types of genetic counseling

Genetic counselors work with people concerned about the risk of an inherited disease or condition. These people represent several different populations. Prenatal genetic counseling is provided to couples that have an increased risk of birth defects or inherited conditions, and are expecting a child or planning a pregnancy. Pediatric genetic counseling is provided to families with children suspected of having a genetic disorder or with children previously diagnosed with a genetic disorder. Adult genetic counseling is provided to adults with clinical features of an inherited disease or a family history of an inherited disease. **Cancer** genetic counseling is provided to those with a strong family history of certain types of cancer. Ethics are an important component of genetic counseling.

Prenatal genetic counseling

There are several different reasons a person or couple may seek prenatal genetic counseling. If a woman is age 35 or older and pregnant, there is an increased chance that her fetus may have a change in the number of chromosomes present. Changes in chromosome number may lead to mental retardation and birth defects. **Down syndrome** is the most common change in chromosome number that occurs proportionally more often in the fetuses of older women. Couples may seek prenatal genetic counseling because of abnormal results of screening tests performed during pregnancy. A blood test called the alpha fetal protein (AFP) test is offered to all pregnant women. This blood test screens for Down syndrome, open spine defects (spina bifida), and another type of mental retardation caused by a change in chromosome number called trisomy 18. When this test is abnormal, further tests are offered to get more information about the chance of these conditions actually occurring in the fetus. Another reason that people seek prenatal genetic counseling is a family history of birth defects or inherited diseases. In some cases, blood tests of the parents may be available to indicate if their children would be at risk of being affected. Genetic counselors assess risk in each case, help persons

to understand their risks, and explore how they feel about or will cope with these risks.

Prenatal tests that are offered during genetic counseling include level II ultrasounds, maternal serum AFP screening, **chorionic villus sampling (CVS)**, and **amniocentesis**. Level II ultrasound is a detailed ultrasound surveying fetal anatomy for birth defects. Ultrasound is limited to detection of structural changes in anatomy and cannot detect changes in chromosome number. The maternal serum AFP screening is used to indicate if a pregnant woman has a higher or lower chance of having a child with certain birth defects. This test can only provide information concerning the probability of a birth defect. The screening cannot diagnose an actual birth defect. CVS is a way of learning how many chromosomes are present in a fetus. A small piece of placental tissue is obtained for these studies during the tenth to twelfth weeks of pregnancy. Amniocentesis is also a way of learning how many chromosomes are present in a fetus. Amniotic fluid is obtained for these studies, usually between 15 and 20 weeks of pregnancy. There is a small risk of **miscarriage** associated with both of these tests. Genetic counseling regarding these procedures involves the careful explanation of benefits and limitations of each testing option. A genetic counselor also tries to explore how persons feel about prenatal testing and the impact of such testing on the pregnancy. Genetic counselors are supportive of any decision a person makes about whether or not to have prenatal tests performed.

Pediatric genetic counseling

Families or pediatricians seek genetic counseling when a child has features of an inherited condition. Any child who is born with more than one birth defect; mental retardation; or dysmorphic features has an increased chance of having a genetic syndrome. A common type of mental retardation in males for which genetic testing is available is Fragile X syndrome. Genetic testing is also available for many other childhood illnesses such as **hemophilia** and **muscular dystrophy**. Genetic counselors work with medical geneticists to determine if a genetic syndrome is present. This process includes a careful examination of family history, medical history of the child, review of pertinent medical records in the family, a **physical examination** of the child, and sometimes blood work or other diagnostic tests. If a diagnosis is made, then a medical geneticist and genetic counselor review what is known about the inheritance of the condition, the natural history of the condition, treatment options, further examinations that may be needed for health problems common in the diagnosed syndrome, and resources for helping the family. The genetic counselor also helps the family adjust to the diagnosis by pro-

viding emotional support and counseling. Many families are devastated by receiving a diagnosis, learning of the likely outcome for the child and by the loss of the hoped for healthy child. There would also be a discussion about recurrence risks in the family and who else in the family may be at risk.

Adult genetic counseling

Adults may seek genetic counseling when a person in the family decides to be tested for the presence of a known genetic condition; when an adult begins exhibiting symptoms of an inherited condition; or when there is a new diagnosis of someone with an adult-onset disorder in the family. In addition, the birth of a child with obvious features of a genetic disease leads to diagnosis of a parent who is more mildly affected. Genetic counseling for adults may lead to the consideration of presymptomatic genetic testing. Testing a person to determine the likelihood for a condition existing before any symptoms occur is an area of controversy. Huntington's disease is an example of a genetic disease for which presymptomatic testing is available. This is a neurological disease resulting in **dementia**. Onset of the condition is between 30 and 50 years of age. Huntington's disease is inherited in an autosomal dominant pattern. If a person has a parent with the disease, the risk of being affected is 50%. Would presymptomatic testing relieve or create **anxiety**? Would a person benefit from removal of doubt about being affected? Would knowing about the condition help a person with life planning? Genetic counselors help people sort through their feelings about such testing and whether or not the results would be helpful to them.

Cancer genetic counseling

A family history of early onset breast, ovarian, or colon cancer in multiple generations of a family is a common reason a person would seek a genetic counselor who works with people who have cancer. While most cancer is not inherited, there are some families in which a dominant gene is present and causing the disease. A genetic counselor is able to discuss the chances that the cancer in the family is related to a dominantly inherited gene. The counselor can also discuss the option of testing for the breast and ovarian cancer genes, BRCA1 and BRCA2. In some cases the persons seeking testing have already had cancer but others have not. Therefore, presymptomatic testing is also an issue in cancer genetics. Emotional support is important for these people, as they have often lost close relatives from cancer and are fearful of their own risks. For families in which a dominant form of cancer is detected through genetic testing, a plan can be made for increased surveillance of disease symptoms.

Ethical issues in genetic counseling

Prenatal diagnosis of anomalies or chromosomal abnormalities may lead to a decision about whether or not a couple wishes to continue a pregnancy. Some couples choose to continue a pregnancy. Prenatal diagnosis gives them additional time to emotionally prepare for the birth of the child and to gather resources. Others choose not to continue a pregnancy in which problems have been diagnosed. These couples have unique emotional needs. Often the child is a very much desired addition to the family and parents are devastated that the child is not healthy. Presymptomatic testing for adult-onset disorders and cancer raises difficult issues regarding the need to know and the reality of dealing with abnormal results before symptoms occur. The National Society of Genetic Counselors has created a Code of Ethics to guide genetic counselors in caring for people. The Code of Ethics consists of four ethical principles:

- **Beneficence** is the promotion of personal well-being in others. The genetic counselor is an advocate for the person being counseled.
- **Non-maleficence** is the concept of doing no harm to a person.
- **Autonomy** is recognizing the value of an individual, the person's abilities and point of view. Important aspects of autonomy are truthfulness with persons, respecting confidentiality, and practicing **informed consent**.
- **Justice** is providing equal care for all, freedom of choice, and providing a high quality of care.

The main ethical principle of genetic counseling is the attempt to provide nondirective counseling. This principle again points to an individual-centered approach to care by focusing on the thoughts and feelings of each person. Five percent of the Human Genome Project budget is designated for research involving the best way to deal with ethical issues that arise as new genetic tests become available. Genetic counselors can help people navigate through the unfamiliar territory of genetic testing.

Preparation

Persons should be apprised of possible outcomes and given the opportunity to discuss their feelings prior to undergoing genetic tests. There is a burden associated with knowing the probability of a future outcome. Difficult decisions may be required as a result of learning genetic information through testing. The process of adequately preparing an individual for genetic counseling is called informed consent. Ethical genetic counselors always obtain informed consent prior to undertaking any genetic tests.

Aftercare

Persons must be provided access to competent counselors and therapists. Such professionals can assist in processing the feelings and reactions that may emerge as a result of receiving the findings of genetic tests.

Complications

The complications that arise from the process of genetic counseling are most commonly mental and emotional. Individuals and couples who have received genetic counseling often experience mental changes such as depression and anguish when they receive unfavorable results about tests. Complications include the need to make difficult decisions regarding themselves, their families, or their unborn children. This is also referred to as a burden of knowing, meaning that likely but unwanted outcomes may become known before they occur. Depending on the condition, personal preferences and situation, persons may elect to continue with a pregnancy that is likely to result in a child with one or more abnormalities, terminate a pregnancy, select a different partner, or decide not to have children. These are all difficult situations that may require the assistance and intervention of a trained mental health counselor or therapist.

Results

The results given to a person during genetic counseling are highly individualized and depend on the nature of tests being performed and the issues of importance to the person being counseled.

The results of the process of genetic counseling vary. Genetic counseling offers information to people, thereby allowing them to make informed choices. Some of the options may not be easy or pleasant to contemplate. However, they are based on hard data rather than on wishes, hopes, or some other non-scientific basis. Genetic counselors have an ethical duty to obtain informed consent from individuals prior to beginning genetic counseling, provide unbiased information and the ability to interact in a non-judgmental or coercive manner.

Health care team roles

Genetic counselors are specially trained members of a health care team who have a master's degree in genetic counseling. They receive referrals from obstetricians, pediatricians, family physicians, and other doctors. They interpret the results of tests from laboratory personnel, medical geneticists, and pathologists. They refer people to therapists and counselors for assistance in resolving issues that arise from the process of genetic counseling.

KEY TERMS

Canavan disease—A serious genetic disease more common among the Eastern European Jewish population that causes mental retardation and early death. Canavan disease is caused by the lack of an enzyme called aspartoacylase.

Cystic fibrosis—A respiratory disease characterized by chronic lung disease, pancreatic insufficiency, and an average age of survival of 29 years. Cystic fibrosis is caused by mutations in a gene on chromosome seven that encode a transmembrane receptor.

Dysmorphic feature—A subtle change in appearance such as low set ears or a flattened nasal bridge that suggests a genetic syndrome may be present.

Fragile X syndrome—The most common inherited cause of mental retardation in males. People with Fragile X syndrome often have large ears, a long face, hyperextensible finger joints, hyperactivity or autism. Fragile X syndrome is caused by an expansion in a gene on the X chromosome. Some females are also affected.

Human Genome Project—An international collaborative project among scientists to map the genetic sequence of all the chromosomes. This project is funded by the National Institute of Health in the United States.

Informed consent—Provision of complete information to a competent individual regarding a treatment or test. Part of informed consent is to ensure a person's understanding of the advantages and disadvantages of a procedure and to obtain voluntary authorization to perform the procedure.

Sickle-cell anemia—A chronic, inherited blood disorder characterized by crescent-shaped red blood cells. It occurs primarily in people of African descent, and produces symptoms including episodic pain in the joints, fever, leg ulcers, and jaundice.

Tay-Sachs disease—A genetic disease affecting young children of eastern European Jewish descent. This disease is caused by the lack of an enzyme called hexosaminidase A. This deficiency results in mental retardation, convulsions, blindness and, finally, death.

Thalassemia—An inherited group of anemias occurring primarily among people of Mediterranean descent. It is caused by abnormal formation of part of the hemoglobin molecule.

Genetic engineering

Definition

Genetic engineering involves altering the genetic structure of embryonic cells or vectors to provide them with desired traits or to eliminate undesirable traits.

Description

For thousands of years, humans have engaged in primitive forms of genetic engineering. They have chosen plants or animals with survival strength and desirable characteristics for further breeding, and have combined different strains of a species in attempts to retain and emphasize desirable characteristics of both. But in the 1970s, the field of genetic engineering took a quantum technologic leap when researchers developed a technique known as recombinant DNA, or gene splicing, enabling them to directly alter the genetic code and sequence of cells. This development transformed genetic engineering

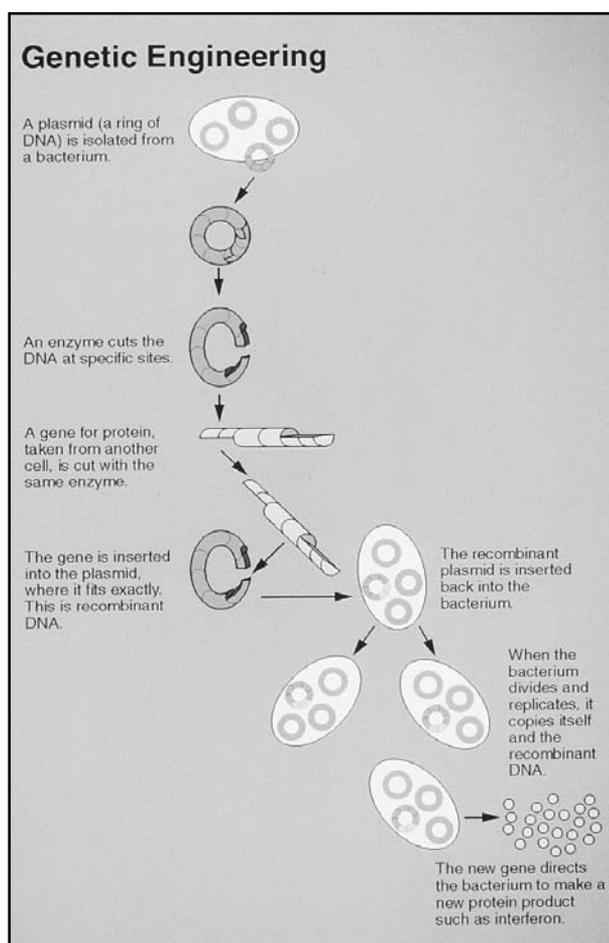

in medicine, food production, and industry. Engineered **bacteria** are even being used to take the place of standard microchip circuitry for computers.

Genes, which are composed of molecules of DNA, determine the physical characteristics that make organisms unique. Gene splicing, which involves introducing new genes into an organism in order to produce new characteristics, is performed in a number of ways. Sometimes a DNA “gun” is used to shoot genes directly into cells such as plant cells. When a gene cannot be directly “cut and pasted” from one organism to another, it may be placed in a harmless bacterium that duplicates repeatedly, acting as a “gene factory.” The bacteria are then used to ferry the genes into cells.

A sheep named Dolly, born in 1997, was produced using a genetic engineering technique known as cloning. Here, scientists replaced the genetic material from one ewe’s egg with genetic material from another ewe, producing an animal genetically unrelated to its surrogate mother. Hundreds of animals have been cloned, including bulls, cows, mice, monkeys, and pigs. Even clones of clones have been produced. Cloning is used to produce laboratory test animals with specific disease-related characteristics. Areas of cloning research range from cloning cows and sheep to produce medicines in their milk, to using cloning to preserve endangered species such as the Indian cheetah and the Asian guar.

Genetic engineering techniques are used to produce several widely used drugs. In addition to the hormone insulin, used to treat some forms of diabetes, these techniques are now used to produce the following: interferon, an antiviral and anticancer drug; tissue plasminogen activator (tPA), which dissolves **blood** clots; erythropoetin, which stimulates red blood-cell production; a hepatitis B vaccine; and others. In food production, genetic engineering can produce tomatoes with a longer shelf life; as well as crops with insect, herbicide, frost, and virus resistance. It is used to increase milk production in dairy cows, and to increase the size and infection-resistance of farmed fish like salmon. In addition, genetically altered bacteria have been used to decompose garbage and petroleum products.

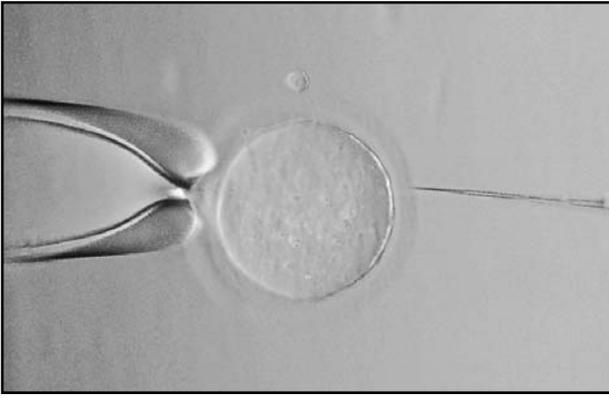

Despite all its advances, the field of genetic engineering is still in its infancy. Now that researchers have mapped much of the human genome (or DNA blueprint), and some of the genes and their mutations responsible for genetic disorders like **cystic fibrosis** have been found, the next challenge is to understand **proteins**. These are the most complex of all known molecules. Each of the body’s genes carries the code to create many different proteins (peptides), which are essentially the workers that carry out the DNA instructions. Understanding how mes-

Many steps are required to make recombinant DNA and final products such as interferon. (National Institutes of Health. Reproduced by permission.)

senger proteins work is essential to preventing or curing disease. This will be a major focus of research over the next decade.

Promising areas of genetic engineering include human **gene therapy** and stem-cell research. Gene therapy involves repairing or replacing mutated genes in order to correct the malfunctions in protein production that can lead to disease. The use of gene therapy is being researched for diseases such as **cancer, muscular dystrophy, hemophilia B**, heart disease, and severe combined immune deficiency disease (known as “bubble boy disease”), among others. Stem cells are the undifferentiated cells from which specialized embryonic cells develop. They are considered one of science’s best hopes for curing disease. Modified stem cells may one day be used to replace diseased cells affecting function throughout the body’s systems. These cells also play an important role in tissue engineering, which involves the manufacture of blood products; artificial skin products; and bio-

Animal cell being microinjected with foreign genetic material. (Photograph by M.Baret/RAPHU. National Audubon Society Collection/Photo Researchers, Inc. Reproduced by permission.)

genetic replacement of organs, **blood vessels**, and cartilage. Other examples of genetic engineering research range from the manufacture of bananas engineered to contain vaccines (to eliminate the challenge of cold vaccine storage in developing countries) to coffee plants that have been altered to “switch off” **caffeine** before the beans even start growing.

Viewpoints

Genetic engineering is controversial and has led to many protests regarding the potential of short- and long-term health and environmental risks. Stem-cell research is particularly controversial. Stem cells have traditionally been culled from aborted fetuses or from embryos left behind after successful **fertility treatments**, or they are produced using cloning technology. Many fear that using stem-cell research to cure genetic disorders or produce body tissues will eventually lead to the process being used to enhance or improve humans, a practice known as positive eugenics, termed by opponents as the “search for the master race.” It is feared that altering human genomes may have unknown consequences for future generations that inherit the changes. Some individuals, including James Watson, co-discoverer of DNA’s double-helix structure, are not opposed to altering DNA to make human “improvements.”

The primary concerns with genetic engineering in plants are that a transferred gene could migrate unintentionally via pollen scattering from a transgenic plant to a related species and alter the ecosystem, or that a plant designed to kill a particular pest could end up killing beneficial insects like bees and butterflies. Transgenic plants could also interbreed with weeds, producing weeds resistant to herbicides. Allergens from one food

KEY TERMS

Cloning—The production of an organism that is genetically identical to its parent.

Deoxyribonucleic acid (DNA)—The genetic material of all cellular organisms and most viruses. DNA carries the information needed to direct proteins. Each molecule of DNA consists of two twisted strands, called a double helix.

Eugenics—A practice involving use of genetic principles to “improve” humankind.

Gene—The basic unit of hereditary traits found in the cells of all living organisms, from bacteria to humans. Genes determine the physical characteristics that an organism inherits, such as hair and eye color.

Human Genome Project—An international scientific collaboration that seeks to identify and clarify the entire human genetic blueprint.

Protein—A molecule made of a sequence of amino acids. Proteins are the most common organic molecules in living organisms and among the most complex.

Recombinant DNA—DNA that has been altered by joining genetic material from two different sources. It usually involves putting a gene from one organism into the genome of a different organism.

Stem cells—The undifferentiated cells from which specialized embryonic cells develop.

crop, such as peanuts, can be transferred to another through genetic engineering. Animal-rights groups have argued that genetically engineered fish may cause problems if they interbreed with unaltered fish, which may change the characteristics of wild fish. The use of bovine growth hormone to increase dairy-cow milk production is also controversial, with critics questioning its safety for both cows and the humans who consume the milk.

Professional implications

The advances in genetic engineering require health care practitioners to consider their responsibilities in handling genetic information. As genetics advances are incorporated into tools for primary health care delivery, the use of genetic assessment testing will expand in medical practice. Health care practitioners, including nurses and allied-health professionals, will need a functional

understanding of the potential ethical, legal, and social issues involved with such tests; special attention must be paid to disclosures for **informed consent**, and medical-record confidentiality. A statement on the Scope and Standards of Genetics Clinical Nursing Practice has been published by the American Nurses Association to guide nurses in their practice of genetic-based health care.

Genetic studies see **Genetic testing**

Genetic testing

Definition

A genetic test examines the genetic information contained inside a person's cells, called DNA, to determine if that person has or will develop a certain disease or could transmit a disease to a child. Genetic tests also determine whether or not couples are at a higher risk than the general population for having a child affected with a genetic disorder.

Purpose

Some families or ethnic groups have a higher incidence of a certain disease than do the population as a whole. For example, individuals of Eastern European, Ashkenazi Jewish descent are at higher risk for carrying genes for rare conditions such as Tay-Sachs disease (a lipid storage disease) that occur much less frequently in populations from other parts of the world. Before having a child, a couple from such a family or ethnic group may want to know if their child would be at risk of having that disease. Genetic testing for this type of purpose is called genetic screening.

During **pregnancy**, a baby's cells can be studied for certain genetic disorders or chromosomal problems such as **Down syndrome**. Chromosome testing is most commonly offered when a mother is 35 years or older at the time of delivery. When there is a family medical history of a genetic disease or there are individuals in a family affected with developmental and physical delays, genetic testing may also be offered during pregnancy. Genetic testing during pregnancy is called prenatal diagnosis.

Prior to becoming pregnant, couples who are having difficulty conceiving a child or who have had multiple miscarriages may be tested to see if a genetic cause can be identified.

A genetic disease may be diagnosed at birth by performing a physical evaluation of the baby and observing characteristics of the disorder. Genetic testing can help to confirm the diagnosis made by a physical evaluation. In addition, biochemical tests (e.g., **blood** phenylalanine measurement) are performed routinely on all newborns to screen for certain genetic diseases that can affect a newborn baby's health shortly after birth.

There are several genetic diseases and conditions in which the symptoms do not occur until adulthood. One such example is Huntington's disease. This is a serious disorder affecting the way in which individuals walk, talk and function on a daily basis. Genetic testing may be able to determine if someone at risk for the disease will in fact develop the disease.

Some genetic abnormalities may make a person more susceptible to certain types of **cancer**. Testing for these abnormalities can help predict a person's risk. Other types of genetic tests help diagnose, predict, and monitor the course of certain kinds of cancer, particularly leukemia, lymphoma, and **breast cancer**.

Precautions

Genetic tests are performed on cells derived from blood, bone marrow, amniotic fluid, or tissues. The

health care worker collecting the specimen should observe **universal precautions** for the prevention of transmission of bloodborne pathogens. Because genetic testing is not always accurate and because there are many concerns surrounding insurance and employment discrimination for an individual receiving a genetic test, **genetic counseling** should always be performed prior to genetic testing. A genetic counselor is an individual with a master's degree in genetic counseling. A medical geneticist is a physician specializing and board certified in genetics.

A genetic counselor reviews a person's family history and **medical records** and the reason for the test. The counselor explains the likelihood that the test will detect all possible causes of the disease in question (known as the sensitivity of the test), and the likelihood that the disease will develop if the test is positive (known as the positive predictive value of the test).

Learning about the disease in question, the benefits and risks of both a positive and a negative result, and what treatment choices are available if the result is positive, will help prepare a person undergoing testing. During the genetic counseling session, an individual interested in genetic testing will be asked to consider how the test results may affect his or her life, family, and future decisions.

After this discussion, persons should have the opportunity to indicate, in writing, that they gave **informed consent** to have the test performed, verifying that the counselor provided complete and understandable information.

Description

Genes and chromosomes

Deoxyribonucleic acid (DNA) is a long molecule made up of two strands of genetic material coiled around each other in a unique double helix structure. Francis Crick and James Watson discovered this structure in 1953. Each strand of DNA consists of a backbone of deoxyribose sugars linked together by phosphate groups. Each sugar is bound (with a covalent bond) to one of four bases, adenine, guanine, thymine or cytosine. The two strands are held together by hydrogen bonds between the bases. Adenine pairs with thymine and guanine pairs with cytosine.

Most of the DNA is found in the nucleus of the cell. Each person's DNA is a unique blueprint, giving instructions for that person's physical traits, such as eye color, hair texture, height, and susceptibility to disease. DNA is organized into structures called chromosomes.

The instructions are contained as a code spelled out by the order of the four bases in each of the strands of DNA. When a base pair is out of order, or is missing, then cells may not produce an important protein or may produce an abnormal protein resulting in a genetic disorder. While genes are found in every nucleated cell of the human body, not every gene is functioning all of the time. Some genes are turned on during critical points in development and then remain silent for the rest of a cell's life. Other genes remain active throughout life so that cells can produce important **proteins** that help humans digest food properly or fight off the **common cold**.

In the human genome there are 3.1 billion bases and approximately 100,000 genes. Approximately 95% of DNA consists of non-coding regions called introns. The remaining 5% consists of coding regions called exons, which are the structural units that form genes. Within the exon, the specific order of the base pairs on a strand of DNA dictates the order of amino acids that comprise the protein made when the gene is transcribed and translated. A grouping of three sequential base pairs within the exon is called a codon. Each codon, or triplet, codes for an amino acid. These are added in tandem to form a protein. A string of many codons together can be thought of as a series of words all coming together to make a sentence. This sentence provides the instructions for cells to make a protein that is needed in order for the body to function properly.

Human DNA strands containing a hundred to several thousand genes are found on structures called chromosomes. Each cell typically has 46 chromosomes arranged into 23 pairs. Each parent contributes one chromosome to each pair. The first 22 pairs are called autosomal chromosomes, or non-sex chromosomes and are assigned a number from one to 22. The last pair are the sex chromosomes and include the X and the Y chromosomes. If a child receives an X chromosome from each parent, the child is female. If a child receives an X from the mother, and a Y from the father, the child is male.

Just as each parent contributes one chromosome to each pair, so each parent contributes one gene from each chromosome. The pair of genes produces a specific trait in the child. In autosomal dominant conditions, it takes only one copy of a gene to influence a specific trait. The stronger gene is called dominant; the weaker gene is said to be recessive. Two copies of a recessive gene are needed to express a trait while only one copy of a dominant gene is needed. Some genes, (for example, those coding for blood groups) exhibit codominant expression. In this case, both genes are active and produce traits. Human sex chromosomes, the X and the Y also contain important genes. Some genetic diseases are caused by missing or altered genes on one of the sex chromosomes. Males are

most often affected by sex chromosome diseases when they inherit an X chromosome with missing or mutated genes from their mothers.

Types of genetic mutations

Genetic disease results from a change, or mutation, in a chromosome or in one of several base pairs on a gene. Some people inherit such mutations from their parents. These are called hereditary or germline mutations. Other mutations can occur spontaneously, or for the first time in an affected child. For many of the adult on-set diseases, genetic mutations can occur over the lifetime of an individual. These are called acquired or somatic mutations and occur while cells are making copies of themselves or dividing in two. Environmental effects, such as radiation or other chemicals, can also contribute to these types of mutations.

There are a variety of different types of mutations that can occur in the genetic code to cause disease. For each genetic disease, there may be more than one type of mutation to cause the disease. For some genetic diseases, the same mutation occurs in every individual affected with the disease. For example, the most common form of dwarfism, called achondroplasia, is caused by a single base pair substitution. This same mutation occurs in all individuals affected with the disease. Other genetic diseases are caused by different types of genetic mutations that may occur anywhere along the length of a gene. For example, **cystic fibrosis**, the most common genetic disease in the Caucasian population, is caused by any of several hundred different gene mutations. Individual families may carry the same mutation as each other, but not as the rest of the population affected with the same genetic disease.

Some genetic diseases occur as a result of a larger mutation that can occur when a chromosome itself is either rearranged or altered or when a baby is born with more than the expected number of chromosomes. There are only a few types of chromosome rearrangements that are possibly hereditary, or passed on from the mother or the father. The majority of chromosome alterations, where a baby is born with too many chromosomes or missing a chromosome, occur sporadically or for the first time with a new baby.

The type of mutation that causes a genetic disease will determine the type of genetic test to be performed. In some situations, more than one type of genetic test will be performed to arrive at a diagnosis. The cost of genetic tests vary. Chromosome studies can cost hundreds of dollars and some gene studies, thousands. Insurance coverage also varies among companies and the policies. It may take several days or several weeks to complete a

test. Research testing, when the exact location of a gene has not yet been identified, can require several months to years for results.

Types of genetic testing

DIRECT DNA MUTATION ANALYSIS. Direct DNA sequencing examines the base pair sequence of a gene for specific mutations. Some genes contain more than 100,000 bases and a mutation of any one base can make the gene nonfunctional and cause disease. As the number of possible mutations increases, the less likely a test is able to detect all of them. DNA sequencing is a research tool that is used to identify the order of bases in cloned genes. Base sequencing identifies the specific mutation. Once this is known a DNA probe can be made that recognizes the mutation. DNA probes typically contain 20-60 bases to insure that they bind only to the specific mutation site. DNA testing for disease genes is usually performed on white blood cells but can also be performed on other tissues.

There are several different lab techniques used to test for a direct mutation. One early approach begins by using chemicals to separate DNA from the rest of the cell. Special enzymes (called restriction enzymes) are added to the DNA. The enzymes then function like scissors and cut the strands in specific places. Next, the DNA fragments are separated by size using a process called electrophoresis. The fragments are treated chemically to separate them into single stranded fragments and transferred to a nylon filter, a process called Southern blotting. The DNA probe is added to the fragments. The probe is designed to bind to the specific mutated portion of the gene. The probe is labeled with a radioactive isotope. When the probe hybridizes with the target sequence containing the mutation, it will render this piece of DNA on the filter radioactive. The radioactivity will expose a piece of x-ray film layered over the nylon filter, and the mutation will appear as a band in the expected location.

When only small quantities of DNA are available, as in prenatal diagnosis, the target DNA from the fetal cells must first be amplified. This is accomplished by a method known as the polymerase chain reaction. This procedure can copy a specific sequence of DNA that frames the gene to be tested. Up to one million copies can be made in as little as two hours.

INDIRECT DNA TESTING. Family linkage studies are performed to study a disease when the exact type and location of the genetic alteration is not known but the general location on the chromosome has been identified. These studies are possible when a chromosome marker has been found to be associated with a disease. Chromosomes contain certain regions that vary in appearance between individuals. These regions are called

A scientist examines a DNA sequencing autoradiogram on a light box. Each group of four strips represents the nucleotide sequence of ACGT (Adenine-Guanine-Cytosine-Thymine) in the DNA of the nematode worm, *Onchocerca volvulus*, a human parasite responsible for river blindness in tropical countries. (Photo Researchers, Inc. Reproduced by permission.)

polymorphisms and do not cause a genetic disease to occur. If a polymorphism is always present in family members with the same genetic disease, and absent in family members without the disease, it is likely that the gene responsible for the disease is near that polymorphism. The gene mutation can be indirectly detected in family members by looking for the polymorphism.

To look for the polymorphism, DNA is isolated from cells in the same way it is for direct DNA mutation analysis. A restriction enzyme known to cut the DNA at the site where the polymorphism occurs is added. If the polymorphism is present, the restriction enzyme will not recognize the site and will not cut the DNA there. This results in a larger size fragment of DNA. If sufficient DNA is present, the fragments can be separated by electrophoresis, and the DNA bands are stained with ethidium bromide to visualize the position of the bands. If the amount of DNA is small, the double stranded fragments can be separated and a DNA probe can be used to determine whether the polymorphism is present. The pattern of banding of a person being tested for the disease is compared to the pattern from a family member affected by the disease.

Linkage studies have disadvantages not found in direct DNA mutation analysis. These studies require multiple family members to participate in the testing. If key family members choose not to participate, the incomplete family history may make testing other members useless. The indirect method of detecting a mutated gene also causes more opportunity for error, and many disease genes are not associated with polymorphisms.

CHROMOSOME ANALYSIS. Various genetic syndromes are caused by structural chromosome abnormali-

ties. To analyze a person's chromosomes, cells are allowed to grow and multiply in the laboratory until they reach a certain stage of growth. The length of growing time varies with the type of cells. Cells from blood and bone marrow take one to two days, fetal cells from amniotic fluid require seven to 10 days.

When the cells are ready, they are placed on a **microscope** slide using a technique to make them swell, allowing easier visualization of chromosomes. The slides are stained. The stain creates a banding pattern unique to each chromosome. Under a microscope, the chromosomes are counted, identified, and analyzed based on their size, shape, and stained appearance.

A karyotype is the final step in the chromosome analysis. After the chromosomes are counted, a photograph is taken of the chromosomes from one or more cells as seen through a microscope. Then the chromosomes are cut out and arranged side-by-side with their partner in ascending numerical order, from largest to smallest. The karyotype is done either manually or using a computer attached to the microscope. Chromosome analysis is also called cytogenetics.

Applications for genetic testing

NEWBORN SCREENING. Genetic testing is used most often for newborn screening. Every year, millions of newborn babies have their blood samples tested for potentially serious genetic diseases. Phenylketonuria is the genetic disease test most commonly performed.

CARRIER TESTING. An individual who has a gene associated with a disease but never exhibits any symptoms of the disease is called a carrier. A carrier is a person who is not affected by a possessed mutated gene, but can pass the gene to an offspring. Genetic tests have been developed that tell prospective parents whether or not they are carriers of certain diseases. If one or both parents are carriers, the risk of passing the disease to a child can be predicted.

To predict the risk, it is necessary to know if the gene in question is autosomal or sex-linked. If the gene is carried on any one of chromosomes one through 22, the resulting disease is called an autosomal disease. If the gene is carried on the X or Y chromosome, it is called a sex-linked disease.

Sex-linked diseases, such as the bleeding condition **hemophilia**, are usually carried on the X chromosome. A woman who carries a disease-associated mutated gene on one of her X chromosomes has a 50% chance of passing that gene to her son. A son who inherits that gene will develop the disease because he does not have another normal copy of the gene on a second X chromosome to

compensate for the abnormal copy. A daughter who inherits the disease associated gene from her mother, on one of her X chromosomes will become a carrier and be at risk for having a son affected with the disease.

The risk of passing an autosomal disease to a child depends on whether the gene is dominant or recessive. A prospective parent carrying a dominant gene, has a 50% chance of passing the gene to a child. A child needs to receive only one copy of the mutated gene to be affected by the disease.

If the gene is recessive, a child needs to receive two copies of the mutated gene, one from each parent, to be affected by the disease. When both prospective parents are carriers, their child has a 25% chance of inheriting two copies of the mutated gene and being affected by the disease; a 50% chance of inheriting one copy of the mutated gene and being a carrier of the disease but not affected; and a 25% chance of inheriting two normal genes. When only one prospective parent is a carrier, a child has a 50% chance of inheriting one mutated gene and being an unaffected carrier of the disease, and a 50% chance of inheriting two normal genes.

Cystic fibrosis is a disease that affects the **lungs** and **pancreas** and is discovered in early childhood. It is the most common autosomal recessive genetic disease found in the Caucasian population: one in 25 people of Northern European ancestry are carriers of a mutated cystic fibrosis gene. The gene, located on chromosome seven, was identified in 1989.

The gene mutation for cystic fibrosis is detected by a direct DNA test. Over 600 mutations of the cystic fibrosis gene have been identified. Each of these mutations cause the same disease. Tests are available for the most common mutations. Tests that check for the 86 most common mutations in the Caucasian population will detect 90% of carriers for cystic fibrosis. The percentage of mutations detected varies according to an individual's ethnic background. When persons test negative, it is likely, but not guaranteed that they do not have the gene. Both prospective parents must be carriers of the gene to conceive a child with cystic fibrosis.

Tay-Sachs disease, also autosomal recessive, affects children primarily of Ashkenazi Jewish descent. Children with this disease die between the ages of two and five. This disease was previously detected by looking for a missing enzyme. The mutated gene has now been identified and can be detected using direct DNA mutation analysis.

PRESYMPTOMATIC TESTING. Not all genetic diseases show their effect immediately at birth or early in childhood. Although the gene mutation is present at birth, some diseases do not appear until adulthood. If a specif-

ic mutated gene responsible for a late-onset disease has been identified, a person from an affected family can be tested before symptoms appear.

Huntington's disease is one example of a late-onset autosomal dominant disease. Its symptoms of mental confusion and abnormal body movements do not appear until middle to late adulthood. The chromosome location of the gene responsible for Huntington's chorea was located in 1983 after studying the DNA from a large Venezuelan family affected by the disease. Ten years later, the gene was identified. A test is now available to detect the presence of the expanded base pair sequence responsible for causing the disease. The presence of this expanded sequence means a person will develop the disease.

Another late onset condition, **Alzheimer's disease**, is not as well understood as Huntington's disease. The specific genetic cause of Alzheimer's disease is not as clear. Although many cases appear to be inherited in an autosomal dominant pattern, many cases exist as single incidents in a family. Like Huntington's disease, symptoms of mental deterioration first appear in adulthood. Genetic research has found an association between this disease and genes on four different chromosomes. The validity of looking for these genes in a person without symptoms or without family history of the disease is still being studied.

CANCER SUSCEPTIBILITY TESTING. Cancer can result from an inherited (germline) mutated gene or a gene that mutated sometime during a person's lifetime (acquired mutation). Some genes, called tumor suppressor genes, produce proteins that protect the body from cancer. If one of these genes develops a mutation, it is unable to produce the protective protein. If the second copy of the gene is normal, its action may be sufficient to continue production, but if that gene later develops a mutation, the person is vulnerable to cancer. Other genes, called oncogenes, are involved in the normal growth of cells. A mutation in an oncogene can cause too much growth, the beginning of cancer.

Direct DNA tests are currently available to look for gene mutations identified and linked to several kinds of cancer. People with a family history of these cancers are those most likely to be tested. If one of these mutated genes is found, the person is more susceptible to developing the cancer. The likelihood that the person will develop the cancer, even with the mutated gene, is not always known because other genetic and environmental factors are also involved in the development of cancer.

Cancer susceptibility tests are most useful when a positive test result can be followed with clear treatment options. In families with familial polyposis of the colon, testing a child for a mutated APC gene can reveal

whether or not the child needs frequent monitoring for the disease. In families with potentially fatal familial medullary thyroid cancer or multiple endocrine neoplasia type two, finding a mutated RET gene in a child provides the opportunity for that child to have preventive removal of the **thyroid gland**. In the same way, MSH1 and MSH2 mutations can reveal which members in an affected family are vulnerable to familiar **colorectal cancer** and would benefit from aggressive monitoring.

In 1994, a mutation linked to early-onset familial breast and ovarian cancer was identified. BRCA1 is located on chromosome 17. Women with a mutated form of this gene have an increased risk of developing breast and ovarian cancer. A second related gene, BRCA2, was later discovered. Located on chromosome 13, it also carries increased risk of breast and ovarian cancer. Although both genes are rare in the general population, they are slightly more common in women of Ashkenazi Jewish descent.

When a woman is found to have a mutation of one of these genes, the likelihood that she will get breast or ovarian cancer increases, but not to 100%. Other genetic and environmental factors may also influence the outcome.

Testing for these genes is most valuable in families where a mutation has already been found. BRCA1 and BRCA2 are large genes; BRCA1 includes 100,000 bases. More than 120 mutations to this gene have been discovered, but a mutation could occur in any one of the bases. Studies show tests for these genes may miss 30% of existing mutations. The rate of missed mutations, the unknown disease likelihood in spite of a positive result, and the lack of a clear preventive response to a positive result, make the value of this test for the general population uncertain.

PRENATAL AND POSTNATAL CHROMOSOME ANALYSIS. Chromosome analysis is usually performed on fetal cells when a mother will be age 35 or older at the time of delivery, has experienced multiple miscarriages, or reports a family history of a genetic abnormality. Prenatal testing is done on the fetal cells from a **chorionic villus sampling** (from the baby's developing placenta) at nine to 12 weeks of gestation or from the amniotic fluid (the fluid surrounding the baby) at 15-18 weeks of pregnancy. Cells from amniotic fluid usually must grow for seven to 10 days before they are ready to be analyzed. Chorionic villi cells have the potential to grow faster and can be analyzed sooner.

Chromosome analysis using blood cells is performed for a child who is born with or later develops signs of mental retardation or physical malformation. In an older child, chromosome analysis may be requested to investigate developmental delays.

Extra or missing chromosomes cause mental and physical abnormalities. A child born with an extra chromosome 21 (trisomy 21) has Down syndrome. An extra chromosome 13 or 18 also produces well known syndromes. A missing X chromosome causes Turner syndrome and an extra X in a male causes Klinefelter syndrome. Other abnormalities are caused by extra or missing pieces of chromosomes. Fragile X syndrome is a sex-linked disease, causing mental retardation in males.

Chromosome material may also be rearranged, such as the end of chromosome 1 moved to the end of chromosome 3. This is called a chromosomal translocation. If no material is added or deleted in the exchange, a person may not be affected. Such an exchange, however, can cause **infertility** or abnormalities if passed to children.

Evaluation of a couple's infertility or repeated miscarriages will include blood studies of both to check for a chromosome translocation. Many chromosome abnormalities are incompatible with life. Fetuses with these abnormalities often spontaneously abort during the first trimester. Cells from a fetus that died before birth can be studied to look for chromosome abnormalities that may have caused the death.

CANCER DIAGNOSIS AND PROGNOSIS. Certain cancers, particularly leukemia and lymphoma, are associated with changes in chromosomes: extra or missing complete chromosomes, extra or missing portions of chromosomes, or exchanges of material (translocations) between chromosomes. Studies show that the locations of the chromosome breaks are at locations of tumor suppressor genes or oncogenes.

Chromosome analysis on cells from blood, bone marrow, or a solid tumor help to diagnose certain kinds of leukemia and lymphoma and often help predict how well a person will respond to treatment. After treatment has begun, periodic monitoring of these chromosome changes in the blood and bone marrow gives a physician information as to the effectiveness of the treatment.

A well-known chromosome rearrangement is found in chronic myelogenous leukemia. This leukemia is associated with an exchange of material between chromosomes 9 and 22. The resulting smaller chromosome 22 is called the Philadelphia chromosome.

Preparation

Most tests for genetic diseases of children and adults are done using blood. To collect the 5-10 mL of blood needed, a health care worker draws blood from a vein in the inner elbow region. Collection of the sample takes only a few minutes.

Prenatal testing is done either on amniotic fluid or a chorionic villus sampling. To collect amniotic fluid, a physician performs a procedure called **amniocentesis**. An ultrasound is done to find the baby's position and an area filled with amniotic fluid. The physician inserts a needle through the woman's skin and the wall of her uterus and withdraws 5-10 mL of amniotic fluid. Placental tissue for a chorionic villus sampling is taken through the cervix. Each procedure takes approximately 30 minutes.

Bone marrow is used for chromosome analysis in a person with leukemia or lymphoma. The person is given **local anesthesia**. Then the physician inserts a needle through the skin and into the bone (usually the hip bone). A sample (0.5 to 2.0 mL) of bone marrow is withdrawn. This procedure takes approximately 30 minutes.

Aftercare

After blood collection, a person may feel discomfort or bruising at the puncture site or may become dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

The chorionic villi sampling, amniocentesis and bone marrow procedures are all done under a physician's supervision. A person to be tested is asked to rest after the procedure and is watched for weakness and signs of bleeding.

Complications

Collection of amniotic fluid and chorionic villi share the risks of **miscarriage**, **infection**, and bleeding. The risks are higher for the chorionic villi sampling. Because of the potential risks for miscarriage, 0.5% following the amniocentesis and 1% following chorionic villi sampling procedure, both of these prenatal tests are offered to couples, but are not required. A woman should tell her physician immediately if she has cramping, bleeding, fluid loss, an increased temperature, or a change in the baby's movement following either of these procedures.

After bone marrow collection, the puncture site may become tender and a person's temperature may rise. These are signs of a possible infection.

Genetic testing involves other nonphysical risks. Many people fear the possible loss of privacy about personal health information. Results of genetic tests may be reported to insurance companies and affect a person's insurability. Some people pay out-of-pocket for genetic tests to avoid this possibility. Laws have been proposed to deal with this problem. Other family members may be affected by the results of a person's genetic test. Privacy of the person test-

KEY TERMS

Autosomal disease—A disease caused by a gene located on chromosomes 1 through 22.

Carrier—A person who has a disease-causing gene but does not show symptoms of that disease.

Chromosome—Structures made up of DNA, on which genes are located.

DNA (Deoxyribonucleic acid)—A long molecule made up of two strands of material coiled around each other in a unique double helix. DNA contains the blueprint for all of a person's traits.

Dominant gene—A gene, whose presence as a single copy, controls the expression of a trait.

Enzyme—A protein produced in a cell.

Gene—A grouping of base pairs that give instruction for a specific trait.

Karyotype—Visual comparison of chromosomes arranged side-by-side with their partner in ascending numerical order, from largest to smallest.

Mutation—Any change in the sequence of DNA.

Positive predictive value (PPV)—The probability that a person with a positive test result has, or will develop a disease or condition.

Recessive gene—A gene that must be present in both copies of the gene pair to allow the expression of a trait.

Sensitivity—The likelihood that a negative test means a person will not have the disease or a mutation.

Sex-linked disorder—A disorder caused by a gene located on a sex chromosome, usually the X chromosome.

ed and the family members affected is a consideration when deciding to have a test and to share the results.

A positive result carries a psychological burden, especially if the test indicates a person will develop a disease, such as Huntington's chorea. The news that a person may be susceptible to a specific kind of cancer, while it may encourage positive preventive measures, may also negatively shadow many future decisions and activities.

A genetic test result may also be inconclusive, meaning no definitive result can be given to the individual or family. This may cause an individual to feel more anxious and frustrated and experience psychological difficulties.

Prior to undergoing genetic testing, genetic counselors should inform individuals to be tested about the likelihood that the test could miss a mutation or abnormality.

Results

Normal results

A normal result for chromosome analysis is 46, XX or 46, XY. This means there are 46 chromosomes (including two X chromosomes for a female or one X and one Y for a male) with no structural abnormalities. A normal result for a direct DNA mutation analysis or linkage study is the absence of gene mutations.

There can be some benefits from genetic testing when an individual tested is not found to carry a genetic mutation. Those who learn with great certainty they are no longer at risk for a genetic disease may choose not to undergo prophylactic therapies and may feel less anxious and relieved.

Abnormal results

An abnormal chromosome analysis report will include the total number of chromosomes and will identify the abnormality found. Tests for gene mutations will report the mutations found.

There are many ethical issues to consider with an abnormal prenatal test result. Many of the diseases tested for during a pregnancy cannot be treated or cured. In addition, some diseases tested for during pregnancy may have a late-onset of symptoms or have minimal effects on an affected individual.

Before making decisions based on an abnormal test result, a person should meet again with a genetic counselor to fully understand the meaning of the results, learn what options are available based on the test result, and what are the risks and benefits of each of those options.

Health care team roles

A family physician or obstetrician often makes an initial recommendation for genetic counseling. A physician specially training in the technique will perform bone marrow aspiration, amniocentesis, or chorionic villus sampling. A nurse or phlebotomist usually collects blood samples. A cytogenetic technologist or clinical laboratory scientist/medical technologist will perform the DNA test depending upon the type of testing requested. A pathologist or geneticist processes and interprets findings of tests. Genetic counselors interpret test results and discuss options. Members of the clergy often assist people who have been tested to make decisions based on test results.

Genital culture

Definition

Genital culture is the use of enrichment and selective media to isolate and identify organisms that cause genital infections such as urethritis, cervicitis, and salpingitis (pelvic inflammatory disease). The primary reason for a genital culture is to isolate *Neisseria gonorrhoeae*, the causative agent of gonorrhea. Other organisms that cause genital infections and can be cultured are *Gardnerella vaginalis*, *Candida albicans*, *Neisseria meningitidis*, *Haemophilus ducreyi*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*.

Purpose

Genital culture is performed on persons who have signs of abnormal discharge or skin lesions in the genital area, or complaints such as itching or **pain** on urination. It is performed on persons who have evidence of other sexually transmitted diseases for which culture is not routinely performed because of the high prevalence of concomitant **infection**. For example, there are approximately three million new cases of *Chlamydia trachomatis* infection in the United States each year and many infected persons also will test positive for *N. gonor-*

rhoeae. Genital culture is also performed on any person who may be a victim of a sexual assault. Genital culture may be performed as a screening test on patients who have no symptoms, but are at increased risk for infection because of sexual behavior, since many sexually transmitted diseases can be carried silently. Also, pre and postnatal genital cultures for gonococcus and group B streptococcus are performed routinely on obstetrical patients.

Although most genital infections are sexually transmitted, children or elderly persons are also at risk. In children, skin or wound infections may cause vaginal or urethral infections, especially when there has been physical injury to the genital area. Persons with deficient immune function and persons on prolonged antibiotic treatments are more susceptible to vaginal yeast infections (e.g., *Candida albicans* or *Torulopsis glabrata* infection). Abscesses may form in the pelvic area and Bartholin's gland following **pregnancy**, abortion, malignancy, obstetrical procedures, obstruction, and other conditions, and these often involve anaerobic **bacteria**.

Precautions

Some infections, particularly gonorrhea, can be difficult to culture. In males it may be necessary to culture other sites that may be infected, such as the anus and mouth, if the patient has corresponding sexual habits which put him at risk. Up to 35% of males and 50% of females who are positive for gonococcal infection will test positive for *Chlamydia trachomatis*. This organism as well as *Treponema pallidum*, the causative agent of **sypilis**, *Trichomonas vaginalis*, human **immunodeficiency** virus, cytomegalovirus, herpes simplex 2, and human papilloma virus are not generally cultured. Because of their high prevalence, tests for these organisms (i.e., immunoassays, DNA probes, tests for antibodies) may also be performed. When performing genital cultures, **universal precautions** for prevention of transmission of bloodborne pathogens must be observed.

Description

Neisseria gonorrhoeae causes approximately 650,000 genital infections in the United States each year. If untreated, gonorrhea can result in permanent damage to the reproductive organs (pelvic inflammatory disease), gonococcal arthritis, skin infection, and neonatal conjunctivitis (when transmitted via pregnancy).

The female patient will be in the dorsal lithotomy position typical for Pap testing. A speculum is moistened with warm water (no lubricant should be used) and inserted into the vagina to secure good visualization of

KEY TERMS

Group B streptococcus—A serotype of *Streptococcus*, *Streptococcus agalactiae*, which is beta hemolytic and can cause neonatal sepsis, pneumonia, or meningitis if present in the birth canal at the time of delivery especially when the delivery is difficult.

Os—The opening of the cervix, which is the mouth of the uterus.

the cervix. Any excess cervical mucous should be removed with a cotton ball (held by ring forceps). A sterile cotton swab is inserted just inside the opening of the cervix (the os) and rotated gently for 30 seconds. Genital swabs are usually placed in transport media that contains charcoal to absorb toxins that inhibit the growth of gonococcus.

Care should be taken not to touch the vaginal surfaces with the swab in order to avoid the transfer of normal vaginal flora. For culture, the sample is placed in Stuart's or Amies transport medium with charcoal added and delivered to the laboratory at room temperature. For DNA probe testing (in which organisms are not cultured, but the presence or absence of their genetic material is confirmed) the swab is broken off at the top of the sterile tube provided, and the tube is capped and sent to the laboratory. For immediate viewing, a swab sample may be placed in normal saline. One drop can then be placed between a slide and coverslip, and viewed beneath the **microscope**. This is called a "wet prep." A wet prep is useful for diagnosing yeast infection and trichomoniasis. Pelvic inflammatory disease samples and samples from genital lesions such as chancres are collected by aspiration. Plating for *H. ducreyi* should be done from the chancre aspirate and performed immediately because the organism is fastidious.

In the male patient, a smaller sterile cotton swab is used to remove cells and any discharge from the last 2 cm of the urethra, and the swab is transported for culture or DNA probe testing as described for the female patient. If visible discharge is present on the surface of the penis, this should be swabbed, and it is unnecessary to enter the urethra. If prostate infection is suspected, **urine culture** should be performed. If infection of the prostate, epididymus or testes is suspected, seminal fluid should be cultured.

All swabs or aspirates are plated on modified Thayer-Martin (MTM) agar or New York City (NYC) agar. These media are selective for the growth of *N. gonorrhoeae*.

orrhoae. MTM is chocolate agar (heated sheep **blood** agar) containing colistin to inhibit the growth of gram negative bacilli, nystatin, or anisomycin to inhibit yeast, vancomycin to inhibit growth of gram-positive bacteria, and trimethoprim to inhibit *Proteus spp.* NYC agar contains amphotericin B instead of nystatin and consists of clear proteose-peptone supplemented agar. In addition, the sample is plated on either 5% sheep blood agar or Columbia agar with 5% sheep blood and colistin and nalidixic acid (CNA) to isolate yeast and *Gardnerella vaginalis*. In addition, special selective and differential agar may be used to isolate *Mycoplasma hominis* and *Ureaplasma urealyticum*. Plates are incubated at 36°C in 5-10% carbon dioxide. MTM or NYC agar are examined for growth at 24 hours and if negative again at 48 hours. After 24 hours, any suspicious colonies are Gram-stained and tested for oxidase, which provides presumptive identification of *Neisseria* if positive. Further biochemical testing may be performed to differentiate *N. gonorrhoeae* from *N. meningitidis* which is sometimes isolated from homosexual males. Isolated colonies should also be tested for penicillin resistance. Plates may be discarded at 48 hours if no growth is seen. Other plates are observed at 24 hours, and any suspicious colonies are isolated and tested biochemically to identify the organism. No growth or negative plates are held an additional 24 hours. Anaerobic cultures are performed on abscesses and by request. Pathogens other than *N. gonorrhoeae* are also tested for antibiotic susceptibility.

Microscopic analysis should always be included with genital culture. Wet preparations can identify both yeast and *Trichomonas vaginalis*. A **Gram stain** of the swab material can identify gram-negative diplococci, which is presumptive evidence of gonococcal infection. In males, a positive finding on the Gram stain obviates the need for culture and the patient can begin antibiotic treatment. In females, the diplococci must be located intracellularly in order to make a presumptive diagnosis of gonorrhea infection, and culture must be performed to confirm the diagnosis. The presence of clue cells, epithelial cells containing gram-negative or gram-variable coccobacilli, can signal the presence of *Gardnerella vaginalis*. In homosexual males engaging in anal intercourse, microscopic examination may reveal *Giardia lamblia* or *Entamoeba histolytica* which originated in the intestinal tract.

For both male and female patients, urine tests for the DNA of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* are available. These tests measure bacterial DNA that is amplified either by the ligase chain reaction (LCR) or the polymerase chain reaction (PCR). Both methods can detect the organisms within four hours, thus affording for more rapid treatment. However, the tests do not

detect any other genital tract pathogens that might be present in the patient.

Preparation

Male patients can improve the accuracy of test results by not urinating for one hour prior to testing. Females should avoid douching for at least 24 hours prior to testing. If one of the DNA tests is to be used, it may be preferable to collect the first urine sample of the day. Women should be informed that having cultures performed is no more uncomfortable than routine Pap testing. Men may experience some temporary discomfort. It is much preferable that these tests be done before any **antibiotics** are started, so that the growth of the causative agent is not suppressed.

Aftercare

Patients should be instructed to have no sexual contacts until test results are back.

Complications

The minor discomforts of genital testing are short lived, and no significant complications are common.

Results

A normal result would be no growth of pathologic organisms, or no evidence of infectious organisms on DNA probe or LCR assay. Any infection identified, or organisms seen, can be appropriately treated and the patient counseled regarding prevention, if the causative agent is transmitted sexually. Yeast infections and bacterial vaginosis do not generally represent sexually transmitted diseases (STDs), whereas gonorrhea, chlamydia, herpes, and trichomonas infections are classed as STDs.

Health care team roles

Genital cultures are ordered by a physician and collected by a physician, nurse, or physician assistant. Culture, microscopic analysis, immunoassay, and DNA testing are performed by clinical laboratory scientists/medical technologists. Wet preparations may also be performed by the physician or physician assistant or nurse practitioner with appropriate training.

Nursing staff have a very important task in educating the patient in what to expect, assisting with obtaining samples, and helping to explain test results to patients. Many patients undergoing genital testing are in need of counseling regarding the risks of careless sexual behav-

ior, and the opportunity should be used by staff for education to reduce risks in the future.

Genital herpes

Definition

Genital herpes (*herpes genitalis*) is a highly contagious sexually transmitted disease (STD) caused by a strain of the herpes simplex virus (HSV). Genital herpes invades the body through mucous membranes, also known as small breaks in the skin.

Description

Genital herpes is characterized by **pain**, itching, and sores (i.e., blister-like lesions) in the genital areas of the body, including the male penis or scrotum, the female labia or vagina, or the urethra, anus, upper thighs, groin, or buttocks. Herpes simplex virus appears in two recognized forms: HSV type 1 and HSV type 2. Previously, it was believed that HSV type 1 only affected the upper body and the face, especially the mouth, appearing often as cold sores. HSV type 2 was believed to be the infecting organism in genital HSV infections. By 2001, it became known that either HSV type can cause infections in either area of the body (i.e., 15% of all genital herpes infections are caused by HSV type 1, and are believed to be the result of oral-to-genital contact). It is not spread by objects (e.g., toilet seat or doorknob), swimming pools, hot tubs, or through the air.

Herpes simplex virus. (Photograph courtesy of the CDC.)

Herpes **viruses** are not new to the modern medicine. The name is derived from the Greek adjective, *herpestes*, which means “creeping,” and refers to the serpent-like pattern often formed by the water blisters (vesicles) of genital herpes. Other members of the herpes virus family share similar traits, also infecting human beings. These traits include varicella zoster virus, the source of both chicken pox and shingles. Epstein-Barr virus, another member of the herpes virus family, is the cause of mononucleosis.

As of 2000, in the United States, there are 45 million adolescents and adults infected with HSV **infection**. Genital herpes is slightly more common in women, possibly because male-to-female transmission of the virus is more effective; it attacks one out of every four women. In contrast, one out of every five men contract genital herpes, and a greater percentage of black versus white males (i.e., 45.9% vs. 17.6%, respectively) become infected with the virus. According to the web site of the Centers for Disease Control, race and ethnicity in the United States are frequently associated with poverty, access to quality health care, whether health care is sought, illicit drug use, and life in communities with high incidences of STDs. Therefore, it is not surprising that HSV 2 infections are more prevalent among African-Americans (45.9%) than European-Americans (17.6%). Among teenagers, the incidence of genital herpes infections has risen steadily, at 30%, since 1970. That increase, five times higher than it was 20 years ago, is most dramatic among white teenagers in the 12–19. Young adults between the ages of 20 and 29 are now twice as likely to have HSV 2 as they were previously.

Causes and symptoms

While anyone can be infected by the herpes virus, not everyone will have symptoms. Risk factors for geni-

tal herpes include: early age at first sexual activity, multiple sexual partners, and other STDs.

Most patients with genital herpes experience a prodrome (i.e., symptoms of oncoming disease) that includes pain, burning, itching, or tingling at the site where blisters will form. This prodromal stage may last anywhere from a few hours, to one to two days. The herpes infection prodrome can occur in both the primary infection and recurrent infections. The prodrome for recurrent infections may be intense, and cause severe burning or stabbing pain in the genital area, legs, or buttocks.

Primary genital herpes

The first symptoms of herpes usually occur within two to seven days after contact with an infected person, but may take up to two weeks. Symptoms of the primary infection are usually more severe than those of recurrent infections. For up to 70% of patients, the primary infection presents with symptoms that affect the whole body (i.e., “constitutional symptoms”), including tiredness, headache, **fever**, chills, muscle aches, and loss of appetite. There may also be painful, swollen lymph nodes in the groin. These symptoms are greatest during the first three to four days of the infection and disappear within one week.

Following the prodrome, herpes blisters form; they are similar in men and women. First, small red bumps appear. These bumps quickly become fluid-filled blisters. In dry areas, the blisters become filled with pus and take on a white-to-gray appearance, become covered with scabs, and heal within two to three weeks. In moist areas, the fluid-filled blisters burst, forming painful ulcers that drain before healing. New blisters may appear over a period of one week or more, and may join together to form very large ulcers. The pain is relieved within two weeks; the blisters and ulcers heal, without scarring, by the third to fourth week after the prodrome.

Women may experience a very severe and painful primary infection. Herpes blisters first appear on the vagina’s entrance, labia majora (i.e., outer lips), and labia minora (i.e., inner lips). Blisters often appear on the clitoris, at the urinary opening, around the anal opening, and on the buttocks and thighs. In addition, women may get herpes blisters on the lips, breasts, and fingers, and in the eyes (due to spreading from contact with the hands). The vagina and cervix are almost always involved. This causes a watery discharge. Other symptoms that occur in women with primary infections are painful or difficult urination (83%), swelling of the urinary tube (85%), **meningitis** (36%), and throat infection (13%). Most women develop painful, swollen lymph nodes (i.e., lymphadenopathy) in the groin and pelvis. About one in ten

women get a vaginal yeast infection as a complication of the primary herpes infection.

In men, the herpes blisters usually form on the penis, but can also appear on the scrotum, thighs, and buttocks. Less than half of the men with primary herpes experience the “constitutional symptoms.” A significant percentage of men (30–40%) have a discharge from the urinary tube. Some develop lymphadenopathy in the groin and pelvis. Men, although with less frequency than women, may experience painful or difficult urination (44%), swelling of the urinary tube (27%), meningitis (13%), and throat infection (7%).

Recurrent genital herpes

One or more outbreaks of genital herpes per year occur in 60–90% of those infected with the herpes virus. About 40% of persons infected with herpes simplex virus type 2 will experience six or more outbreaks each year. Genital herpes recurrences are less severe than the primary infection; however, women still experience more severe symptoms and pain than men. Constitutional symptoms are not usually present. Blisters appear at the same sites during each outbreak. Usually, there are fewer blisters, less pain, and a shorter time span from symptom onset to healing than in the primary infection. One out of every four women experience painful or difficult urination during recurrent infection. Both men and women may develop lymphadenopathy.

The **immune system** will naturally create antibodies to fight viruses; herpes viruses are no exception. Herpes viruses, however, share a survival characteristic that makes it very difficult for the immune system to actually eliminate these viruses from the body. Herpes viruses evade antibodies by traveling via nerve pathways and hiding in **neurons** (i.e., nerve cells). These small colonies of surviving viruses enter what is known as the latent, or dormant phase, and remain that way until reactivated. The mechanisms by which the herpes virus is reactivated are not completely understood. Reactivation, however, can cause further outbreaks of the infection. The latent phase of the herpes virus can last for days, months, or years.

One of the ways that viruses differ from **bacteria** is in their reproductive ability. While bacteria reproduce independently, viruses require cells from their hosts to do so. When the herpes virus reactivates, it enters cells in its primary site of infection—in this case, the genital region—and causes the cells there to make more virus. Thousands of new herpes virus cells are released into the body’s system before each cell dies. This cell death and resulting tissue damage are the actual cause of the lesions that appear during an outbreak of genital herpes.

Reactivation of herpes viruses in human beings is specific to each individual, different in both triggers and severity. Evidence, however, supports the prediction that virtually all people infected with HSV type 2 will experience some form of recurrence; this averages to approximately four times per year. HSV type 1 infections are less likely to result in further symptomatic outbreaks, with an overall average recurrence rate of once per year. Rates of recurrence tend to diminish over time.

Newborn babies who are infected with herpes virus experience a very severe, potentially fatal disease. This is called “neonatal herpes infection.” In the United States, one in every three women of childbearing age are infected with the herpes virus; only one in 2,000 newborns will be born infected. Newborns can be infected during passage through the birth canal or during the **pregnancy**, should the embryonic sac rupture early. Doctors will normally perform a cesarean section (cs) on women who go into labor with active genital herpes.

All newborn infants should be checked for symptoms of neonatal herpes. Symptoms include skin lesions, listlessness, fever, and lack of appetite. Left untreated, it can cause damage to the infant’s **brain** and central nervous system or death.

The reasons for the reactivation of herpes viruses is not yet completely understood, but research has identified some triggers that are either causative, or suspected of being causative, of recurrent outbreaks.

Among these are:

- prolonged exposure to ultraviolet light (i.e., sunburn), which often reactivates facial herpes infections
- excessive friction or injury to genital areas
- compromise of the strength of the body’s immune system, the result of herpes virus’ recurrence, and its accompanying symptoms of fatigue and illness
- **stress** (This has also been considered a prime culprit in bringing about outbreaks. Through mid-2001, however, clinical research has not proved the a causal relationship between stress and reactivation. The investigators of one clinical study have shown a connection between decreased ability to cope with stress and recurrent infections.)
- the presence of HIV (Human **Immunodeficiency Virus**) (Human Immunodeficiency Virus has demonstrated a weakening of the immune system, with a consequent increase in the strength and severity of genital herpes infections.)
- the presence of either HSV type 1 or HSV type 2, or both, that are transmitted to others through direct bodily contact (This includes any sexual interaction [i.e.,

A close-up view of a penis with a blister (center of image) caused by the herpes simplex virus. (Photograph by Dr. P. Marazzi, Custom Medical Stock Photo. Reproduced by permission.)

vaginal, anal, or oral], kissing, or skin-to-skin contact. It is passed along with or without the presence of open sores or other prodromal symptoms. Notably, HSV infections are symptom free the majority of the time. For this reason, the virus is often transmitted by people infected with HSV who are not even aware that they are infected, or believe that lack of symptoms means that they are not contagious.)

Interestingly, an August 2000 report in the *New England Journal of Medicine* stated that in a University of Washington study, the majority of people who tested positive for HSV 2 infections reported no symptoms whatsoever. Another group of researchers at the University of Washington has assembled a list of ailments about which the subjects complained; they did not know that they had genital herpes. These ailments included:

For women:

- hemorrhoids
- physical irritation from sexual contact
- heat rash
- aching or itching during menses
- allergy to condoms or spermicide
- allergy to elastic in panty hose

For men:

- jock itch
- zipper burn
- hemorrhoids
- acne
- physical irritation from wearing tight jeans
- physical irritation from sexual contact

Diagnosis

Because genital herpes is so prevalent, it is diagnosed primarily by the presentation of symptoms. A diagnosis can often be made upon **physical examination**, and taking of a complete sexual history.

Because a mild case of genital herpes may be overlooked during a routine physical examination, laboratory tests are very important. When possible, it is helpful to know the type of HSV with which a patient is infected. As noted previously, HSV type 2 is potentially life-threatening to newborn infants.

Viral culture is one of the most accurate and specific tests for identifying HSV type 1 or 2. As healing sores do not shed much virus, a sample from an open sore should be taken for viral culture. The doctor must determine the exact cause of the sores. The above-mentioned tests should be performed to confirm that the herpes virus is causing the genital sores.

Other conditions that may produce genital sores are:

- syphilis
- chancroid
- lymphogranuloma venereum
- granuloma inguinale
- herpes zoster
- erythema multiform
- inflammatory bowel disease
- contact dermatitis
- candidiasis
- impetigo

Because of this, a viral culture test should be performed to be absolutely certain that the sores are caused by the HSV.

The results of serological tests (i.e., **blood** tests [either by finger-stick or blood draw] that reveal antibodies to HSV) are available within one day. They, too, are considered very accurate tests that can be performed whether open lesions are present or not. The disadvantage of this blood test is that it must be taken no earlier than 12 days post-infection; in a first infectious outbreak,

antibodies sometimes cannot be detected for three months.

Because most newborns who are infected with herpes virus are born to mothers with no symptoms of infection, it is important to check all newborn babies for symptoms. A culture of any skin sore should be taken to determine if it is caused by HSV. Babies should be checked for sores in their mouths and for signs of herpes infection in their eyes.

Treatment

There is no cure for the herpes virus. There are, however, **antiviral drugs** available that have some effect in lessening the symptoms and decreasing the length of herpes outbreaks. There is evidence that some of these medications may also prevent future outbreaks.

The antiviral drugs work by interfering with the replication of the viruses and are most effective when taken as early in the infection process as possible. For the best results, drug treatment should begin during the prodrome stage, before blisters are visible. Depending on the length of the outbreak, drug treatment could continue for up to 10 days.

Acyclovir (Zovirax) is the drug of choice for herpes infection and can be given intravenously, taken by mouth (orally), or applied directly to sores as a topical ointment. Acyclovir has been in use for many years; only 5 out of 100 patients (5%) experience side effects. Side effects of acyclovir treatment include nausea, vomiting, itchy rash, and **hives**. Although acyclovir is the recommended drug for treating herpes infections, other drugs may be used. They include famciclovir (Famvir), valacyclovir (Valtrex), vidarabine (Vira-A), idoxuridine (Herplex Liquifilm, Stoxil), trifluorothymidine (Viroptic), and penciclovir (Denavir).

Acyclovir is effective in reducing the severity of both the primary infection and recurrent outbreaks. When taken intravenously or orally, acyclovir reduces the healing time, virus shedding period, and duration of vesicles. The drug is taken three or five times daily depending on the dose for a period of 10 days. Recurrent herpes is treated with the same doses for a period of five days. Intravenous (IV) acyclovir is given to patients who require hospitalization because of severe primary infections or herpes complications, such as aseptic meningitis or sacral ganglionitis (i.e., inflammation of nerve bundles).

Patients with frequent outbreaks (i.e., greater than six to eight per year) may benefit from long-term use of acyclovir, called “suppressive therapy.” Patients on suppressive therapy typically have longer periods between herpes outbreaks. The specific dosage used for suppres-

sion would need to be determined for each patient and should be reevaluated every few years. Alternatively, patients may use short-term suppressive therapy to lessen the chance of developing an active infection on special occasions, such as a wedding, or during holidays.

There are several things that a patient may do to lessen the pain of genital sores. Wearing loose fitting clothing and cotton underwear is helpful. Removing clothing or wearing loose pajamas while at home may reduce pain, as may soaking in a tub of warm water and using a blow dryer on the “cool” setting to dry the infected area. Application of an ice pack on the affected area for 10 minutes, followed by five minutes without the ice pack, then repeating this procedure, may relieve pain. A **zinc** sulfate ointment may also help to heal the sores. Baking soda compresses may be soothing.

Neonatal herpes

Newborn babies with herpes virus infections are treated with acyclovir IV or vidarabine for 10 days. These drugs have greatly reduced neonatal deaths and increased the number of babies who appear normal at one year of age. Infected babies may be treated with long-term suppressive therapy.

Alternative treatment

An imbalance in the amino acids lysine and arginine is thought to be one contributing factor in herpes virus outbreaks. A ratio of lysine to arginine that is in balance (i.e., more lysine than arginine) appears to optimize the function of the immune system work. Thus, a diet that is rich in lysine may help prevent recurrences of genital herpes. Foods that contain high levels of lysine include most vegetables, legumes, fish, turkey, beef, lamb, cheese, and chicken. Patients may take 500 mg of lysine daily and increase to 1,000 mg three times a day during an outbreak. Intake of the amino acid arginine should be reduced. Foods rich in arginine that should be avoided are chocolate, peanuts, almonds, and other nuts and seeds.

Since clinical experience indicates a connection between high stress and herpes outbreaks, some patients may respond well to stress-reduction and **relaxation** techniques. **Acupressure** and massage may relieve tiredness and stress. **Meditation, yoga, tai chi, and hypnotherapy** can also help relieve stress and promote relaxation.

Some herbs, including echinacea (*Echinacea* spp.) and garlic (*Allium sativum*), are believed to strengthen the body’s defenses against viral infections. Red marine algae (family *Dumontiaceae*), both taken internally and applied topically, is thought to be effective in treating HSV type 1 and 2 infections. Other topical treatments may be helpful in inhibiting the growth of the herpes

KEY TERMS

Groin—The region of the body that lies between the abdomen and the thighs.

Latent virus—A nonactive virus which is in a dormant state within a cell. Herpes virus is latent in cells of the nervous system.

Prodrome—Symptoms which warn of the beginning of disease. The herpes prodrome consists of pain, burning, tingling, or itching at a site before blisters are visible.

Recurrence—The return of an active herpes infection following a period of latency.

Lesion—A morbid, or diseased, change in tissue formation at a local site.

virus, in minimizing the damage it causes, or in helping the sores heal. Zinc sulfate ointment seems to help sores heal and to fight recurrence. Lithium succinate ointment may interfere with viral replication. An ointment made with glycyrrhizinic acid, a component of licorice (*Glycyrrhiza glabra*), seems to inactivate the virus. Topical applications of **vitamin E** or tea tree oil (*Melaleuca* spp.) help dry up herpes sores. Specific combinations of homeopathic remedies may also be helpful treatments for genital herpes.

Prognosis

Although physically and emotionally painful, genital herpes is usually not a life-threatening disease. The primary infection can be severe and may require hospitalization for treatment. Complications of the primary infection may involve the cervix, **urinary system**, anal opening, and the nervous system. Persons who have a decreased ability to produce an **immune response** to infection (called “immunocompromised”) due to disease or medication are at risk for a very severe, possibly fatal, herpes infection. Even with antiviral treatment, neonatal herpes infections can be fatal or cause permanent nervous system damage.

Prevention

The only way to prevent genital herpes is to avoid contact with infected persons. This is not an easy solution because many people aren’t aware that they are infected and can easily spread the virus to others. Avoid all sexual contact with an infected person during a herpes outbreak. Because the herpes virus can be spread at any

time, condom use is recommended to prevent the spread of virus to uninfected partners. It is also important, however, to realize that condoms cannot stop the transmission of the herpes virus from body areas other than the sexual organs. Though research continues, there is no herpes vaccine proven effective in human beings.

Health care team roles

As genital herpes infections and their consequences may dramatically vary among people, there is diverse and varied involvement of health care team members. These include:

- Primary care physicians, nurse practitioners, and alternative health care providers, all of whom will be involved in physical examinations of people complaining of symptoms. Genital herpes can be diagnosed and treated by the family doctor, dermatologist (i.e., a doctor who specialize in skin diseases), urologists (i.e., doctors who specialize in the urinary tract diseases of men and women and the genital organs of men), gynecologists (i.e., doctors who specialize in the diseases of women’s genital organs) and infectious disease specialists. Any of these may also pick up the presence of unknown genital herpes infections on routine examinations.
- Physicians or nurse practitioners routinely do viral cultures. A sterile cotton swab is wiped over open sores and the sample used to infect human cells in culture. Cells killed by the herpes virus have a certain appearance under microscopic examination. The results of this test are available within two to ten days. Though it is considered quite accurate, there are estimates that up to 20% of viral culture tests give a false negative reading. Other areas that may be sampled, depending upon the disease symptoms in a particular patient, include the urinary tract, vagina, cervix, throat, eye tissues, and cerebrospinal fluid. Direct staining and microscopic examination of the lesion sample may also be used.
- Finger-stick or blood-drawn laboratory tests are usually done by either nurses or laboratory technicians, but are sometimes carried out by physicians or nurse practitioners.
- Obstetricians (i.e., physicians who deliver newborn babies), nurse midwives (i.e., nurses who deliver newborn babies) and obstetrical nurses (i.e., nurses who assist in the delivery of newborns and the care of mothers and infants after birth) will be involved in assuring that mothers infected with active genital herpes are provided a safe delivery (usually by cesarian section), and that newborns are thoroughly checked for signs and symptoms of the disease. As noted previously, many newborns are born infected with herpes virus to moth-

ers who had no symptoms of infection. Therefore, it is important to check all newborn babies for skin sores or lesions inside the mouth, and for signs of herpes infection in their eyes.

- Physicians, nurse practitioners, and alternative health practitioners will prescribe medications or herbs and diet to alleviate the symptoms of genital herpes.
- Nurses will be involved in the day-to-day care, including the provision of comfort measures, such as the administration of analgesic medications, warm baths, and applying compresses and ointments to those seriously ill enough to require hospitalization or nursing **home care**. Many of these will be immune system-compromised people, such as those who have AIDS.

Patient education

All health care providers will be involved in providing education about genital herpes. Because STDs are such a sensitive area of health care, it will be important for the health care provider to show understanding and sensitivity for health care consumers infected with HSV. Information and education, given without suggestion of judgment, can be among the most important care provided. It should emphasize that there is currently no *cure* for genital herpes, that the disease is extremely pervasive, and that precautions must be used during sexual contact in order to avoid infecting others. An important goal of **patient education** should be to make the patient aware that condoms are an excellent means of protection from HSV and pregnancy. The patients should also learn what laboratory tests will need to be done, and what medications, or treatments, can help alleviate symptoms.

The diagnosis and treatment of this infectious disease should be covered by most insurance providers.

Geriatric nutrition

Definition

Geriatric **nutrition** applies nutrition principles to delay effects of aging and disease, to aid in the management of the physical, psychological, and psychosocial changes commonly associated with growing old.

Purpose

The number of people over 65 years of age jumped from 4% of the U.S. population in 1900 to 13% in 1990, and is expected to reach 20% in 2030, due primarily to advances in health care. "Elderly" was once defined as being age 65 or above, but the growing number of active and healthy older people has caused that definition to expand to "young old" (65 to 75), "old old" (75 to 85), and "oldest old" (85 and beyond). The over-85 age group is the one that is growing most rapidly.

The cornerstone of geriatric nutrition is a well-balanced diet. This provides optimal nutrition to help delay the leading causes of death: **heart** disease, **cancer**, and stroke. In addition, ongoing research indicates that dietary habits, such as restricting one's calorie intake and consuming antioxidants, may increase longevity.

Precautions

Physiological changes

With age comes many physical changes. Once the body reaches physiologic maturity, the rate of degenerative change exceeds the rate of cell regeneration. However, people age at different rates, so the elderly population is not a homogeneous group; there is great variability among individuals.

The following are typical physiologic changes that can affect nutritional status:

- Body composition changes as fat replaces muscle, in a process called sarcopenia. Research shows that **exercise**, particularly weight training, slows down this process. Because of the decrease in lean body mass, basal metabolic rate (BMR) declines about 5% per decade during adulthood. Total caloric needs drop, and lowered protein reserves slow the body's ability to

respond to injury or surgery. Body water decreases along with the decline in lean body mass.

- Gastrointestinal (GI) changes include a reduction in digestion and absorption. Digestive hormones and enzymes decrease, the intestinal mucosa deteriorates, and the gastric emptying time increases. As a result, two conditions are more likely: pernicious anemia and constipation. Pernicious anemia may result because of hypochlorhydria, which decreases **vitamin B₁₂** absorption and affects approximately one third of older Americans. Constipation, despite considerable laxative use among older people, may result from slower GI motility, inadequate fluid intake, or physical inactivity.
- Musculoskeletal changes occur. A progressive drop in bone mass starts when people are in their 30s or 40s; this accelerates for women during **menopause**, making the skeleton more vulnerable to **fractures** or **osteoporosis**. Adequate intake of **calcium** and **vitamin D** helps to retain bone.
- Geriatric nutrition must take into account sensory and oral changes. Decreases in all the senses, particularly in the **taste** buds that affect perception of salty and sweet tastes, may affect appetite. Xerostomia, lack of salivation, affects more than 70% of the elderly. Also, denture wearers chew less efficiently than those with natural teeth.
- Other organ changes may occur. Insulin secretion is decreased, which can lead to carbohydrate intolerance, and renal function deteriorates in the 40s for some people.
- Cardiovascular changes may occur. Reduced sodium intakes become important, as **blood pressure** increases in women over age 80 (but, interestingly, it declines in older men). Serum cholesterol levels peak for men at age 60 but continue to rise in women until age 70.
- Immunocompetence decreases with age. The lower immune function means less ability to fight infections and malignancies. **Vitamin E**, **zinc**, and some other supplements may increase immune function.

Psychosocial changes

A number of changes may occur in the aging person's social and psychological status, potentially affecting appetite and nutrition status. These include:

- Depression, the most common cause of unexplained weight loss in older adults, occurs in approximately 15% of adults over age 65, with a much higher incidence in those living in extended-care facilities.
- Memory impairment caused by various types of **dementia**, **Alzheimer's disease**, or other neurological

diseases rises dramatically, with half of all persons over age 85 affected. Weight loss and improper nutrition are potential problems.

- Alcohol abuse is often unreported, especially since approximately one third of alcoholics age 65 years or older begin drinking later in life. Excessive alcohol intake (over 15% of total calories) increases morbidity and mortality, and leads to both physical and psychosocial problems.
- Social isolation becomes more common because of declining income, health problems, loss of spouse or friends, and assistance needs. All of these may affect appetite and possibly nutritional status.

Description

Basic energy and nutrient needs

Calorie requirements decrease with age, although individuals vary greatly depending on their activity level and health status. Diets that fall below 1,800 calories a day may be low in protein, calcium, **iron**, and **vitamins**, so should feature nutrient-dense foods.

Protein needs of healthy older adults are the same as for other adults, with 0.8 to 1 gm of protein per kg of body weight recommended. Most older people without debilitating disease eat adequate protein, but those with infections or severe disease may become protein-mal-nourished due to increased protein requirements and poor appetites. Seniors do better eating more complex **carbohydrates**, which increase fiber, vitamins, and **minerals**, and help with insulin sensitivity. Lactase-treated milk or fermented dairy products are suggested if lactose intolerance develops. Because caloric needs drop and heart disease is so prevalent, reducing total dietary fat and especially the amount of saturated **fats** is advised.

Mineral deficiencies are uncommon in older adults, and recommended amounts are the same or similar to those for younger adults. Iron-deficiency anemia related to nutrition is rare, and more likely due to **blood** loss. Of the vitamins, vitamin D intakes are often lower than recommended, especially among homebound or institutionalized people who lack sun exposure (the most accessible source of vitamin D). The antioxidant vitamins, vitamin E, carotenoids, and **vitamin C**, continue to receive attention because of their potential to improve immune function and ward off disease. Requirements for **riboflavin**, vitamins B₆ and B₁₂, and zinc are increased in the elderly. However, needs for **vitamin A** decrease.

Dysphagia

The incidence of **dysphagia**, or difficulty in swallowing, increases with age. Dysphagia results from con-

ditions such as stroke, Alzheimer's or **Parkinson's disease, multiple sclerosis**, or physiological changes such as loss of teeth or poorly fitting dentures. Inadequate dietary intake as a result of dysphagia can lead to weight loss, **dehydration**, and nutritional deficiencies. The American Dietetic Association has developed Level 1 through Level 4 dysphagia diets, which provide varying textures and liquids based on the severity of the condition.

Fluid balance

Dehydration is the most common cause of fluid and electrolyte disturbances in older adults. Reduced thirst sensation and fluid intake, medications such as diuretics and **laxatives**, and increased fluid needs during illness contribute to dehydration. Adequate water-intake guidelines are 1 ml water/kcal energy consumed (for example, 1.8 L for an 1,800-calorie intake), or 25–30 ml/kg of weight for most individuals.

Skin integrity

Skin breakdown is a common problem, particularly in bedridden or immunologically impaired people. The most common skin breakdown is the **pressure ulcer**, which occurs in 4% to 30% of hospitalized patients and 2% to 23% of residents of skilled-care **nursing homes**.

Pressure ulcers are graded or staged to classify the degree of tissue damage. Those with more serious Stage II to Stage IV ulcers have increased nutritional needs. Protein needs increase to 1–1.5 gm protein/kg, caloric needs increase to 30–35 kcal/kg, and 25–35 cc fluid/kg is recommended.

Malnutrition

While most elderly people maintain adequate nutritional status, institutionalized and hospitalized older adults are at higher risk for malnutrition than individuals who are living independently. Cancer cachexia, the weak, emaciated condition resulting from cancer, accounts for about half of malnutrition cases in institutionalized adults.

Two common forms of malnutrition are protein-calorie malnutrition, in which the person appears ill-nourished; and protein malnutrition, in which an overweight person may have depleted protein stores. Nutrition support may involve higher protein and caloric amounts, nutritional supplements such as Ensure, or enteral tube feedings that provide nutrient solutions into the GI tract.

Preparation

Assessment

The following are used to assess nutritional needs:

- A thorough medical history, **physical examination**, and dietary history can provide a general picture of the individual's nutritional status. Lab values also provide valuable information.
- Weight evaluation may be recommended. Normal weight status guidelines include a BMI of 21 to 27 (BMI = weight in pounds x 704.5/ht(in) squared) or Ideal Body Weight +/-10%. Guidelines for significant weight loss include 10% weight loss in six months, 5% in one month, or 2% in one week.
- Dehydration evaluation involves physical assessment (poor skin turgor, dark urine, flushed skin), and assessment of recent fluid and food intake. High laboratory levels of blood urea nitrogen (BUN), albumin, serum sodium, and serum osmolality can indicate dehydration.

Aftercare

Laboratory values, particularly albumin for protein status and sodium and BUN for hydration status, should continue to be assessed after treatment. Tube feedings need to be continually monitored to prevent aspiration.

Results

Normal laboratory values in the elderly

- Protein status: albumin 4 to 6 gm/dL; prealbumin: 19 to 43 mg/dL.
- Anemia status: hemoglobin: 12 to 18 gm/dL; **hematocrit** 33% to 49% (can be slightly lower in the elderly); MCV: 80 to 95 μm^3 ; MCHC: 27 to 31 pg; B_{12} : 100 to 1,300 pg/mL.
- Hydration: serum sodium: 135 to 147mEq/L; serum osmolality: 285 to 295 mOsm/kg; BUN 10 to 20 mg/dL (can be slightly higher in elderly).

Health care team roles

- Registered dietitians play the primary role in assessing and coordinating geriatric nutrition care.
- Nursing staff also assesses patients, and physicians oversee total care and ordering of lab tests.
- A speech-language therapist typically conducts a swallowing assessment and coordinates care for dysphagia.

KEY TERMS

Hypochlorhydria—A deficiency of hydrochloric acid in the gastric juice.

Osteoporosis—A loss of bone density leading to fractures because the skeleton is unable to sustain ordinary stresses.

Pressure ulcer—Any lesion caused by unrelieved pressure resulting in damage to the underlying tissue.

Sarcopenia—A deficiency of muscle or flesh that occurs in the elderly.

Gestational diabetes

Definition

Gestational **diabetes mellitus** (GDM) is a condition that occurs during **pregnancy**. Like other forms of diabetes, GDM involves a defect in the way the body processes and uses sugars (glucose) in the diet. Gestational diabetes, however, has a number of characteristics that are different from other forms of diabetes. This form of diabetes does not include women who are diabetic before they become pregnant. Gestational diabetes usually occurs in the second and third trimesters of the pregnancy.

Description

Glucose is a form of sugar that is present in many foods, including sweets, potatoes, pasta, and breads. The body uses glucose to provide energy. It is stored in the **liver**, muscles, and fatty tissue. The **pancreas** produces a hormone (a chemical produced in one part of the body that travels to another part of the body in order to exert its effect) called insulin. Insulin is required to allow glucose to enter the liver, muscles, and fatty tissues, thus reducing the amount of glucose in the **blood**. In persons with diabetes, blood levels of glucose remain abnormally high. The inability of the pancreas to produce enough insulin is the cause of these high levels of glucose.

In gestational diabetes, the pancreas is not at fault. The problem is in the placenta. During pregnancy, the placenta provides the baby with nourishment. It also produces a number of hormones that interfere with the body's usual response to insulin. This condition is referred to as "insulin resistance." The development of insulin resistance is primarily caused by a substance called lactogen, which is produced during pregnancy, and from increased blood levels of the hormones progesterone and estrogen. The blood levels of these substances tend to peak in the second and third trimester of the pregnancy, which is when GDM is most likely to occur. Most pregnant women do not develop GDM because the pancreas works to produce extra quantities of insulin to compensate for insulin resistance. However, when a woman's pancreas cannot produce enough extra insulin, blood levels of glucose remain abnormally elevated, and the woman is considered to have GDM. It is believed that some women with borderline blood sugar problems before pregnancy are more likely to have long-term blood sugar regulation problems after developing GDM.

As of January 2001, about 200,000, or 7%, of pregnant women in the United States develop GDM every year. Women at risk for GDM include those who:

- are overweight
- have immediate family members with a history of Type II diabetes
- have previously given birth to a large (over 9 lbs [4 kg]) baby
- have previously had a baby who was stillborn, or born with a birth defect
- have an excess amount of amniotic fluid (the cushioning fluid within the uterus that surrounds the developing fetus)
- are over 25 years of age
- belong to an ethnic group proved to experience higher rates of GDM. (In the United States, these groups

include Hispanic-Americans, American Indians, and African-Americans, as well as individuals from Asia, India, and the Pacific Islands.)

- have had GDM during a previous pregnancy
- have persistent evidence of excess glucose in the urine
- have a history of chronic drug abuse involving agents such as corticosteroids

Causes and symptoms

Most women with GDM have no recognizable symptoms. However, leaving GDM undiagnosed and untreated is dangerous to the developing fetus. Left untreated, a woman with diabetes will have consistently high blood sugar. This sugar will cross the placenta and the unborn baby's pancreas will respond to this high level of sugar by constantly producing large amounts of insulin. The insulin will allow the cells of the fetus to take in glucose, where it will be converted to fat and stored. A fetus that has been exposed to consistently high levels of sugar may be abnormally large. Such a baby may grow so large that he or she cannot be born through the vagina, but will instead need to be born through a surgical procedure (cesarean section).

Furthermore, when the baby is born, the baby will still have an abnormally large amount of insulin circulating in the blood. After birth, when the mother and baby are no longer connected via the placenta and umbilical cord, the baby will no longer be receiving the mother's high level of sugar. The baby's high level of insulin, however, will very quickly use up the glucose circulating in its bloodstream, predisposing the baby to a dangerously low level of blood glucose (i.e., a condition called hypoglycemia).

Diagnosis

Since GDM most often exists with no symptoms detectable by the patient, and since its existence puts the developing baby at considerable risk, screening for the disorder is a routine part of **prenatal care**. This screening is usually done between the 24th and 28th week of pregnancy. By this point in the pregnancy, the placental hormones have reached a sufficient level to cause insulin resistance. Screening for GDM involves the pregnant woman drinking a special solution that contains exactly 50 grams of glucose. An hour later, the woman's blood is drawn and tested for its glucose level. A level less than 130-140 mg/dl is considered normal.

When the screening glucose level is over the safe level, a special three-hour glucose tolerance test is performed. This involves following a special diet for three

A woman with gestational diabetes injects herself with insulin daily to treat her condition. (Photograph by Mark Clarke. Science Source/Photo Researchers. Reproduced by permission.)

days prior to the test. This diet is designed to contain at least 150 grams of carbohydrate each day. Just before the test, the patient is instructed to eat and drink nothing (except water) for 8–14 hours. A blood sample is then tested to determine the fasting glucose level. The patient then drinks a special solution containing exactly 100 grams of glucose, and her blood is tested every hour for the next three hours. If two or more of these levels are elevated over normal, the patient is considered to have GDM.

Treatment

Treatment for GDM will depend on the severity of the diabetes. Mild forms can be treated with diet (i.e., decreasing the intake of sugars and **fats**). Many women are put on strict, detailed diets, and are asked to stay within a certain range of calorie intake. **Exercise** is sometimes used to keep blood sugar levels lower. Patients are often asked to regularly measure their blood sugar. This

KEY TERMS

Corticosteroids—Hormonal steroid substances that originate in the cortex of the adrenal gland.

Estrogen—A female sex hormone responsible for secondary sexual characteristics and cyclic changes in women.

Glucose—A form of sugar. The final product of the breakdown of carbohydrates (starches).

Insulin—A hormone produced by the pancreas that is central to the processing of sugars and carbohydrates in the diet.

Ketoacidosis—Excessive acidic condition in the body caused by excess production of ketone bodies.

Lactogen—A substance that stimulates the production of milk in female animals.

Placenta—An organ that is attached to the inside wall of the mother's uterus and to the fetus via the umbilical cord. The placenta allows oxygen and nutrients from the mother's bloodstream to pass into the unborn baby.

Progesterone—A hormone that is responsible for the changes that occur in the second half of the menstrual cycle.

is done by poking a finger with a needle called a lancet, putting a drop of blood on a special type of paper, and feeding the paper into a meter that analyzes and reads the blood sugar level. When diet and exercise do not keep blood glucose levels within an acceptable range, a patient may need to take regular shots of insulin.

Many babies born to women with GDM are large enough to cause more difficult deliveries, and they may require the use of cesarean section. Once the baby is born, it is important to carefully monitor its blood glucose levels. These levels may drop sharply and dangerously once the baby is no longer receiving large quantities of sugar from the mother. When this occurs, it is easily resolved by giving the baby glucose.

Prognosis

Prognosis for women with GDM, and their babies, is generally good. Mothers who develop GDM need to be evaluated for glucose intolerance six to eight weeks after the birth of the baby. This evaluation usually involves a two-hour oral glucose tolerance test with 75 grams of

glucose, although follow-up methods may vary. Almost all such women stop being diabetic after the baby's birth. However, clinicians have also demonstrated that nearly 50% of these women will develop a permanent form of diabetes within 15 years. A woman who has had GDM during one pregnancy has about a 66% chance of having it again during any subsequent pregnancies. In addition, women with GDM are at increased risk for developing complications, such as infections, temporary low blood sugar, high **blood pressure**, and ketoacidosis.

Health care team roles

Women with GDM will likely be evaluated and treated by a variety of personnel in the allied health field. The obstetric nurse, physician, or nurse midwife will gather a detailed medical history, which may provide information suggesting the patient is at increased risk for developing GDM. Laboratory technicians play an important role in the diagnosis of GDM by testing urine and blood for excessive glucose levels. An **amniocentesis** conducted by an imaging technician is often performed in women with GDM because of the potential abnormal growth changes in the fetus.

Most patients with GDM can manage their blood sugar levels through dietary changes. A nutritional therapist plays a critical role in planning a regimen for these women. An exercise therapist can also play a significant role in the prevention and ongoing treatment of women with GDM. Exercise can help prevent excessive weight gain by the mother, which can reduce the severity of the diabetes. In addition, exercise tends to normalize blood glucose levels. If the patient requires insulin, then the nurse or physician will generally instruct the patient on how to administer the insulin. The nurse will also likely advise on how to perform blood glucose monitoring. The pharmacist can play a role in the education of the patient in this matter as well.

Prevention

There is no known way to actually prevent GDM, particularly since this condition is due to the effects of normal hormones of pregnancy. However, the effects of insulin resistance can be best handled through careful attention to diet, avoiding becoming overweight throughout life, and participating in a reasonable exercise program.

Gingivitis

Definition

Gingivitis is a disorder involving inflammation of the gingiva (gum tissue). It is sometimes called gum disease.

Description

Periodontal disease is a worldwide problem. This mildest form of periodontal disease, gingivitis, is inflammation strictly limited to the gingiva and does not manifest changes in the underlying bone. When bony changes become evident, the condition is termed **periodontitis**.

There is commonly little or no discomfort with gingivitis. The only people who escape gingivitis are very young infants; otherwise, it affects all age groups and people of all ethnic and racial backgrounds. A bacterial **infection** of the gums, it causes the gum tissues to turn red and swollen. Mild gingivitis causes little **pain**, and may be overlooked by the dentist; however, if left unchecked, it can turn into severe gingivitis. Many people experience varying degrees of gingivitis throughout their lives, but overlook it. It commonly develops during **puberty** or in early adulthood, and may persist or recur frequently.

In studies cited by the American Academy of Periodontology (AAP) in Boston, Massachusetts, 1,259 patients between the ages of 13 and 65 were studied. Of

those 1,259 between ages 13 and 15, 80% had some form of gingivitis, while 95% had gingivitis at age 60. Males were more frequently affected than females, with the overall average being 88% and 80%, respectively.

Causes and symptoms

The etiology of gingivitis is especially varied and has been divided into local and systemic factors.

Local factors

- microorganisms
- food impaction
- faulty or irritating restorative **orthodontic appliances**
- breathing through the mouth, rather than the nose
- tooth malposition
- chemical or drug application

Microorganisms are the **bacteria** found in plaque. The bacteria that destroy living tissue release many destructive enzymes. Specific microorganisms sometimes cause inflammatory reactions in the gingiva. Streptococcal and Staphylococcal are the bacteria known to destroy tissue and cause inflammation.

Food impaction, or general oral neglect, is the most common cause of gingivitis. The food impacts around the teeth and accumulation of debris on the teeth causes irritation of the gingiva by the toxins in the plaque. The byproducts of the toxins cause swelling of the tissue and redness to occur.

Faulty or irritating restoration, or appliances, may act as irritants to the gum tissue and thus induce gingivitis. Overhanging margins on **dental fillings** may directly irritate the gingiva and cause food to become impacted; this further adds to making the gum tissue even more tender. When prosthetic or orthodontic appliances encroach on the gingival tissues, gingivitis may occur—the result of the pressure and the trapping of food and bacteria. The tissue may become inflamed, redden, and become painful to the touch.

Mouth breathing (not breathing through the nose) causes drying of the oral mucous membrane and irritates the gum tissue, causing inflammation and hyperplasia of the tissue.

Tooth malposition results in repeated abnormal forces during the eating and chewing of food. Calculus may be deposited on the surface of the tooth that has no force to aid in keeping it clean. Bacteria may begin to attack the tissue around the tooth, resulting in a combination of inflammation and gum recession.

KEY TERMS

Calculus—A hard deposit that forms on the teeth, also known as hardened plaque and tartar.

Edematous—An abnormal accumulation of serous fluid in the tissues.

Gingiva—The gum tissue.

Gum recession—The gum tissue backing away from the crown of tooth towards the root.

Hyperemia—Swelling of the gum tissue.

Local—Pertaining to or being in one particular place.

Systemic—Pertaining to, or affecting the whole body.

Chemical or drug application may cause many gum tissue anomalies. A number of drugs are at least potentially capable of inducing gingivitis. Over-the-counter (OTC) drugs can be harmful to the gum tissue and act as an acid burn if used. Silver nitrate and general aspirin have acidic affects on the gum tissue, causing redness and tenderness to the touch. Dilantin sodium produces swelling of the gum tissue due to the chemicals in the drug.

Systemic factors

- nutritional disturbances
- **pregnancy**
- diabetes and other conditions that cause endocrine dysfunction

Nutritional disturbances can create imbalances in the body system that effect changes in the gum tissue. Insufficient **vitamin C** may cause redness and swelling, along with tenderness. The inadequate intake, absorption, and utilization of some other **vitamins, minerals,** and food can affect the gum tissue, causing swelling and redness.

Pregnancy gingivitis refers to the changes the gingiva undergoes during pregnancy. The clinical appearance of the gingiva in pregnant women may vary—from no change to a smooth, shiny, deeply reddened, marginal gingival hyperemia (swelling of the gum tissue) of the papilla on the upper roof of the mouth. Gingivitis commonly appears at the end of the first trimester of pregnancy, and may remit or even completely disappear at the termination of the pregnancy.

Diabetes mellitus is also associated with severe periodontal disease. Uncontrolled diabetes can cause a metabolic change in the gum tissue and decrease an individual's resistance to infection.

Endocrine dysfunctions during puberty may lead to changes in the gum tissue (puberty gingivitis). The gingiva appears hyperemic (having an excess of **blood**) and edematous (swollen). Most studies have revealed that the main cause of these changes in the gingiva is caused by breathing through the mouth.

Diagnosis

A patient may have gingivitis and periodontitis in different parts of the mouth at the same time. A general dentist can examine the patient and look for calculus deposits on the teeth and under the gum line. A dental explorer or a cleaning instrument will then be used by the dentist to probe the gum tissue or to check for plaque buildup. Commonly, the practitioner will ask the patient if the gums bleed while flossing and brushing. The dentist needs to be made aware of any medications being taken that might be a causative factor in the gingivitis. Information provided by the patient may lead to a gingivitis diagnosis.

Treatment

The goal of treating gingivitis is for reduction of the gingival inflammation. The general dentist, or registered dental hygienist (RDH) commonly cleans the teeth. This may involve the use of various instruments or devices to loosen and remove deposits from the teeth (scaling). Gingivitis is reversible with professional treatment and good home **oral hygiene** care. Changing toothbrushes every three months commonly improves **dental hygiene** in eliminating the bacteria in the mouth. Increased intake of vitamin C may aid in the development of healthy gum tissue. It is strongly recommended that strict oral hygiene be maintained for one's lifetime, or gingivitis will probably recur.

Prognosis

The prognosis for gingivitis is excellent. Once a program of good dental hygiene, such as proper toothbrushing and frequent prophylaxis (cleaning) is implemented, the symptoms of gingivitis will begin to disappear; this can happen in as little as one week. If there is poor response to good local therapy, a search should be made for systemic factors, which might be complicating the case.

Regular dental cleanings and exams are recommended at least every six to twelve months.

Health care team roles

An RDH is usually the first person seen by the patient when a cleaning is scheduled. The RDH role is to inform the patient of the condition of the gum tissues and consult with the general dentist about the treatment plan. After evaluating the case, ways to improve oral hygiene or to identify the irritant causing the gingivitis—such as a popcorn kernel, seed, or tartar buildup—will be suggested. Removal will then be done by the dentist.

Proper brushing and flossing is usually demonstrated by the RDH. This will aid in the maintenance of oral hygiene. The front desk receptionist may be responsible for keeping track of the recall records and following up with patients, by phone, who need appointment every six months.

Prevention

Prevention of gingivitis is simple and easy. Proper brushing techniques and proper flossing to remove any irritants or bacteria helps to stop gingivitis from growing. Regular dental checkups and cleanings will aid in reducing the risk of gingivitis.

For people who are prone to gingivitis, it may be recommended that they brush and floss after every meal, and at bedtime. Electric toothbrushes may be recommended for patients who have problems with strength or dexterity of their hands. Special appliances or tools, such as toothpicks, special toothbrushes, and water irrigation devices may be recommended for patients who are particularly prone to plaque deposits. These supplements do not replace brushing and flossing, but are enhancements in the prevention of gingivitis.

Glaucoma

Definition

Glaucoma is a condition where the optic nerve is subject to damage—usually, but not always, because of excessively high intraocular pressure (pressure within the eye, also called IOP). If untreated, the optic nerve damage results in progressive, permanent **vision** loss, starting with unnoticeable blind spots in the field of vision, progressing to tunnel vision, and then to blindness.

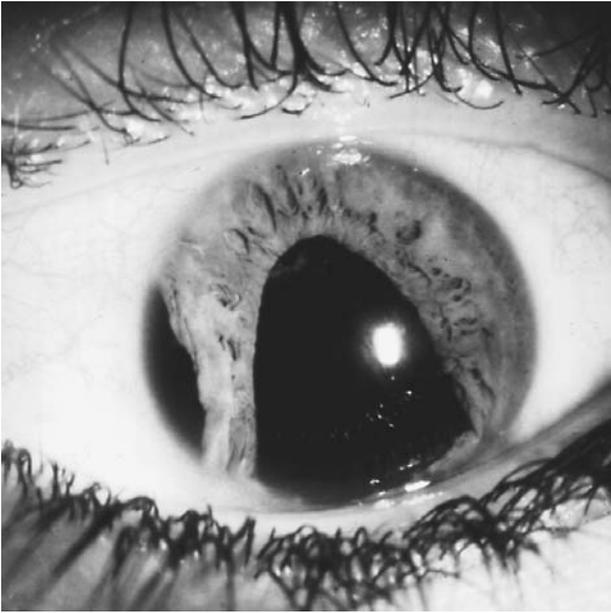

Description

More than 2 million people in the United States have glaucoma, and 80,000 of them are legally blind as a result. It is the leading cause of preventable blindness in the United States and the most frequent cause of blindness in African-Americans, whose glaucoma risk is three times higher than the rest of the population. The risk of glaucoma increases with age, but it can strike any age group, even newborns and fetuses.

Glaucoma is a class of diseases. There are at least 20 different forms that can be divided into two categories: open-angle glaucoma and narrow-angle glaucoma. To understand glaucoma, it is useful to understand eye structure.

The eyes are spherical. A tough, non-leaky protective sheath (the sclera) covers the eye with the exception of the clear cornea at the front and the optic nerve at the back. Light comes into the eye through the cornea, then passes through the lens, which focuses it onto the retina (the innermost surface at the back of the eye). The rods and cones of the retina transform the light energy into electrical messages, which are transmitted to the **brain** by the optic nerve.

The iris is located between the dome-shaped cornea and the lens. It controls the amount of light that enters the

A close-up view of an inflamed eye in acute glaucoma, with an irregularly enlarged pupil. (Custom Medical Stock Photo. Reproduced by permission.)

eye by opening and closing the pupil. The iris, cornea, and lens are bathed in a liquid called the aqueous humor, which is similar to plasma. This liquid is continually produced by the nearby ciliary body and moved out of the eye into the bloodstream by a system of drainage canals (the trabecular meshwork). The drainage area is located in front of the iris, in the angle formed between the iris and the cornea.

Glaucoma occurs if the aqueous humor is not removed rapidly enough or if it is made too rapidly, causing pressure to build up. This high pressure distorts the shape of the optic nerve and destroys nerve cells. The destruction of nerve cells results in blind spots—spots where the image from the retina is not transmitted to the brain.

Open-angle glaucoma accounts for over 90% of all cases. It is called “open-angle” because the angle between the iris and the cornea is open, allowing drainage of the aqueous humor. It is usually chronic and progresses slowly. In narrow-angle glaucoma, the angle where aqueous fluid drainage occurs is narrower than normal, thus causing the fluid to drain more slowly and increasing the risk that the flow may be blocked. When the drainage area is blocked, a closed-angle glaucoma attack results. This can occur, for example, if the iris and lens suddenly adhere to each other and the iris is pushed forward. In patients with very narrow angles, this can occur when the eyes dilate (e.g., when entering a dark room or when taking certain medications).

One rare form of open-angle glaucoma is different. People with normal-tension glaucoma have optic nerve damage in the presence of normal IOP. As of 2001, the mechanism of this disease is unknown.

Glaucoma is also a secondary condition of over 60 widely diverse diseases and can result from injury as well.

Causes and symptoms

The cause of vision loss in all forms of glaucoma is optic nerve damage. There are many underlying causes and forms of glaucoma. Most causes are not known, but it is evident that different processes are involved, and a malfunction in any one of them could cause glaucoma. For example, eye trauma may result in the angle becoming blocked, or, as a person ages, the lens may become larger and push the iris forward. The cause of optic nerve damage in normal-tension glaucoma is also unknown, but there is speculation that the optic nerves of these patients are susceptible to damage at lower pressures than what is usually considered to be abnormally high. It is probable that most glaucoma is inherited. At least 10 defective genes that cause glaucoma have been identified.

Initially, chronic open-angle glaucoma has no noticeable symptoms. The pressure build-up is gradual and there is no discomfort. Moreover, the vision loss is gradual and one eye fills-in the image where its partner has a blind spot. However, left untreated, vision loss becomes evident, and the condition can be painful.

Acute closed-angle glaucoma is obvious from the beginning of an attack. The symptoms are blurred vision, severe **pain**, sensitivity to light, nausea, and halos around lights. The normally clear cornea may be hazy. This is an ocular emergency and needs to be treated immediately. Similarly, congenital glaucoma is evident at birth. Symptoms include bulging eyes, cloudy corneas, excessive tearing, and sensitivity to light.

Diagnosis

The initial glaucoma diagnosis is made through an **eye examination** by an optometrist (O.D.) or ophthalmologist (M.D.). The examination begins with an ophthalmic assistant, technician, or scribe gathering patient information, including any family history of glaucoma. Then the ophthalmic assistant takes a reading of the patient’s intraocular pressure (IOP). IOP is measured with an instrument called a tonometer, using a technique called applanation tonometry. The test is performed after anesthetic drops are administered to the eye. The anesthetic allows the examiner to touch the patient’s eyeball without causing discomfort for the patient. Another type

of tonometry called noncontact applanation shoots a puff of air into the patient's eye. This is slightly less accurate than applanation tonometry.

Next, an O.D., M.D., or skilled ophthalmic assistant uses an ophthalmoscope (a hand-held instrument with a light source) to examine the optic nerve, retina, and back of the eye. Other types of lenses may also be used to examine the back of the eye. A slit lamp (biomicroscope) allows the physician or assistant examine the cornea, iris, and lens.

Visual field tests (perimetry), performed by an O.D., M.D., or ophthalmic assistant, can detect blind spots in a patient's field of vision before the patient is aware of them. Certain defects may indicate glaucoma.

Another test, gonioscopy, is used to distinguish between narrow-angle and open-angle glaucoma. A gonioscopy lens, which is a hand-held contact lens with a mirror, allows visualization of the angle between the iris and the cornea.

Physicians may also perform a nerve fiber layer assessment which can show early damage to the eye. Fundus photography or stereoscopic photography through a dilated pupil may also be performed by an O.D., M.D., or ophthalmic assistant to document the appearance of the optic nerve so that changes may be detected on subsequent examinations.

Blood pressure also is monitored, as some prescribed treatments may raise pressure and **heart** rate.

Intraocular pressure can vary throughout the day. For that reason, patients should schedule several return visits to measure the IOP at different times of day. This yields the most accurate diagnosis.

Treatment

The first line of glaucoma treatment is the use of prescription eyedrops. Several classes of medications are effective at lowering IOP and thus preventing optic nerve damage in chronic and neonatal glaucoma. Beta blockers (e.g. timolol), carbonic anhydrase inhibitors (e.g. acetazolamide), and alpha-2 agonists (e.g. brimonidine tartrate) inhibit aqueous humor production. Miotics (e.g. pilocarpine) and prostaglandin analogues (e.g. latanoprost) increase the outflow of aqueous humor.

It is important for patients to inform their doctors of any health conditions they have or any medications they take, including over-the counter drugs. Certain drugs used to treat glaucoma are not prescribed for patients with pre-existing conditions. The drugs prescribed to treat glaucoma all have side effects, so patients taking them should be monitored closely, especially for cardio-

vascular, pulmonary, and behavioral symptoms. Each medication lowers IOP by a different amount, and a combination of medications may be necessary. To ensure that IOP is lowered sufficiently, it is important that patients take their medications and be monitored regularly. IOP should be measured three to four times per year.

Normal-tension glaucoma is treated by reducing IOP to less-than-normal levels, on the theory that overly susceptible optic nerves are less likely to be damaged at lower pressures. Research underway may point to better treatments for this form of glaucoma.

Attacks of acute closed-angle glaucoma are medical emergencies. IOP is rapidly lowered by successive deployment of acetazolamide, hyperosmotic agents, a topical beta-blocker, and pilocarpine. Epinephrine should not be used because it exacerbates angle closure.

Trabeculectomy, to open the drainage canals or make an opening in the iris, can be effective in increasing the outflow of aqueous humor. This surgery is usually successful, but the effects often last less than one year. Nevertheless, this is an effective treatment for patients whose IOP is not sufficiently lowered by drugs and for those who can't tolerate the drugs.

Laser peripheral iridotomy is a procedure used almost exclusively to treat narrow angle glaucoma. It involves creating a small opening in the peripheral iris that allows aqueous fluid to drain from behind the iris directly to the anterior chamber. This procedure typically result in "opening up" the narrow angle between the iris and the cornea, in essence converting a narrow angle into an open angle.

Argon laser trabeculoplasty is usually recommended when medications have not been able to sufficiently control IOP, although it is increasingly advocated as primary therapy for patients who are not good candidates for the use of glaucoma medications or who cannot use eyedrops. In this procedure, the beam of an argon laser is directed at the trabecular meshwork. Typically about 180° of the trabecular meshwork is treated with laser spots. As a result of this procedure, the drainage of aqueous fluid out of the eye increases, thus lowering IOP.

Gene therapy may also be part of future treatments. A mutation in the gene myocilin is believed to cause most cases of juvenile glaucoma, and 3–4% of adult glaucoma. As of 2001, researchers are investigating drugs that inhibit myocilin production. The drug therapy would not just treat IOP, but also could be used before glaucoma's onset.

KEY TERMS

Agonist—A drug that mimics one of the body's own molecules.

Alpha-2 agonist (alpha-2 adrenergic receptor agonist)—A class of drugs that binds to and stimulates alpha-2 adrenergic receptors, causing responses similar to those of adrenaline and noradrenaline. They inhibit aqueous humor production and have a wide variety of side effects, including dry mouth, fatigue, and drowsiness.

Aqueous humor—A transparent liquid, contained in the anterior chamber (between the cornea and lens) of the eye, that is composed of water, sugars, vitamins, proteins, and other nutrients.

Beta blocker (beta-adrenergic blocker)—A class of drugs that binds to beta-adrenergic receptors and thereby decreases the ability of the body's own natural epinephrine to bind to those receptors, leading to inhibition of various processes in the body's sympathetic system. Beta blockers can slow the heart rate, constrict airways in the lungs, lower blood pressure, and reduce aqueous secretion by ciliary tissues in the eye.

Carbonic anhydrase inhibitor—A class of diuretic drugs that inhibits the enzyme carbonic anhydrase, an enzyme involved in producing bicarbonate, which is required for aqueous humor production by the ciliary tissues in the eye. Thus, inhibitors of this enzyme decrease aqueous humor production. Some side effects of these drugs are urinary frequency, kidney stones, loss of the sense of taste, depression, and anemia.

Cornea—Clear, bowl-shaped structure at the front of the eye. It is located in front of the colored part of the eye (iris). The cornea lets light into the eye and partially focuses it.

Gonioscope—An instrument used to examine the trabecular meshwork. It consists of a magnifier and a lens equipped with mirrors, which sits on the patient's cornea.

Hyperosmotic drugs—A class of drugs for glaucoma that increases the osmotic pressure in the blood, which then pulls water from the eye into the blood.

Iris—The colored part of the eye just behind the cornea and in front of the lens that controls the amount of light sent to the retina.

Lens (the crystalline lens)—A transparent structure in the eye that focuses light onto the retina.

Miotic—A drug that causes pupils to contract.

Ophthalmoscope—An instrument, with special lighting, designed to view structures in the back of the eye.

Optic nerve—The nerve that carries visual messages from the retina to the brain.

Prostaglandin—A group of molecules that exerts local effects on a variety of processes including fluid balance, blood flow, and gastrointestinal function.

Prostaglandin analogue—A class of drugs that are similar in structure and function to prostaglandin.

Retina—The inner, light-sensitive layer of the eye containing rods and cones.

Sclera—The tough, fibrous, white outer protective covering that surrounds the eye.

Tonometry—The measurement of pressure.

Trabecular meshwork—A sponge-like tissue located near the cornea and iris that functions to drain the aqueous humor from the eye into the blood.

Vitamin C, vitamin B₁ (**thiamine**), chromium, **zinc**, and rutin may reduce IOP.

Patients using alternative methods to attempt to prevent optic nerve damage should be advised they also need the care of a traditionally trained ophthalmologist or optometrist who is licensed to treat glaucoma, so that IOP and optic nerve damage can be monitored.

Prognosis

About half of the people who have glaucoma are not aware of it. For them, the prognosis is not good, and

many of them will become blind. On the other hand, the prognosis for treated glaucoma is excellent.

Health care team roles

Nursing and allied health professionals play an important part in the diagnosis and treatment of glaucoma. Skilled ophthalmic technicians and assistants record the patient history and perform many of the preliminary tests. Depending on skill level, these ophthalmic assistants may perform measurement of visual acuity under both low and high illumination, assessment of ocular

motility and binocularity, visual fields, measurement of IOPs with tonometers, evaluation of pupillary responses, and refraction.

Before surgical procedures, nurses and assistants also prepare the operating room (OR). Many ophthalmologists now have their own ambulatory surgery centers where skilled technicians and ophthalmic nurses play a critical role in preparing the OR and patients for the surgery. Ophthalmic nurses also assist the ophthalmologists during surgery and discuss outcomes with patients post-operatively.

Nurses and assistants assist patients by explaining the sometimes difficult regimen of glaucoma medication. In some cases, patients require several doses of a combination of medications. Ophthalmic nurses and assistants show patients the correct technique for inserting eye-drops, and reinforce the physician's instructions for medication compliance.

Patient education

Ophthalmic assistants and nurses help to ensure that patients return to the physician's office in a timely manner so that IOPs can be monitored. Nurses and assistants also emphasize the importance of adhering to the eyedrop schedule to keep IOPs at a lower level, and answer any questions concerning proper **eyedrop instillation**.

Prevention

Because glaucoma may not initially cause symptoms, the best form of prevention is to have regular eye exams.

Patients with narrow angles should avoid certain medications (including some over-the-counter medications, such as some cold or allergy medications). Patients who are glaucoma-susceptible (i.e. have narrow angles and borderline IOPs) should be advised to read the warning labels on over-the-counter medicines and inform physicians of products they are considering taking. Steroids may also raise IOP, so patients may need to be monitored more frequently if it is necessary for them to use steroids.

Not enough is known about the underlying mechanisms of glaucoma to prevent the disease itself. However, prevention of optic nerve damage from glaucoma is essential and can be accomplished when glaucoma is diagnosed and treated. As more is learned about the genes that cause glaucoma, it may become possible to

test DNA and identify potential glaucoma patients, so they can be treated before IOPs become elevated.

Gliding joint

Definition

A gliding joint is a synovial joint in which the bony surfaces that the joint holds together are flat, or only slightly rounded. (A synovial joint is the living material that holds two or more bones together but also permits these bones to move relative to each other.) A more precise interpretation of the international Latin anatomical term for the gliding joint would be “joint that joins flat bony surfaces.” The wrists have good examples of gliding joints (as well as joints of other types).

Description

If the bony surfaces of two bones which meet at a joint actually touched each other, then motion would cause friction that would soon produce wear and tear on the touching ends of the bones. An engineer designing a mechanical counterpart would arrange for lubricating oil to prevent such wear and tear and facilitate smooth movement between the two metal “bones.” A joint thus joins bones together (indeed, it is called a “joint” because it “joins” them) but also keeps them slightly separated to prevent their damaging each other in motion.

A kind of cartilage special to joints covers the ends of the bones being joined. A membrane hermetically seals two (or more) bone-ends with their cartilage, enclosing them in a kind of living capsule. For the sake of simplicity, the following example discusses a joint with only two bones. Inside this membrane capsule, there is a short distance between the cartilage of one bone and the cartilage of the other, because even cartilage rubbing directly against cartilage would produce wear and tear. But the gap between the cartilage surfaces is not a vacuum and is not filled with air. It is filled with synovial fluid. This synovial fluid is in a sense the equivalent of the motor oil which lubricates moving parts of an automobile engine.

The interior of a synovial joint has negative pressure in relation to air pressure. For this reason, air pressure pushes the bones together tightly into the capsule while the fluid keeps them from actually touching. The hermetically sealed membrane capsule in this paradoxical fashion aids the tight joining while it ensures the slight separation.

This negative pressure in the joint continues to work even after death. Of course, the two bones are kept together in a living body not only by the membrane capsule and the synovial fluid but also by the tissues around the bones. If in dissecting a corpse one removes the tissues leaving only the membrane capsule, the pair of

KEY TERMS

Articulation—A synonym for “joint.”

Carpals—The eight small bones that form the wrist and are joined to the metacarpals of the hand and to the bones of the forearm.

Metacarpals—The five bones of the hand that are joined to the carpal bones of the wrist and to the digits.

Neoplasm—New and abnormal growth of tissue, which may be non-cancerous (benign) or cancerous (malignant)

Synovial fluid—A transparent, sticky fluid that lubricates joints and nourishes the cartilage in a joint. (It is also found in tendons, sheaths, and bursae.)

Tarsals—The seven bones located between the bones of the lower leg and the metatarsals.

Vertebrae—Bones of the spine.

bones will remain tightly joined. But if one pierces the capsule and allows air to rush inside, one then has normal atmospheric pressure inside the capsule instead of the negative pressure of the interior of the joint when it is hermetically sealed by the capsule, and now the bones come easily apart.

Synovial fluid has another important quality. Most bodily tissues are nourished by **blood vessels**, but the cartilage on bone-ends in joints does not have blood vessels. Synovial fluid provides the **nutrition** for the cartilage that keeps it alive, strong, and healthy. The wall of the membrane capsule has two layers. The outer layer is fibrous. The inner layer produces the synovial fluid, and hence is called the synovial layer.

Function

A gliding joint allows three different kinds of motion: linear motion, such as smooth sliding of bone past bone (the bones seem to glide past each other, hence the name “gliding” joint), angular motion such as bending and stretching, and circular motion. The ends of the bones that a gliding joint joins are nearly flat or only slightly curved and thus facilitate the characteristic sliding, bending, and twisting movements.

Role in human health

The role of gliding joints in human health (the same as that played by the other types of synovial joints) is to

allow freedom of movement and thus provide flexibility to the skeleton.

Common diseases and disorders

The gliding joints (and the other joints) can be affected by such conditions as the following:

- **Ankylosis:** The fusion of bones across a joint. It is often a complication of arthritis.
- **Ankylosing spondylitis:** A type of inflammatory arthritis that progresses to ankylosis. It occurs chiefly in young men.
- **Capsulitis:** Inflammation of the membrane capsule that produces and encloses the synovial fluid.
- **Dislocation:** The displacing of a bone from its normal position, causing tendons to stretch and strain.
- **Neoplasms:** Abnormal growths (neoplasms) involving the gliding joints are rare. If such growths occur, they usually involve non-cancerous (benign) growths of cartilage or of tendons and their sheaths at the joints of the wrists. Synovial sarcoma is a cancerous (malignant) growth of cells resembling those of the synovial layer of the membrane capsule. It is found at the contact surfaces of bones in a joint, usually in the larger joints of young adults.
- **Rheumatoid arthritis:** A common form of chronic inflammation of the joints. It causes swelling, **pain**, stiffness, elevated temperature, and redness of the joints. It is a disease of connective tissue and leads to the destruction of bone, cartilage, and ligaments in the joint.

Glucose tests

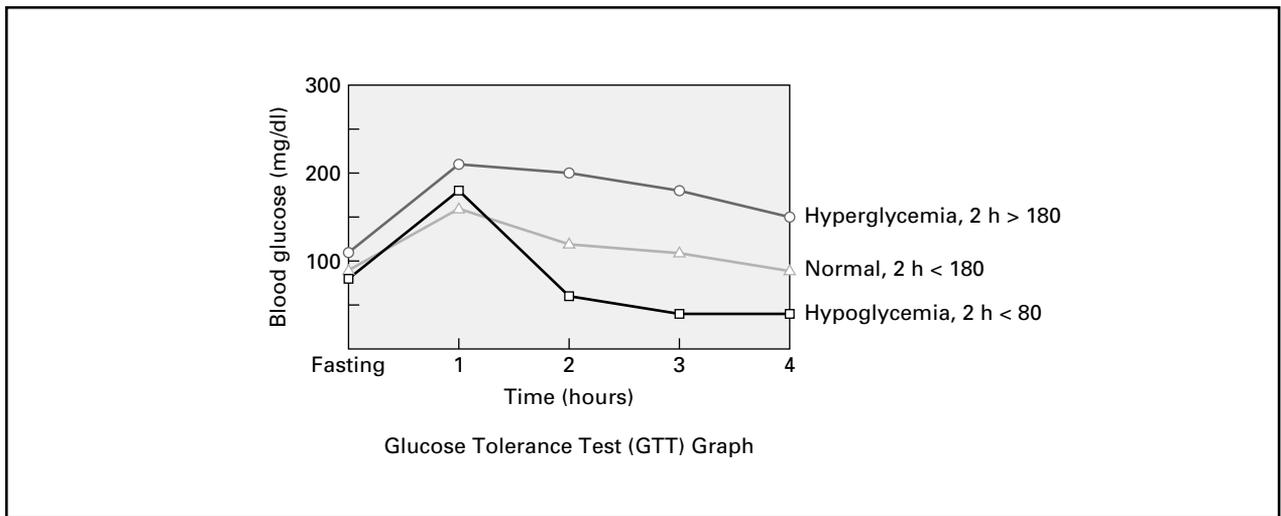

Definition

Glucose tests are used to determine the concentration of glucose in **blood**, urine, cerebrospinal fluid, and other body fluids. These tests are used to detect an increased blood glucose (hyperglycemia), a decreased blood glucose (hypoglycemia), increased glucose in the urine (glycosuria), and a decrease in cerebrospinal, serous, and synovial fluid glucose.

Purpose

Glucose tests are used in a variety of situations including:

- **Screening persons for diabetes mellitus.** The American Diabetes Association (ADA) recommends that a fasting plasma glucose (fasting blood sugar) be used to diagnose diabetes. People without symptoms of diabetes should be tested when they are 45 years old and again every three years. People in high-risk groups should be tested before the age of 45 and tested more frequently. If the person already has symptoms of diabetes, a blood glucose test without fasting, called a casual plasma glucose test, may be performed. In difficult diagnostic cases, a glucose challenge test called a two-hour oral glucose tolerance test is recommended. If the result of any of these three tests is abnormal, it must be confirmed with a second test performed on another day. The same test or a different test can be used, but the result of the second test must be abnormal as well in order to establish a diagnosis of diabetes.
- **Screening for gestational diabetes.** Diabetes that occurs during **pregnancy** is called gestational diabetes. This condition is associated with **hypertension**, increased birth weight, and a higher risk for pre-eclampsia. Women who are at risk are screened when they are 24-28 weeks pregnant. A woman is considered at risk if she is older than 25 years, is not at her normal body weight, has a parent or sibling with diabetes, or is in an ethnic group that has a high rate of diabetes (Hispanic, Native American, Asian, African-American).
- **Blood glucose monitoring.** Daily measurement of whole blood glucose identifies diabetics who require intervention to maintain their blood glucose within an acceptable range as determined by their physician. The Diabetes Control and Complications Trial (DCCT) demonstrated that persons with diabetes who maintained blood glucose and glycated hemoglobin at or near normal decreased their risk of complications by 50-75%. Based on results of this study, the American Diabetes Association (ADA) recommends routine gly-

Glucose tolerance test (GTT). (Delmar Publishers, Inc. Reproduced by permission.)

cated hemoglobin testing to measure long-term control of blood sugar.

- Diagnosis and differentiation of hypoglycemia. Low blood glucose associated with neuroglycopenia produces symptoms such as confusion, **memory** loss, and seizure. Demonstration that such symptoms are the result of hypoglycemia requires evidence of a low blood glucose at the time of symptoms and reversal of the symptoms by glucose. In documented hypoglycemia, blood glucose tests are used along with measurements of insulin and C-peptide (a fragment of proinsulin) to differentiate between fasting and postprandial causes.
- Analysis of glucose in body fluids. High levels of glucose in body fluids reflect a hyperglycemic state and is otherwise not clinically significant. However, low body fluid glucose levels indicate increased glucose utilization which is often caused by **infection** (e.g., **meningitis** causes a low CSF glucose); inflammatory disease (e.g., rheumatoid arthritis causes a low pleural fluid glucose); or malignancy (e.g., a leukemia or lymphoma such as Hodgkin's disease infiltrating the **central nervous system** or serous cavity).

Precautions

Diabetes must be diagnosed as early as possible. If left untreated, it will result in progressive vascular disease that may damage the **blood vessels**, nerves, **kidneys**, **heart**, and other organs. **Brain** damage can occur from glucose levels below 40 mg/dL and **coma** from levels above 450 mg/dL. For this reason, plasma glucose levels below 40 mg/dL or above 450 mg/dL are com-

monly used as alert values. Point-of-care and home glucose monitors measure glucose in whole blood rather than plasma and are accurate generally within a range of glucose concentration between 40 and 450 mg/dL. In addition, whole blood glucose measurements are generally 10% lower than serum or plasma glucose owing to the greater water content of the red blood cells. Results are not definitive beyond the manufacturer's stated measuring range, and should be repeated as soon as possible to avoid hypoglycemic **shock**, cardiac arrest, coma, and other complications of an extremely abnormal glucose result.

Other endocrine disorders and several medications can cause both hyperglycemia and hypoglycemia. For this reason, abnormal glucose test results must be interpreted by a physician.

A nurse or phlebotomist who collects the sample for a plasma glucose test should follow standard precautions for the prevention of transmission of bloodborne pathogens. Glucose is a labile substance; therefore, plasma or serum must be separated from the blood cells and refrigerated as soon as possible. Samples that must be transported unrefrigerated to a distant site should be collected in a tube with an additive such as sodium fluoride to inhibit glycolysis. Blood glucose methods are largely free of interferences. However, hemolysis may increase the glucose result when measured by the hexokinase method, and high levels of ascorbic acid may reduce the glucose result when measured by the glucose oxidase method. Glycated hemoglobin measurements may be affected by abnormal hemoglobin pigments, such as methemoglobin and structural hemoglobin abnormalities such as hemoglobin S. Splenectomy can result in an

increase and hemolytic anemia a decrease in glycated hemoglobin.

Exercise, diet, anorexia, and smoking affect the results of the oral glucose tolerance test. Drugs that decrease tolerance to glucose and affect the test include steroids, oral contraceptives, estrogens, and thiazide diuretics.

Description

The body uses glucose to produce the majority of the energy it needs to function. Glucose is absorbed from the gastrointestinal tract directly and is also derived from digestion of other dietary **carbohydrates**. It is also produced inside cells by the processes of glycogen breakdown (glycogenolysis) and reverse glycolysis (gluconeogenesis). Insulin is made by the **pancreas** and facilitates the movement of glucose from the blood and extracellular fluids into the cells. Insulin also promotes cellular production of **lipids** and glycogen and opposes the action of glucagon which increases the formation of glucose by cells.

Diabetes may result from a lack of insulin or a subnormal response to insulin. There are three forms of diabetes: Type I or insulin dependent (IDDM), type II or noninsulin dependent (NIDDM), and gestational diabetes (GDM). Type I diabetes usually occurs in childhood and is associated with low or absent blood insulin and production of ketones even in the absence of stressed metabolic conditions. It is caused by autoantibodies to the islet cells in the pancreas that produce insulin, and persons must be given insulin to control blood glucose and prevent ketosis. Type II accounts for 85% or more of persons with diabetes. It usually occurs after age 40, and is usually associated with **obesity**. Persons who have a deficiency of insulin may require insulin to maintain glucose, but those who have a poor response to insulin may not. Ketosis does not develop under normal metabolic conditions but may occur with **stress**. Gestational diabetes is a form of glucose intolerance that first appears during pregnancy. It abates after delivery, but over a 10-year span approximately 30-40% of females with gestational diabetes go on to develop noninsulin dependent diabetes.

There are a variety of ways to measure a person's blood glucose.

Whole blood glucose tests

Whole blood glucose testing can be performed by a person in his or her home, or by a member of the health care team outside the laboratory. The test is usually performed using a drop of whole blood obtained by finger

puncture. Care must be taken to wipe away the first drop of blood because this is diluted with tissue fluid. The second drop is applied to the dry reagent test strip or device. All whole blood glucose analyzers use the glucose oxidase reaction to measure glucose concentration. In the home test kits, the enzymes glucose oxidase and peroxidase, a buffer, and dye are immobilized on the testing device. When the blood contacts the reaction zone, it hydrates the reagents. The glucose oxidase utilizes oxygen to oxidize the glucose forming gluconic acid and hydrogen peroxide. The peroxidase enzyme catalyzes the oxidation of the dye by the hydrogen peroxide producing a colored product. The test strip or device is inserted into a portable analyzer that measures the amount of color produced. Concentration of glucose is determined by comparing the color intensity, called the reflectance density, to that for a standard measured the same way. Point-of-care devices often utilize the same method. However, some devices employ the polarographic glucose oxidase method. In this procedure, the glucose oxidase is impregnated into a glucose permeable membrane that covers an electrode. Peroxidase and dye are not required. Glucose from the sample diffuses through the membrane and the glucose oxidase catalyzes the formation of hydrogen peroxide inside the electrode. The peroxide is unstable and reforms oxygen and water. The oxygen is reduced at the cathode of the electrode producing a current that is proportional to glucose concentration.

Fasting plasma glucose test

The fasting plasma glucose test requires an eight-hour fast. The person must have nothing to eat or drink except water. The person's blood is usually collected by a nurse or phlebotomist via venipuncture. Either serum, the liquid portion of the blood after it clots, or plasma may be used. Plasma is the liquid portion of unclotted blood that is collected in an anticoagulant. The glucose is measured by an enzymatic glucose method. The glucose oxidase-peroxidase or glucose oxidase-polarographic methods may be used and are similar to those described above. Two additional methods used are the hexokinase and glucose dehydrogenase methods. These methods both result in the production of NADH (NADPH) in proportion to the glucose concentration in the sample. The reaction is measured in an automated chemistry analyzer which measures light absorption. The amount of light absorbed by the NADH at 340 nm is directly proportional to the glucose in the sample. Enzymatic methods measure no sugar other than glucose, and the same normal range can be used. The ADA recommends a normal range for fasting plasma glucose of 55-109 mg/dL. A glucose level equal to greater than 126 mg/dL is indica-

Normal findings for glucose tolerance test (GTT, oral glucose tolerance test [OGTT])**Blood test**

Fasting	70–115 mg/dl (<6.4 mmol/L)
30 minutes	<200 mg/dl (<11.1 mmol/L)
1 hour	<200 mg/dl (<11.1 mmol/L)
2 hours	<140 mg/dl (<7.8 mmol/L)
3 hours	70–115 mg/dl (<6.4 mmol/L)
4 hours	70–115 mg/dl (<6.4 mmol/L)
Urine test	Negative

SOURCE: Pagana, K.D. and T.J. Pagana. *Mosby's Diagnostic and Laboratory Test Reference*. 3rd ed. St. Louis: Mosby, 1997.

tive of diabetes. A fasting plasma glucose level of 110–125 mg/dL is referred to as “impaired fasting glucose.”

Oral glucose tolerance test (OGTT)

The oral glucose tolerance test is done to see how well the body handles a standard amount of glucose. There are many variations of this test. A two-hour OGTT as recommended by the ADA is described below. The person must have at least 150 grams of carbohydrate each day, for at least three days before this test. The person must take nothing but water and abstain from exercise for 12 hours before the glucose is given. At 12 hours after the start of the fast, the person is given 75 grams of glucose to ingest in the form of a drink or standardized jelly beans. A health care provider draws a sample of venous blood two hours following the dose of glucose. The serum or plasma glucose is measured by an enzymatic method. A glucose concentration equal to or greater than 200 mg/dL is indicative of diabetes. A level below 140 mg/dL is considered normal. A level of 140–199 mg/dL is termed “impaired glucose tolerance.”

Testing for gestational diabetes

The screening test for gestational diabetes is performed between 24 and 28 weeks of pregnancy. No special preparation or fasting is required. The patient is given an oral dose of 50 grams of glucose and blood is drawn one hour later. A plasma or serum glucose less than 140 mg/dL is normal and requires no follow-up. If the glucose is 140 mg/dL or higher, a three-hour oral glucose tolerance test is performed. The same pretest preparation is followed as for the two-hour OGTT described earlier except that 100 grams of glucose is given orally. Blood is drawn at the end of the fast and at one, two, and three hours after the glucose is ingested. Gestational diabetes is diagnosed if two or more of the following results are obtained:

- fasting plasma glucose greater than 105 mg/dL
- one-hour plasma glucose greater than 190 mg/dL
- two-hour plasma glucose greater than 165 mg/dL
- three-hour plasma glucose greater than 145 mg/dL

Glycated hemoglobin blood glucose test (G-Hgb)

The glycated (glycosylated) **hemoglobin test** is used to monitor the effectiveness of diabetes treatment. Glycated hemoglobin is a test that indicates how much glucose was in a person's blood during a two- to three-month window beginning about four weeks prior to sampling. The N-terminal valine of the beta globin chain of hemoglobin forms an irreversible amide bond with glucose and other carbohydrates. The additional carbohydrate increases the negative charge of the hemoglobin molecule. When the various hemoglobins are separated by chromatography the hemoglobin bound to glucose is located in the fastest fraction called HbA_{1c}. Since the glucose inside the red cells is in equilibrium with the plasma glucose, a spurious increase in the plasma level will increase the percentage of glycated hemoglobin. The test is a measure of the time-averaged blood glucose over the 120-day life span of the red blood cells. The normal range for glycated hemoglobin measured as HbA_{1c} is 3–6%. Values above 8% indicate that a hyperglycemic episode occurred sometime during the window monitored by the test (two to three months beginning four weeks prior to the time of blood collection). The following formula estimates the average blood glucose during this window: (% G-Hgb x 33.3 mg/dL) - 86 = average blood glucose. Methods available to measure glycated hemoglobin include column and high performance liquid chromatography, electrophoresis, and ion capture. The first three are based upon the fact that glycated hemoglobin has a greater negative charge than nonglycated hemoglobin. Ion capture is a novel method based upon the ability of glycated hemoglobin to suppress the fluorescence of a dye.

The ADA recommends that glycated hemoglobin testing be performed during a person's first diabetes evaluation, again after treatment is begun and glucose levels are stabilized, then repeated semiannually. If the person does not meet treatment goals, the test should be repeated quarterly.

A related blood test, fructosamine assay, measures the amount of albumin in the plasma that is bound to glucose. Albumin has a shorter half-life than red blood cells, and this test reflects the time-averaged blood glucose over a period of two to three weeks prior to sample collection.

Preparation

Blood glucose tests require either whole blood, serum or plasma collected by venipuncture or finger puncture. No special preparation is required for a casual blood glucose test. An eight-hour fast is required for the fasting plasma or whole blood glucose test. A 12-hour fast is required for the two-hour OGTT and three-hour OGTT tests. In addition, the person must abstain from exercise in the 12-hour fasting period. Medications known to affect carbohydrate **metabolism** should be discontinued three days prior to an OGTT test if possible, and the person must maintain a diet of at least 150 grams of carbohydrate per day for at least three days prior to the fast.

Aftercare

After the test or series of tests is completed (and with the approval of his or her doctor), the person should eat, drink, and take any medications that were stopped for the test.

The patient may feel discomfort when blood is drawn from a vein. Bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure should be applied to the puncture site until the bleeding stops to reduce bruising. Warm packs can also be placed over the puncture site to relieve discomfort.

Complications

The patient may experience weakness, fainting, sweating, or other reactions while fasting or during the test. If this occurs, he or she should immediately inform their physician or nurse.

Results

Normal values listed below are for children and adults. Results may vary slightly from one laboratory to another depending upon the method of analysis used.

- fasting plasma glucose test: 55-109 mg/dL
- oral glucose tolerance test at two hours: less than 140 mg/dL.
- glycated hemoglobin: 3-6%
- fructosamine: 1.6-2.7 mmol/L for adults (5% lower for children)
- gestational diabetes screening test: less than 140 mg/dL
- cerebrospinal glucose: 40-80 mg/dL
- serous fluid glucose: equal to plasma glucose

Blood glucose test (blood sugar, fasting blood sugar [FBS])

	Normal findings	Possible critical values
Cord	45–96 mg/dl (2.5–5.3 mmol/L)	
Premature infant	20–60 mg/dl (1.1–3.3 mmol/L)	
Newborn	30–60 mg/dl (1.7–3.3 mmol/L)	<30 and >300 mg/dl
Infant	40–90 mg/dl (2.2–5.0 mmol/L)	<40 mg/dl
Child <2 years	60–100 mg/dl (3.3–5.5 mmol/L)	
Child >2 years to adult	70–105 mg/dl (3.9–5.8 mmol/L)	Male: <50 and >400 mg/dl Female: <40 and >400 mg/dl
Elderly	increase in normal range after age 50 years	

SOURCE: Pagana, K.D. and T.J. Pagana. *Mosby's Diagnostic and Laboratory Test Reference*. 3rd ed. St. Louis: Mosby, 1997.

- synovial fluid glucose: within 10 mg/dL of the plasma glucose

- urine glucose (random semiquantitative): negative

For the diabetic person, the ADA recommends an ongoing blood glucose goal of less than or equal to 120 mg/dL.

The following results are suggestive of diabetes mellitus, and must be confirmed with repeat testing:

- fasting plasma glucose test: greater than or equal to 126 mg/dL
- oral glucose tolerance test at two hours: equal to or greater than 200 mg/dL
- casual plasma glucose test (nonfasting, with symptoms): equal to or greater than 200 mg/dL
- gestational diabetes three-hour oral glucose tolerance test: two or more of the limits below are exceeded
- fasting plasma glucose: greater than 105 mg/dL
- one-hour plasma glucose greater than 190 mg/dL
- two-hour plasma glucose greater than 165 mg/dL
- three-hour plasma glucose greater than 145 mg/dL

Health care team roles

Prior to the test the health care professional administering an OGGT should describe the symptoms of hypoglycemia to the patient and tell the patient to alert a health care worker should he or she experience any of those symptoms. A phlebotomist, or sometimes a nurse, collects the blood, and a clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) or clinical laboratory technician CLT(NCA)/medical laboratory

KEY TERMS

Diabetes mellitus—A disease in which a person cannot effectively use glucose to meet the needs of the body. It is caused by a lack of the hormone insulin.

Glucose—The main form of sugar (chemical formula $C_6H_{12}O_6$) used by the body for energy.

Glycated hemoglobin—A test that measures the amount of hemoglobin bound to glucose. It is a measure of how much glucose has been in the blood during a 2-3 month period beginning approximately one month prior to sample collection.

technician MLT(ASCP) performs the testing. Results are interpreted by a physician. Critically high or low glucose levels should be immediately called to the attention of the patient's nurse or doctor. Physicians and nurses are responsible for educating patients about how to best manage their diabetes.

Gout

Definition

Gout is a form of acute arthritis that causes severe **pain** and swelling in the joints. It most commonly affects the big toe, but may also affect the heel, ankle, hand, wrist, or elbow. Attacks of gout usually come on suddenly, stop after five to 10 days, and can keep recurring.

Description

Gout is different from other forms of arthritis because it occurs when there are high levels of uric acid circulating in the **blood**, which can cause urate crystals to settle in the tissues of the joints. Uric acid, which is found naturally in the bloodstream, is formed as the body breaks down waste products, mainly those containing purine, a substance that is produced by the body and found in high concentrations in some foods, including brains, **liver**, sardines, anchovies, and dried peas and beans. Normally, the **kidneys** filter uric acid out of the blood and excrete it in the urine. Sometimes, however, the body produces too much uric acid or the kidneys

aren't efficient enough at filtering it from the blood. As a result, it builds up in the blood stream, a condition known as hyperuricemia. Some people are more susceptible to gout because of inherited genes. Being overweight and eating a rich diet also increases susceptibility. In some cases, another disease (such as lymphoma, leukemia, or hemolytic anemia) may be the underlying cause of the uric acid buildup that results in gout.

Hyperuricemia doesn't always cause gout. However, over the course of years, sharp urate crystals build up in the synovial fluid of the joints. Often, some precipitating event, such as an **infection**, surgery, a stubbed toe, or even a heavy drinking binge can cause inflammation. White blood cells, mistaking the urate crystals for a foreign invader, flood into the joint and surround the crystals, causing inflammation (the redness, swelling, and pain that are the hallmarks of a gout attack).

Causes and symptoms

As a result of high levels of uric acid in the blood, needle-like urate crystals gradually accumulate in the joints. Urate crystals may be present in the joint for a long time without causing symptoms. Infection, injury to the joint, surgery, drinking too much, or eating the wrong kinds of foods may suddenly bring on the symptoms, which include pain, tenderness, redness, warmth, and swelling of the joint. In many cases, the gout attack begins in the middle of the night. The pain is often so excruciating that the patient cannot bear weight on the joint or tolerate the pressure of bedcovers. The inflamed skin over the joint may be red, shiny, and dry, and the inflammation may be accompanied by a mild **fever**. These symptoms may go away in about a week and disappear for months or years at a time. However, over the course of time, attacks of gout recur more and more frequently, last longer, and affect more joints. Eventually, stone-like deposits known as tophi may build up in the joints, ligaments, and tendons, leading to permanent joint deformity and decreased motion. In addition to causing the tophi associated with gout, hyperuricemia can cause **kidney stones**, also called renal calculi or uroliths.

Gout affects an estimated one million Americans. Men are more commonly affected than women by a ratio of 4 to 1. Uric-acid levels tend to increase in men at **puberty**, and, because it takes 20 years of hyperuricemia to cause gout symptoms, men commonly develop gout in their late 30s or early 40s. Women more typically develop gout later in life, starting in their 60s. According to some medical experts, estrogen protects against hyperuricemia. When estrogen levels fall during **menopause**, urate crystals can begin to accumulate in the joints. Excess body weight, regular excessive alcohol intake, the

use of **blood pressure** medications called diuretics, and high levels of certain fatty substances in the blood (serum triglycerides) associated with an increased risk of heart disease can all increase a person's risk of developing gout.

Diagnosis

Usually, physicians can diagnose gout based on the **physical examination** and medical history (a person's description of symptoms and other information). Doctors can also administer a test that measures the level of uric acid in the blood. While normal uric acid levels don't necessarily rule out gout and high levels don't confirm it, the presence of hyperuricemia increases the likelihood of gout. The development of a tophus can confirm the diagnosis of gout. The most definitive way to diagnose gout is to take a sample of fluid from the joint and test it for urate crystals.

Treatment

The goals of treatment for gout consist of alleviating pain, avoiding severe attacks in the future, and preventing long-term joint damage. In addition to taking pain medications as prescribed by their doctors, people having gout attacks are encouraged to rest and to increase the amount of fluids that they drink.

Acute attacks of gout can be treated with nonaspirin, **nonsteroidal anti-inflammatory drugs** (NSAIDs) such as naproxen sodium (for example, Aleve), ibuprofen (for example, Advil), or indomethacin (for example, Indocin). In some cases, these drugs can aggravate a peptic ulcer or existing kidney disease and cannot be used. Doctors sometimes also use colchicine (for example, Colbenemid), especially in cases where nonsteroidal anti-inflammatory drugs cannot be used. Colchicine may cause **diarrhea**, which tends to go away once the patient stops taking it. **Corticosteroids** such as prednisone (for example, Deltasone) and adrenocorticotropic hormone (for example, Acthar) may be given orally or may be injected directly into the joint for a more concentrated effect. While all of these drugs have the potential to cause side effects, they are used for only about 48 hours and are not likely to cause major problems. However, aspirin and closely related drugs (salicylates) should be avoided because they can ultimately worsen gout.

Once an acute attack has been successfully treated, doctors try to prevent future attacks of gout and long-term joint damage by lowering uric acid levels in the blood. There are two types of drugs for correcting hyperuricemia. Uricosuric drugs, such as probenecid (for example, Benemid) and sulfinpyrazone (for example,

KEY TERMS

Allopurinol—A drug that corrects hyperuricemia by inhibiting urate production.

Colchicine—A drug used to treat painful flare-ups of gout.

Corticosteroids—Medications related to a natural body hormone called hydrocortisone, which are used to treat inflammation.

Hyperuricemia—High levels of a waste product called uric acid in the blood.

Probenecid—A drug that corrects hyperuricemia by increasing the urinary excretion of urate.

Purine—A substance found in foods that is broken down into urate and may contribute to hyperuricemia and gout.

Sulfinpyrazone—A drug that corrects hyperuricemia by increasing the urinary excretion of urate.

Synovial fluid—Fluid surrounding the joints which acts as a lubricant, reducing friction between the joints.

Tophi—Stone-like deposits of uric acid crystals that may build up in the joints, ligaments, and tendons, and lead to permanent joint deformity and decreased motion.

Urate crystals—Crystals formed by high levels of uric acid in the blood.

Anturane), lower the levels of urate in the blood by increasing its removal from the body (excretion) through urine. These drugs may promote the formation of kidney stones, and they may not work for all persons, especially those with kidney disease. Allopurinol (for example, Zyloprim), a type of drug called a xanthine-oxidase inhibitor, blocks the production of urate in the body and can dissolve kidney stones as well as treating gout. The potential side effects of allopurinol include rash, a skin condition known as dermatitis, and liver dysfunction. Once people begin taking these medications, they must take them for life or the attacks of gout will continue to return.

Alternative treatment

The alternative medicine approach to gout focuses on correcting hyperuricemia by losing weight and limiting the intake of alcohol and purine-rich foods. In addition, consuming garlic (*Allium sativum*) has been recom-

mended to help prevent gout. Increasing fluid intake, especially by drinking water, is also recommended. During an acute attack, contrast **hydrotherapy** (alternating three-minute hot compresses with 30-second cold compresses) can help dissolve the crystals and quickly resolve pain.

Prognosis

Gout cannot be cured but usually it can be successfully managed. As tophi dissolve, joint mobility generally improves. In some cases, however, medicines alone do not dissolve the tophi and they must be surgically removed. Lowering uric acid in the blood also helps to prevent or improve the kidney problems that may accompany gout.

Health care team roles

Family practitioners or internists, nurse practitioners, and physician assistants commonly make a diagnosis of and treat gout. Nurses also provide **patient education** and monitor the patient's progress after treatment is begun.

Prevention

For centuries, gout has been known as a “rich man's disease” or a disease of overindulgence in food and drink. While this view is perhaps a little overstated and oversimplified, lifestyle factors clearly influence a person's risk of developing gout. Since **obesity** and excessive alcohol intake are associated with hyperuricemia and gout, losing weight and limiting alcohol intake can help ward off gout. **Dehydration** may also promote the formation of urate crystals, so people taking diuretics or “water pills” may be better off switching to another type of blood pressure medication. All people are advised to drink at least six to eight glasses of water each day. Since purine is broken down in the body into urate, it may also be helpful to avoid foods high in purine, such as organ meats, sardines, anchovies, red meat, gravies, beans, beer, and wine.

Gram stain

Definition

The Gram stain test is the most extensively performed procedure in diagnostic microbiology. It is used to classify **bacteria** as either gram-positive or gram-negative based upon their ability to retain the crystal violet stain following decolorization. In addition, the Gram stain provides vital diagnostic information, aids in the selection of culture media, and dictates initial selection of **antibiotics** for treatment and antimicrobial susceptibility testing.

Purpose

The Gram stain is used to detect the presence of bacteria, yeast, and other cells in direct smears prepared from swabs, aspirates, secretions, etc. from any part of the body where **infection** is suspected. Direct smears are often made of throat swabs, sputum, genital swabs, **wounds**, abscesses, cerebrospinal fluid (CSF), serous fluids, joint fluid, urine, and stool. Gram stain is also performed to help identify colonies isolated from cultures. In addition to gram-negative or gram-positive, organisms are evaluated for size, shape, arrangement, number, and any special characteristics such as bipolar staining and the presence of spores. These characteristics often point the way to the most efficient selection of biochemical tests needed to identify the organism. The finding of organisms on direct examination of some specimens is sufficient to establish a preliminary diagnosis and justify immediate antibiotic treatment pending confirmation by culture or other means. The Gram stain is very useful in identifying anaerobic bacteria by comparing the microscopic morphology and number of organisms to culture results. Significant numbers of characteristic bacteria on Gram stain not appearing on aerobic culture often signals the presence of an anaerobic infection.

The Gram stain will identify male patients with *Neisseria gonorrhoeae* genital infections with a specificity approaching 100% and a sensitivity above 90%. In female patients, the sensitivity and specificity are lower owing to the presence of other genital flora, but the test is still sufficiently specific to justify immediate antibiotic therapy when symptoms of pelvic inflammatory disease are present. The presence of bacteria on Gram stain of concentrated CSF is presumptive evidence of bacterial **meningitis** and reason to begin antibiotic therapy. The Gram stain is positive in the majority of bacterial meningitis cases. Recovery of bacteria from other normally sterile fluids including exudative pleural, pericardial, and abdominal fluid and inflammatory joint fluid is also pre-

KEY TERMS

Crystal violet—A rosaniline dye staining all bacterial cells but retained only by gram-positive bacteria.

Decolorizer—A solution of alcohol or acetone-alcohol which removes crystal violet from the cell wall of gram-negative bacteria.

Gram stain—A test for classifying and characterizing bacteria by microscopic analysis following staining by the procedure developed by Hans Christian Gram.

Gram's iodine—A solution of iodine and potassium iodide which causes crystal violet to adhere more tightly to the bacterial cell wall.

Safranin O—A water soluble counterstain that is used to visualize gram-negative bacteria.

sumptive evidence of an infectious process. Gram stain detects approximately 70% of pleural fluids and 50% of pericardial fluids that are infected.

Description

The Gram stain was discovered by Hans Christian Gram in the late 1800s. There are several modifications but all Gram stain procedures involve four steps: staining with crystal violet, reaction with Gram's iodine, decolorization, and counterstaining. Material from a direct specimen or culture is transferred to the slide using a dropper, needle, or swab. The material is spread in the center of a glass slide until visible, and allowed to air dry. The slide is heat-fixed and allowed to cool before staining. The slide is flooded with an alcoholic solution of basic crystal violet for 30 seconds. This dye stains all cells a bright blue or purple color. Excess dye is removed with a stream of tap water and the slide is flooded with Gram's iodine (mordant) solution which should remain on the slide for one minute. The iodide displaces chloride in the dye causing it to adhere more strongly to the cell wall. The slide is rinsed in tap water to remove the mordant. Next, a stream of decolorizer is used to rinse the slide for 10 seconds followed immediately by tap water. The most commonly used decolorizer is a 1:1 solution of acetone and 95% ethanol. Gram-positive cells have a thick cell wall rich in teichoic acid. The gram-negative bacteria have a thin cell wall that is rich in **lipids**. The decolorizer is able to penetrate through the thinner lipopolysaccharide-rich cell wall of the gram-negative bacteria and wash

away the crystal violet. The slide is flooded with Safranin O counterstain and then blotted or air-dried.

The slide is examined using a light **microscope** first under low power and then using an oil immersion lens at 1000X. The nature and number of leukocytes and epithelial cells are recorded along with the number, size, shape, and gram-stain reaction of any bacteria. Gram-positive bacteria and yeast stain blue or purple while gram-negative bacteria, white cells, epithelial cells, and trichomonads stain red. Some gram-positive bacteria, especially old colonies and those from treated patients, may not resist decolorization and appear gram-negative. Some species, for example, *Mycobacterium tuberculosis* may stain gram-negative or gram-positive and are referred to as gram-variable. In addition to staining, bacteria are classified according to shape as round (coccus) or rod-shaped (bacillus). This gives four general categories; gram-positive cocci (eg. *Staphylococcus* spp.), gram-positive bacilli (eg. *Clostridium* spp.), gram-negative cocci (eg. *Neisseria* spp.), and gram-negative bacilli (*Salmonella* spp.). Other organisms may fall between these shapes (cocci) or may be variable (pleomorphic) or cigar-shaped (fusiform). Such characteristics are important leads to identification.

Preparation

For collection of samples, patients may need to be properly positioned and given specific instructions (e.g. how to produce sputum). Urine specimens should be collected from a catheter or using the midstream void technique after cleansing of the outer genitalia. **Blood**, CSF, synovial and serous fluids, and aspiration needle biopsy specimens require disinfection of the puncture site with alcohol followed by an iodine solution. Specimens should be transported in a syringe or transferred to an airtight sterile container. Swabs should be placed in transport medium to prevent drying. When collecting specimens (with the exception of urine), health care workers must follow standard precautions for the prevention of occupational exposure to bloodborne pathogens.

Aftercare

All positive Gram stain results should be confirmed by culture, DNA analysis, or serological evidence. However, in the appropriate clinical setting (e.g. the finding of bacteria in cerebrospinal fluid) antibiotics should be administered immediately. In these situations the Gram stain result provides critical information for the selection of proper antibiotic therapy. For example, gram-positive bacteria are most likely susceptible to penicillins, cephalosporins, vancomycin, and erythromy-

cin. Gram-negative bacteria are most likely susceptible to aminoglycosides, cephalosporins, and tetracyclines.

Health care team roles

Specimens may be collected or collection assisted by a physician, nurse, or physician assistant. Gram stain is performed by a clinical laboratory scientist, NCA(CLS) or medical technologist, MT(ASCP) or by a clinical laboratory technician, NCA(CLT) or medical laboratory technician, MLT(ASCP).

Gross motor skills

Definition

Gross motor skills encompass the abilities required to control the large muscles of the body for walking, running, sitting, crawling, and other activities. The muscles required to perform gross motor skills are generally found in the arms, legs, back, abdomen, and torso.

Description

Motor skills are deliberate and controlled movements requiring both muscle development and maturation of the **central nervous system**. In addition, the **skeletal system** must be strong enough to support the movement and weight involved in any new activity. Once these conditions are met, children learn new physical skills by practicing them until each skill is mastered.

Gross motor skills involve control of the extremities (arms, legs, hands, and feet) and torso. There is an orderly sequence for development of these muscles. Although

norms for motor development have been charted in great detail by researchers and clinicians over the past 50 years, the pace of development varies considerably from one child to the next. As skills become more complex, the degree of variation increases among normal children. The normal age for learning to walk has a range of several months, while the age range for turning one's head, a simpler skill that occurs much earlier, is considerably shorter. In addition to variations among children, an individual child's rate of progress varies as well, often including rapid spurts of development and frustrating periods of delay. Although rapid motor development in early childhood is often a good predictor of coordination and athletic ability later in life, no strong correlation has been demonstrated between a child's rate of motor development and intelligence. In most cases, a delay in mastering a specific motor skill is temporary and does not indicate a serious problem. However, medical advice should be sought when children lag significantly behind their peers in motor development or if they regress and lose previously acquired skills.

Function

Gross motor skills develop over a relatively short period of time. Most development occurs during childhood. However, soldiers, some athletes, and others who engage in activities requiring high degrees of endurance may spend years improving their level of muscle and body coordination and gross motor skills.

Infancy and toddler period

The sequence of gross motor development is determined by two developmental principles that also govern physical growth. The cephalo-caudal pattern, or head-to-toe development, refers to the way the upper parts of the body, beginning with the head, develop before the lower ones. Thus, infants can lift their heads and shoulders before they can sit up, which, in turn, precedes standing and walking. The other pattern of both development and maturation is proximal-distal, or trunk to extremities. One of the first things an infant achieves is head control. Although they are born with virtually no head or neck control, most infants can lift their heads to a 45-degree angle by the age of four to six weeks, and they can lift both their heads and chests at an average age of eight weeks. Most infants can turn their heads to both sides within 16 to 20 weeks and lift their heads while lying on their backs within 24 to 28 weeks. By about 36 to 42 weeks, or nine to ten months, most infants can sit up unassisted for substantial periods of time with both hands free for playing.

One of the major tasks in gross motor development is locomotion, or the ability to move from one place to another. Infants progress gradually from rolling (eight to ten weeks) to creeping on their stomachs and dragging their legs behind them (six to nine months) to actual crawling (seven months to a year). While infants are learning these temporary means of locomotion, they are gradually becoming able to support increasing amounts of weight while in a standing position. In the second half year of life, babies begin pulling themselves up on furniture and other stationary objects. By the ages of 28 to 54 weeks, on average, they begin “cruising,” or navigating a room in an upright position by holding on to the furniture to keep their balance. Eventually, they are able to walk while holding on to an adult with both hands, and then requiring only one adult hand. They usually take their first uncertain steps alone between the ages of 36 and 64 weeks and are competent walkers by the ages of 52 to 78 weeks. By the age of two years, children have begun to develop a variety of gross motor skills. They can run fairly well and negotiate stairs holding on to a banister with one hand and putting both feet on each step before going on to the next one. Most infants this age climb (some very actively) and have a rudimentary ability to kick and throw a ball.

Preschool

During a child’s first two years, most parents consider gross motor skills a very high priority. A child’s first steps are the most universally celebrated developmental milestone. By the time a child is a preschooler, however, many parents shift the majority of their attention to the child’s cognitive development in preparation for school. In addition, gross motor activity at these ages requires increasing amounts of space, equipment, and supervision. However, gross motor skills remain very important to a child’s development, and maintaining a youngster’s instinctive love of physical activity can make an important contribution to future fitness and health.

By the age of three, children walk with good posture and without watching their feet. They can also walk backwards and run with enough control for sudden stops or changes of direction. They can hop, stand on one foot, and negotiate the rungs of a jungle gym. They can walk up stairs alternating feet but usually still walk down putting both feet on each step. Other achievements include riding a tricycle and throwing a ball, although they have trouble catching it because they hold their arms out in front of their bodies independently of the direction of the ball. Four-year-olds can typically balance or hop on one foot, jump forward and backward over objects, and climb and descend stairs alternating feet. They can bounce and catch balls and throw with accuracy. Some four-year-olds

can also skip. Children this age have gained an increased degree of self-consciousness about their motor activities that leads to increased feelings of pride and success when they master a new skill. However, it can also create feelings of inadequacy when they think they have failed. This concern with success can also lead them to try daring activities beyond their abilities, so they need to be very carefully monitored.

School-age

School-age children who are not going through the rapid, unsettling growth spurts of early childhood or adolescence are quite skilled at controlling their bodies and are generally good at a wide variety of physical activities, although the ability varies on the level of maturation and the physique of each child. Motor skills are approximately equal in boys and girls at this stage, except that boys have more forearm strength and girls have greater flexibility. Five-year-olds can skip, jump rope, catch a bounced ball, walk on their tiptoes, balance on one foot for more than eight seconds, and engage in beginning acrobatics. Many can even ride a small two-wheeler bicycle. Eight- and nine-year-olds typically can ride a bicycle, swim, roller-skate, ice-skate, jump rope, scale fences, use a saw, hammer, and garden tools, and play a variety of sports. However, many of the sports prized by adults, often scaled down for play by children, require higher levels of distance judgment and hand-eye coordination, as well as quicker reaction times, than are reasonable for middle childhood. Games that are well suited to the motor skills of elementary school-age children include kick ball, dodge ball, and team relay races.

In adolescence, children develop increasing coordination and motor ability. They also gain greater physical strength and prolonged endurance. Adolescents are able to develop better distance judgment and hand-eye coordination than their younger counterparts. With practice, they can master the skills necessary for adult sports.

For some persons, the development of gross motor ability and endurance continues into adulthood. Athletes and members of the military routinely engage in activities designed to further enhance their gross motor development.

Role in human health

Encouraging gross motor skills requires a safe, open play space, peers to interact with, and some adult supervision.

Promoting the development of gross motor abilities is considerably less complicated than developing **fine motor skills**. Helping a child succeed in gross motor

tasks requires patience and opportunities for a child to practice desired skills. Parents and other persons must understand the level of development before assisting a child to master gross motor skills. Children reach developmental milestones at different rates. Pushing a child to perform a task which is impossible due to development status promotes frustration and disappointment. Children should be allowed to acquire gross motor skills at their own rates.

Common diseases and disorders

There are a range of diseases and disorders that affect gross motor skill development and skills. Among young persons, developmental problems such as genetic disorders, **muscular dystrophy**, **cerebral palsy**, and some neurological conditions adversely impact gross motor skill development. Among older persons, arthritis is a common condition. Arthritis affects the joints of the hands and feet, thus impairing the ability of muscles to perform desired movements. Stroke can impair gross motor coordination. **Parkinson's disease** affects motor movements. **Alcoholism** and drug use and withdrawal each cause motor problems.

H

***H. pylori* test**

Definition

H. pylori tests are used in gastroenterology to detect the presence of the *Helicobacter pylori* bacterium that causes peptic ulcer disease. *H. pylori* is a Gram-negative, motile, microaerophilic **bacteria** so named because of its spiral shape.

Purpose

H. pylori **infection** of the mucosal lining of the duodenum is a known cause of duodenal ulcers. *H. pylori* is also strongly implicated in other gastric conditions, including acute and chronic **gastritis**, gastric ulcers, **stomach cancer**, and lymphoma associated with the lymphoid tissues of the gastrointestinal mucosa.

There are different kinds of *H. pylori* tests, but they all have the same purpose: to determine if a person has the *H. pylori* bacteria in his or her gastrointestinal tract. After a patient has been diagnosed with a peptic ulcer disease, the gastroenterologist usually tests for the bacteria and, if it is present, treats it with a combination of two **antibiotics**. Following treatment the patient may be tested again to determine that the treatment was successful.

H. pylori may be diagnosed from tests performed on endoscopic biopsy specimens from the stomach or duodenal mucosa, breath analysis, tests on plasma or serum for specific antibodies, or tests on stool for *H. pylori* antigens.

ENDOSCOPIC BIOPSY. A culture can be done on tissue obtained by biopsy, but is generally not performed because recovery of organisms is variable. Biopsy specimens taken from the stomach or duodenum may also be examined for Gram-negative spiral rods indicative of infection, but more often are tested for *H. pylori* by adding a sample of the tissue to a broth containing urea. The bacterium produces urease, which hydrolyses the

urea and forms carbon dioxide and ammonia. The ammonia increases the pH of the medium causing the pH indicator to turn red.

BREATH TESTS. These tests are based on detection of carbon dioxide gas produced from the hydrolysis of urea. Breath tests are non-invasive and highly accurate in determining if the bacterium is present. They are often used when an endoscopy is contraindicated and to follow-up antibiotic treatment. The patient is given an oral dose of urea labeled with radioactive carbon. The carbon is carried to the **lungs** by the **blood**. The patient exhales into a vial and the radioactivity of the expelled air in the vial is measured. A nonradioisotopic breath test is also available.

SEROLOGICAL TESTS FOR ANTIBODIES TO *H. PYLORI*. ELISA (enzyme-linked immunosorbent assay) and other immunoassay methods are available for IgG, IgA, and IgM antibodies to *H. pylori*. The IgM test detects antibodies formed two to four weeks after infection. IgG and IgA tests require up to two months after infection before becoming positive. These tests are accurate and reliable screening tests for exposure to *H. pylori*. However, antibodies persist after successful treatment. For this reason, the breath test is preferred after treatment to identify drug resistant cases.

Precautions

Endoscopy may be contraindicated by a history of gastrointestinal (GI) bleeding, recent GI surgery, and diverticula in the esophagus. Breath testing using a radioisotopic preparation is contraindicated in **pregnancy**. The breath test may be negative if the patient is receiving antibiotic therapy and certain medications.

Preparation

Endoscopy is an invasive procedure, and is performed in a hospital or clinic usually on an outpatient basis. Overnight fasting is required. To reduce the dis-

KEY TERMS

Endoscope—A thin, lighted tube with a tiny camera attached to the end. It allows the doctor to see the lining of the esophagus, stomach, and duodenum.

Endoscopy—A procedure that uses an endoscope.

Gastroenterology—The study of the digestive system and diseases and disorders affecting it.

Invasive procedure—A medical procedure that requires entrance of a foreign object into the human body.

Non-invasive procedure—A medical procedure that does not require entrance of a foreign object into the human body.

Serology—Blood tests.

Urea—A waste product of the breakdown of proteins.

comfort associated with the procedure, the patient is mildly sedated and a topical anesthetic is sprayed in the throat. **Vital signs** and history are important to insure that the patient does not have a condition that contraindicates the procedure. An intravenous line is used to instill fluids and the sedative.

For the breath test, a dose of radiolabeled urea is given orally to the patient. For serological tests, venipuncture is performed using standard precautions for prevention of exposure to bloodborne pathogens.

Aftercare

Following endoscopy, patients should be observed while recovering from sedating medications for any signs of GI bleeding or **pain** and treated accordingly. The patient should remain under medical supervision until fully alert. After venipuncture, hemostasis should be accomplished by applying direct pressure to the puncture site.

Complications

Endoscopy may be associated with GI bleeding, allergic reaction to medications, and throat or abdominal pain. Rare complications also include perforation of an upper GI organ, aspiration of gastric fluid, and phlebitis. Breath and serological tests are not associated with significant complications.

Health care team roles

Endoscopy is performed by a gastroenterologist with the assistance of registered nurses. Breath testing can be administered by a physician or nurse. Venipuncture is performed by a physician, nurse or phlebotomist. Serological testing is performed by a clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) or clinical laboratory technician, CLT(NCA)/medical laboratory technician, MLT(ASCP).

Head and neck cancer

Definition

The term head and neck cancers refers to a group of cancers found in the head and neck region. This includes tumors found in:

- The oral cavity (mouth): the lips, the tongue, the teeth, the gums, the lining inside the lips and cheeks, the floor of the mouth (under the tongue), the roof of the mouth, and the small area behind the wisdom teeth are all included in the oral cavity.
- The oropharynx: includes the back one-third of the tongue, the back of the throat, and the tonsils.

- **Nasopharynx:** includes the area behind the nose.
- **Hypopharynx:** the lower part of the throat.
- **The larynx** (voice box, located in front of the neck in the region of the Adam's apple): in the larynx, the **cancer** can occur in any of the three regions—the glottis (where the vocal cords are); the supraglottis (the area above the glottis), and the subglottis (the area that connects the glottis to the windpipe).

The most frequently occurring cancers of the head and neck area are oral cancers and laryngeal cancers. Almost half of all the head and neck cancers occur in the oral cavity, and a third are found in the larynx. By definition, the term “head and neck cancers” usually excludes tumors that occur in the **brain**.

Description

Head and neck cancers involve the respiratory tract and the digestive tract, and they interfere with the functions of eating and breathing. Laryngeal cancers affect speech. Loss of any of these functions is significant. Hence, early detection and appropriate treatment of head and neck cancers is of utmost importance.

Roughly 10% of all cancers are related to the head and the neck. For cancer of the pharynx and oral cavity, there was an estimated 30,200 new cases in 2000. Incidence rates are highest in women and men over age 40, and more than twice as high in men as in women. The rates of oral cancers and deaths due to this cancer have been declining.

Among the major cancers, the survival rate for head and neck cancers is one of the poorest. Less than 50% of the patients survive five years or more after initial diagnosis. This is because the early signs of head and neck cancers are frequently ignored. Hence, when they are first diagnosed, these types of cancers are often in an advanced stage and not very amenable to treatment.

The risk for both **oral cancer** and laryngeal cancer seems to increase with age. Most of the cases occur in individuals over 40 years of age, the average age at diagnosis being 60. While oral cancer strikes men twice as often as it does women, laryngeal cancer is four times more common in men than in women. Both diseases are more common in African Americans than among Caucasians.

Causes and symptoms

Although the exact cause for these cancers is unknown, tobacco is regarded as the single greatest risk factor: 75–80% of the oral and laryngeal cancer cases occur among smokers. Heavy alcohol use has also been

included as a risk factor. A combination of tobacco and alcohol use increases the risk for oral cancer by six to 15 times more than for users of either substance alone. In rare cases, irritation to the lining of the mouth, due to jagged teeth or ill-fitting dentures, has been known to cause oral cancer. Exposure to asbestos also appears to increase the risk of developing laryngeal cancer.

In the case of lip cancer, just like skin cancer, exposure to sun over a prolonged period has been shown to increase the risk. In the Southeast Asian countries (India and Sri Lanka), chewing of betel nut has been associated with cancer of the lining of the cheek. An increased incidence of nasal cavity cancer has been observed among furniture workers, probably due to the inhalation of wood dust. A virus (Epstein-Barr) has also been shown to cause nasopharyngeal cancer.

Head and neck cancers are one of the easiest to detect. The early signs can be both seen and felt. The signs and symptoms depend on the location of the cancer:

- **Mouth and oral cavity:** a sore that does not heal within two weeks, unusual bleeding from the teeth or gums, a white or red patch in the mouth, or a lump or thickening in the mouth, throat, or tongue.
- **Larynx:** persistent hoarseness or **sore throat**, difficulty breathing, or **pain**.
- **Hypopharynx and oropharynx:** difficulty in swallowing or chewing food or ear pain.
- **Nose, sinuses, and nasopharyngeal cavity:** pain, bloody discharges from the nose, blocked nose, and frequent sinus infections that do not respond to standard **antibiotics**.

When detected early and treated appropriately, head and neck cancers have an excellent chance of being cured completely.

Diagnosis

Specific diagnostic tests used depend on the location of the cancer. The standard tests are:

Physical examination

The first step in diagnosis is a complete and thorough examination of the oral and nasal cavity, using mirrors and other visual aids. The tongue and the back of the throat are examined as well. Any suspicious looking lumps or lesions are examined with fingers (palpation). In order to look inside the larynx, the doctor may sometimes perform a procedure known as **laryngoscopy**. In indirect laryngoscopy, the doctor looks down the throat with a small, long handled mirror. Sometimes the doctor inserts a lighted tube (laryngoscope or a fiberoptic scope)

through the patient's nose or mouth. As the tube goes down the throat, the doctor can observe areas that cannot be seen by a simple mirror. This procedure is called a direct laryngoscopy. Sometimes patients may be given a mild sedative to help them relax, and a local anesthetic to ease any discomfort.

Blood tests

The doctor may order **blood** or other immunological tests. These tests are aimed at detecting antibodies to the Epstein-Barr virus.

Imaging tests

X rays of the mouth, the sinuses, the **skull**, and the chest region may be required. A computed tomography scan (CT scan), a procedure in which a computer takes a series of x ray pictures of areas inside the body, may be done. Ultrasonograms (images generated using sound waves) or an MRI (**magnetic resonance imaging**) a procedure in which a picture is created using magnets linked to a computer), are alternate procedures which a doctor may have done to get detailed pictures of the areas inside the body.

Biopsy

When a sore does not heal or a suspicious patch or lump is seen in the mouth, larynx, nasopharynx, or throat, a biopsy may be performed to rule out the possibility of cancer. The biopsy is the most definitive diagnostic tool for detecting the cancer. If cancerous cells are detected in the biopsied sample, the doctor may perform more extensive tests in order to find whether, and to where, the cancer may have spread.

Treatment

The cancers can be treated successfully if diagnosed early. The choice of treatment depends on the size of the tumor, its location, and whether it has spread to other parts of the body.

In the case of lip and mouth cancers, sometimes surgery is performed to remove the cancer. Radiation therapy, which destroys the cancerous cells, is also one of the primary modes of treatment, and may be used alone or in combination with surgery. If lip surgery is drastic, rehabilitation cosmetic or reconstructive surgery may have to be considered. Some cancers of the lip may be removed by Mohs' surgery, also known micrographic surgery. Using this method, the surgeon removes the tumor in thin slices, examining them immediately under the **microscope** to look for cancer cells. More slices are taken until

the cancer is completely removed. The amount of normal tissue removed is minimized using this method.

Cancers of the nasal cavity are often diagnosed late because they have no specific symptoms in their early stages, or the symptoms may just resemble chronic sinusitis. Hence, treatment is often complex, involving a combination of **radiotherapy** and surgery. Surgery is generally recommended for small tumors. If the cancer cannot be removed by surgery, then radiotherapy is used alone.

Treatment of oropharynx cancers (cancers that are either in the back of the tongue, the throat, or the tonsils) generally involves radiation therapy and/or surgery. After aggressive surgery and radiation, rehabilitation is often necessary and is an essential part of the treatment. The patient may experience difficulties with swallowing, chewing, and speech and may require a team of health care workers, including speech therapists, prosthodontists, occupational therapists, etc.

Cancers of the nasopharynx are different from the other head and neck cancers in that there does not appear to be any association between alcohol and tobacco use and the development of the cancer. In addition, the incidence is seen primarily in two age groups: young adults and 50–70 year-olds. The Epstein-Barr virus has been implicated as the causative agent in most patients. While 80–90% of small tumors are curable by radiation therapy, advanced tumors that have spread to the bone and cranial nerves are difficult to control. Surgery is not very helpful and, hence, is rarely attempted. Radiation remains the only treatment of choice to treat the cancer that has metastasized (traveled) to the lymph nodes in the neck.

In the case of cancer of the larynx, radiotherapy is the first choice to treat small lesions. This is done in an attempt to preserve the voice. If the cancer recurs later, surgery may be attempted. If the cancer is limited to one of the two vocal cords, laser excision surgery is used. In order to treat advanced cancers, a combination of surgery and radiation therapy is often used. Because the chances of a cure in the case of advanced laryngeal cancers are rather low with current therapies, the patient may be advised to participate in clinical trials so they may get access to new experimental drugs and procedures, such as **chemotherapy**, that are being evaluated.

When only part of the larynx is removed, a relatively slight change in the voice may occur—the patient may sound slightly hoarse. However, in a total laryngectomy, the entire voice box is removed. The patients then have to re-learn to speak using different approaches, such as esophageal speech, tracheo-esophageal (TE) speech, or by means of an artificial larynx.

In esophageal speech, the patients are taught how to create a new type of voice by forcing air through the esophagus (food pipe) into the mouth. This method has a high success rate of approximately 65% and patients are even able to go back to jobs that require a high level of verbal communication, such as telephone operators and salespersons.

In the second approach, TE speech, a small opening called a fistula, is created surgically between the trachea (breathing tube to the **lungs**) and the esophagus (tube into the **stomach**) to carry air into the throat. A small tube, known as the “voice prosthesis,” is placed in the opening of the fistula to keep it open and to prevent food and liquid from going down into the trachea. In order to talk, the stoma (or the opening made at the base of the neck) must be covered with one’s thumb during exhalation. As the air is forced out from the trachea into the esophagus, it vibrates the walls of the esophagus. This produces a sound that is then modified by the lips and tongue to produce normal sounding speech.

In the third approach, an artificial larynx, a battery driven vibrator, is placed on the outside of the throat. Sound is created as air passes through the stoma (opening made at the base of the neck) and the mouth forms words.

Recent developments have been made with the use of lasers for treating many types of cancer. Laser therapy destroys cancer cells by the use of high-intensity light. It is often used to relieve symptoms of cancer such as bleeding or obstruction, particularly when other treatments are ineffective. **Laser surgery** can also treat cancer by shrinking or destroying tumors. Laser surgery is a standard treatment for certain stages of glottis. Although there are several different kinds of lasers, only the Carbon dioxide (CO₂) laser, Neodymium:yttrium–aluminum–garnet (Nd:YAG) laser, and argon laser are widely used in medicine. The CO₂ and Nd:YAG lasers are used to shrink or destroy tumors. Laser surgery is also used to help relieve symptoms caused by cancer (palliative care) in addition to its use in destroying cancer cells.

Since cancer cannot grow or spread without forming new **blood vessels**, research is being conducted to find ways to stop angiogenesis. Scientists are exploring the use of natural and synthetic angiogenesis inhibitors, also called anti-angiogenesis agents, in anticipation that these chemicals will prevent tumor spread by inhibiting new blood vessel formation.

Taxanes are a group of cancer drugs that includes paclitaxel (Taxol) and docetaxel (Taxotere). Taxanes inhibit cancer cell growth by arresting **cell division**. They are also known as antimetabolic or antimicrotubule agents or mitotic inhibitors.

Photodynamic therapy (also called PDT, photoradiation therapy, **phototherapy**, or photochemotherapy) is a treatment for some types of cancer including larynx and oral cavity.

Important research is being conducted investigating new treatments for several head and neck cancers. There are many new promising treatments and improvements to current therapies such as:

- Tumor growth factors. These hormone-like substances that are naturally occurring in the body typically promote cell growth. Some tumors may grow quickly because of excessive growth factors. New drugs like C-225 may help inhibit tumor growth. C-225 targets a specific area on the cancer cells’ surface; it may eventually be used to treat other cancers such as colon, prostate, bladder, ovarian, and non-small cell **lung cancer**.
- New chemotherapy techniques. Intraarterial chemotherapy, where drugs are injected into arteries feeding the cancer, is being tested in combination with radiation therapy in an attempt to improve their effectiveness. Another new approach uses intralesional chemotherapy (injecting the drug directly into the tumor). Preliminary results have been promising with these new chemotherapies.
- New radiotherapy methods. Studies have been underway testing the efficacy of new radiation regimens delivering twice-a-day irradiation. Higher cure rates have been demonstrated.
- Vaccines may be effective by helping the **immune system** to recognize and attack the cancer cells.

Prognosis

Comorbidities (other illnesses) that may be present are an important determinant of overall survival in people with head and neck cancer.

Oral cavity

With early detection and immediate treatment, survival rates can be dramatically improved. For lip and oral cancer, if detected at its early stages, almost 80% of the patients survive five years or more. However, when diagnosed at the advanced stages, the five year survival rate drops to a mere 18%.

Nose and sinuses

Cancers of the nasal cavity often go undetected until they reach an advanced stage. If diagnosed at the early stages, the five-year survival rates are 60–70%. However,

KEY TERMS

Angiogenesis—The formation of blood vessels around a tumor.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Chemotherapy—Treatment of cancer with synthetic drugs that destroy the tumor either by inhibiting the growth of the cancerous cells or by killing the cancer cells.

Clinical trials—Highly regulated and carefully controlled patient studies, where either new drugs to treat cancer or novel methods of treatment are investigated.

Computerized tomography scan (CT scan)—A medical procedure where a series of x rays are taken and put together by a computer in order to form detailed pictures of areas inside the body.

Growth factors—Growth factors or human growth factors are compounds made by the body that function to regulate cell division and cell survival. Some growth factors are also produced in the laboratory by genetic engineering and are used in biological therapy. Growth factors are significant because they can induce angiogenesis, the formation of blood vessels around a tumor. These growth factors also encourage cell proliferation, differentiation, and migration on the surfaces of the endothelial cells.

Laryngoscopy—A medical procedure that uses flexible, lighted, narrow tubes inserted through the

mouth or nose to examine the larynx and other areas deep inside the neck.

Magnetic resonance imaging (MRI)—A medical procedure used for diagnostic purposes where pictures of areas inside the body can be created using a magnet linked to a computer.

p53 gene—A tumor suppressor gene that typically inhibits the tumor growth. This gene is often altered in many types of cancer.

Radiation therapy—Treatment using high energy radiation from x-ray machines, cobalt, radium, or other sources.

Stoma—When the entire larynx must be surgically removed, an opening is surgically created in the neck so that the windpipe can be brought out to the neck. This opening is called the stoma

Taxanes—Anticancer drugs that inhibit cancer cell growth by arresting cell division. Also known as antimetabolic or antimicrotubule agents or mitotic inhibitors.

Ultrasonogram—A procedure where high-frequency sound waves that cannot be heard by human ears are bounced off internal organs and tissues. These sound waves produce a pattern of echoes which are then used by the computer to create sonograms, or pictures of areas inside the body.

X rays—High energy radiation used in high doses, either to diagnose or treat disease.

if cancers are more advanced, only 10–30% of the patients survive five years or more.

Oropharynx

In cancer of the oropharynx, 60–80% of the patients survive five years or more if the cancer is detected in the early stages. As the cancer advances, the survival rate drops to 15–30%.

Nasopharynx

Patients who are diagnosed with early stage cancers that have originated in the nasopharynx have an excellent chance of a complete cure (almost 95%). Unfortunately, most of the time the patients are in an advanced stage at the time of initial diagnosis. With the new chemotherapy

drugs, the five year survival rate has improved and 5–40% of the patients survive five years or longer.

Larynx

Small cancers of the larynx have an excellent five-year survival rate of 75–95%. However, as with most of the head and neck cancers, the survival rates drop dramatically as the cancer advances. Only 15–25% of the patients survive five years or more after being initially diagnosed with advanced laryngeal cancer.

Advances in detecting head and neck cancer at an early stage are being made. Patients' prognoses will improve as technological advances are made. Some of the research that is being conducted includes DNA mutations (changes) that occur in genes. Damage to certain DNA can lead to increased growth of abnormal cells and

formation of cancers. Recent studies suggest that tests to detect p53 gene alterations may allow very early detection of oral and oropharyngeal tumors. Other substances under investigation that may help early prognosis of cancers are epidermal growth factor receptor, transforming growth factor-alpha, and cyclin D1.

Using targeted chemoradiation, one clinical study revealed that statistical projections for overall and cancer-related five-year survival was 38.8% and 53.6%, respectively for patients with advanced (stage III-IV) carcinoma of the head and neck.

Health care team roles

Depending on the diagnosis, disease stage, level of nursing care required, and different psychosocial factors, the patient's health care needs will vary. The care required is unique to each patient and family. For patients who will be in transitional care, an optimal integration between inpatient and outpatient care is needed to ensure the best care possible. Outpatient care includes **home care**, rehabilitation centers, **nursing homes**, and hospice care. Health care teams should make the transition from the different types of inpatient and outpatient care as easy as possible. Effective communication between professionals is critical.

A dental team with experience in oral oncology, may reduce the risk of oral complications for patients with oral cancers.

Prevention

Refraining from the use of all tobacco products (cigarettes, cigars, pipe tobacco, chewing tobacco), consuming alcohol in moderation, and practicing good **oral hygiene** are some of the measures that one can take to prevent head and neck cancers. Since there is an association between excessive exposure to the sun and lip cancer, people who spend a lot of time outdoors in the sun should protect themselves from the sun's harmful rays. Regular physical examinations, or mouth examination by the patient himself, or by the patient's doctor or dentist, can help detect oral cancer in its very early stages.

Since working with asbestos has been shown to increase one's risk of getting cancer of the larynx, asbestos workers should follow safety rules to avoid inhaling asbestos fibers. Also, malnutrition and vitamin deficiencies have been shown to have some association with an increased incidence of head and neck cancers. The American Cancer Society recommends eating a healthy diet, consisting of at least five servings of fruits and vegetables every day, and six servings of food from other plant sources such as cereals, breads, grain products, rice, pasta,

and beans. Reducing one's intake of high-fat food from animal sources is advised. Following the *The Dietary Guidelines for Americans* published by the United States Department of Agriculture and Health and Human Services can provide a broad overall view of good **nutrition**.

These dietary guidelines include these seven basic recommendations:

- Eat a variety of foods.
- Control your weight.
- Eat a low-fat, low-cholesterol diet.
- Eat plenty of vegetables, fruits, and grains.
- Eat sugar in moderation.
- Use salt in moderation.
- If you drink alcohol, do so in moderation; no more than two drinks per day of wine, beer, or spirits.

The Food Guide Pyramid was created by the United States Department of Agriculture to help Americans choose foods from each food grouping. The food pyramid, developed by nutritionists, provides a visual guide to healthy eating.

Crystal Heather Kaczowski, MSc.

Head injury

Definition

Injury to the head may damage the scalp, **skull**, or **brain**. The most important consequence of head injury is traumatic brain injury. Head injury may occur either as a closed head injury such as the head hitting a car's windshield, or as a penetrating head injury such as when a bullet pierces the skull. Both may cause damage that ranges from mild to profound. Very severe injury can be fatal because of profound brain damage.

Description

External trauma to the head is capable of damaging the brain, even if there is no external evidence of damage. More serious injuries can cause skull fracture, **blood** clots between the skull and the brain, or bruising and tearing of the brain tissue itself.

Injuries to the head can be caused by traffic accidents, **sports injuries**, **falls**, workplace accidents, assaults, or bullets. Most people have had some type of head injury at least once in their lives, but rarely do they require a hospital visit.

Each year, approximately two million people suffer from a serious head injury. Up to 750,000 of them are severe enough to require hospitalization. Brain injury is most likely to occur in males between ages 15 and 24, usually as a result of car and motorcycle accidents. About 70% of all accidental deaths are due to head injuries, as are most of the disabilities that occur after trauma.

A person who has had a head injury and who is experiencing the following symptoms should seek immediate medical care:

- serious bleeding from the head or face
- loss of consciousness, however brief
- confusion and lethargy
- lack of pulse or breathing
- clear fluid drainage from the nose or ear

Causes and symptoms

A head injury may cause damage both from the direct physical injury to the brain and from secondary factors such as lack of oxygen, brain swelling, and disturbance of blood flow. Both closed and penetrating head injuries can cause swirling movements throughout the brain, tearing nerve fibers and causing widespread bleeding or a blood clot in or around the brain. Swelling may

raise pressure within the skull (intracranial pressure) and may block the flow of oxygen to the brain.

Head trauma may cause a **concussion**, in which there is a brief loss of consciousness without visible structural damage to the brain. In addition to loss of consciousness, initial symptoms of brain injury may include:

- **memory** loss and confusion
- vomiting
- dizziness
- partial **paralysis** or numbness
- shock
- anxiety

After a head injury, there may be a period of impaired consciousness, followed by a period of confusion and impaired memory with disorientation and a breakdown in the ability to store and retrieve new information. Others may experience temporary (retrograde) amnesia following head injury. As a person recovers, memory slowly returns. Post-traumatic amnesia refers to loss of memory for events during and after an accident.

Epilepsy occurs in 2–5% of those who have experienced a head injury. It is much more common in people who have had severe or penetrating injuries. Most cases of epilepsy appear immediately after an accident or within the first year. They become less likely with increased time following an accident.

Closed head injury

Closed head injury refers to brain trauma without any penetrating injury to the brain. It may be the result of a direct blow to the head, of a moving head being rapidly stopped, or by a sudden deceleration of the head without striking another object. The kind of injury the brain receives in a closed head injury is determined by whether or not the head was unrestrained upon impact and the direction, force, and velocity of the blow. If a head was resting on impact, the maximum damage will be found at the impact site. A moving head will cause a *contrecoup* injury in which the brain damage occurs on the side opposite the point of impact, as a result of the brain slamming into that side of the skull. A closed head injury also may occur without the head being struck, such as when a person experiences **whiplash**, because the brain is of a different density than the skull, and can be injured when delicate brain tissues hit against the rough, jagged inner surface of the skull.

Penetrating head injury

If the skull is fractured, bone fragments may be driven into the brain. Any object that penetrates the skull may

implant foreign material and dirt into the brain, leading to an **infection**.

Skull fracture

A skull fracture is a medical emergency that must be treated promptly to prevent possible brain damage. Such an injury may be obvious if blood or bone fragments are visible. It is possible for a fracture to have occurred without any apparent damage. A skull fracture should be suspected if any of the following are observed:

- blood or clear fluid leaking from nose or ears
- unequal pupil size
- bruises or discoloration around the eyes or behind the ears
- swelling or depression of the part of the head

Intracranial hemorrhage

Bleeding (hemorrhage) inside the skull may accompany a head injury and cause additional damage to the brain. A blood clot (hematoma) may occur if a blood vessel between the skull and the brain ruptures. When the blood leaks out and forms a clot, it can press against brain tissue, causing symptoms that may arise within a few hours to a few weeks after the injury. If the clot is located between the bones of the skull and the covering of the brain (dura), it is called an epidural hematoma. If the clot is between the dura and the brain tissue itself, the condition is called a subdural hematoma. In other cases, bleeding may occur deeper inside the brain. This condition is called intracerebral hemorrhage, or intracerebral contusion.

If the blood flow within the skull is not stopped, it can lead to unconsciousness and death. The signs and symptoms of bleeding within the skull include:

- nausea and vomiting
- headache
- loss of consciousness
- unequal pupil size
- lethargy

Post-concussion syndrome

If a head injury is mild, there may be no symptoms other than a slight headache, or there also may be confusion, dizziness, and blurred **vision**. While the head injury may seem to have been quite mild, in many cases symptoms persist for days or weeks. Up to 60% of persons who sustain a mild brain injury continue to experience a range of symptoms called post-concussion syndrome, for as long as six months or a year after the injury.

A three-dimensional computed axial tomography (CAT) scan of a human skull showing a depressed skull fracture above the right eye. (Custom Medical Stock Photo. Reproduced by permission.)

The symptoms of postconcussion syndrome can result in a puzzling interplay of behavioral, cognitive, and emotional complaints that can be difficult to diagnose, including:

- headache
- dizziness
- mental confusion
- behavior changes
- memory loss
- cognitive deficits
- depression
- emotional outbursts

KEY TERMS

Amnesia—Loss of memory.

Computed tomography (CT) scan—A diagnostic technique in which the combined use of a computer and x rays produce clear cross-sectional images of tissue.

Contrecoup injury—Brain damage occurring on the side opposite to the point of impact.

Contusion—Bruise.

Electroencephalogram (EEG)—A record of the tiny electrical impulses produced by the brain's activity.

Hematoma—Blood clot.

Hemorrhage—Heavy or uncontrolled bleeding.

Magnetic resonance imaging (MRI)—A diagnostic technique that provides high quality cross-sectional images of organs within the body without using x rays or other radiation.

Positron emission tomography (PET) scan—A computerized diagnostic technique that uses radioactive substances to examine structures of the body.

Post-traumatic amnesia—Loss of memory for events during and after an accident.

Retrograde amnesia—Memory loss for events in the past that occurs over a period of time.

Diagnosis

The extent of damage in a severe head injury can be assessed with computed tomography (CT) scan, **magnetic resonance imaging (MRI)**, **positron emission tomography (PET) scan**, electroencephalograms (EEG), and routine neurological and neuropsychological evaluations.

Physicians use the Glasgow **Coma Scale** to evaluate the extent of brain damage based on observing a person's ability to open his or her eyes, respond verbally, and respond to stimulation by moving (motor response). Persons can score from three to 15 points on this scale. People who score below eight when they are admitted usually have suffered a severe brain injury and will need rehabilitative therapy as they recover. In general, higher scores on the Glasgow Coma Scale indicate less severe brain injury and a better prognosis for recovery.

Persons with a mild head injury who experience symptoms are advised to seek out the care of a specialist. Unless a family physician is thoroughly familiar with medical literature in this newly emerging area, experts warn that there is a good chance that a complaint after a mild head injury will be downplayed or dismissed. In the case of mild head injury or postconcussion syndrome, CT and MRI scans, electroencephalograms (EEG), and routine neurological evaluations may all be normal because the damage is so subtle. In many cases, these tests cannot detect the microscopic damage that occurs when fibers are stretched in a mild, diffuse injury, in which the axons in the brain lose some of their covering and become less efficient. This mild injury to the white matter reduces the quality of communication between different parts and the brain. A PET scan, which evaluates cerebral blood flow and brain **metabolism**, may be of help in diagnosing mild head injury, although many experts still considered this to be an experimental procedure.

Persons with continuing symptoms after a mild head injury should call a local chapter of a head-injury foundation that can refer them to the best nearby expert.

Treatment

If a concussion, bleeding inside the skull, or skull fracture is suspected, a person should be kept quiet in a darkened room, with head and shoulders raised slightly on pillow or blanket.

After initial emergency treatment, a team of specialists may be needed to evaluate and treat any problems that result. A penetrating wound may require surgery. Those individuals with severe injuries or with a deteriorating level of consciousness may be kept hospitalized for observation. If there is bleeding inside the skull, the blood may need to be surgically drained. If a clot has formed, it may need to be removed. Severe skull **fractures** also require surgery. Supportive care and specific treatments may be required if a person experiences further complications. People who experience seizures, for example, may be given anticonvulsant drugs, and people who develop fluid on the brain (hydrocephalus) may have a shunt inserted to drain the fluid.

In the event of long-term disability that occurs as a result of head injury, a variety of treatment programs are available, including long-term rehabilitation, coma treatment centers, transitional living programs, behavior management programs, life-long residential or day treatment programs, and independent living programs.

Prognosis

Prompt diagnosis and treatment can help alleviate some of the problems after a head injury. However, it is usually difficult to predict the outcome of a brain injury in the first few hours or days. A person's prognosis may not be known for many months or even years.

The outlook for someone with a minor head injury is generally good, although recovery may be delayed, and symptoms such as headache, dizziness, and cognitive problems can persist for up to a year or longer after an accident.

Serious head injuries can be devastating, producing permanent mental and physical disability. Epileptic seizures may occur after a severe head injury, especially a penetrating brain injury, a severe skull fracture, or a serious brain hemorrhage. Recovery from a severe head injury may take five years or longer to completely heal. Risk factors associated with an increased likelihood of memory problems or seizures after head injury include age, length and depth of coma, duration of post-traumatic and retrograde amnesia, presence of focal brain injuries, and initial Glasgow Coma Scale score.

Health care team roles

First aid may be given by **emergency medical technicians**. Physicians trained in emergency medicine often provide initial care in a hospital. Neurosurgeons and neurologists may be asked to assist with care. Rehabilitation specialists such as physicians, physical therapists, speech therapists, or occupational therapists may provide rehabilitation. Nurses provide supportive care throughout, including 24-hour care, home nursing care, and **patient education**.

Prevention

Many severe head injuries could be prevented by wearing protective headgear during certain sports, or helmets when riding a bike or motorcycle. Seat belts and airbags can prevent many head injuries that result from motor vehicle accidents. Appropriate protective headgear should always be worn on the job where head injuries are a possibility.

Head trauma see **Head injury**

Health care financing

Definition

Health care financing provides people in the United States with access to health care programs. Health care financing is directed and administered by the United States Department of Health and Human Services and the Health Care Financing Administration. Some health care financing benefits and privileges are also provided through the Department of Veteran's Affairs.

Description

Health care financing provides health care benefits to people who are either elderly or needy, or who otherwise meet the criteria for specific benefit programs. The three largest health care programs provided by the federal and state governments to citizens of the United States are **Medicare**, **Medicaid**, and the State Children's Health Insurance Program. Together Medicare, Medicaid, and

SCHIP provide health insurance for over 74 million Americans. Each program targets a different portion of the population and the health care needs of that particular population.

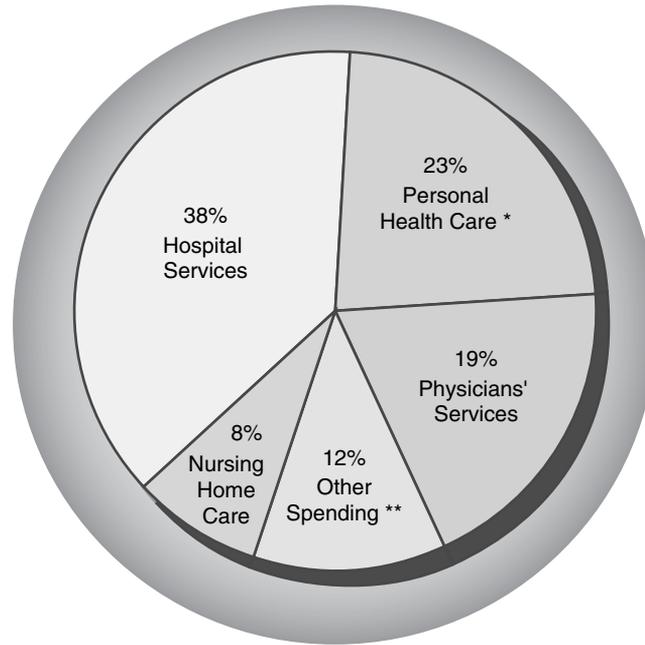

Medicare is a federal health insurance program to which all Americans aged 65 years or older are entitled. The program was started in 1965 by the Social Security Administration to provide health care for the aged. The program went into effect in 1966. In 1973, Medicare was expanded to include people who suffer from certain specific debilitating diseases such as permanent kidney failure. Medicare is an entitlement program like Social Security and does not rely on financial need to qualify a recipient. Approximately 40 million people are currently enrolled in the Medicare federal health insurance program.

Medicaid is a health insurance program for financially needy people. The Medicaid program was developed in 1965 along with the Medicare program and was put into effect in 1966. The program receives federal and state funds. Medicaid follows the operation guidelines set by the HCFA, but is operated by state welfare or health departments. Benefits vary from state to state. The people who qualify for Medicaid benefits are primarily children and their families who also qualify for public financial assistance such as the food stamp program. Elderly and disabled adults may also receive Medicaid assistance if they live in a qualifying, low-income household. Medicaid benefits have been expanded to include women with breast or cervical **cancer**, people living with **AIDS**, and home health care for people who qualify for long-term care.

SCHIP is a medical insurance program for children through the age of 18 years whose parents earn too much money to qualify for Medicaid, but who still earn too little to pay for insurance through a private company. The funds are regulated and delivered to each of the 50 states through the HCFA, but specific benefits are distributed at the discretion of each state. Benefits vary from state to state.

Other health care programs and benefits that are available to American citizens are Tricare and the Indian Health Service. Both programs target specific groups of beneficiaries and are distributed through government services.

Tricare, formerly known as CHAMPUS, is the health care program for the United States military. It benefits both active-duty and retired military personnel and their dependants. It also benefits veterans of foreign wars. The Tricare system allows recipients to choose their own doctor through a civilian health care system or to make use of the comprehensive health care services offered through military hospitals and clinics. Coverage

Note:

*Other personal health care = dental, home health care, medications, vision care.

** Other spending = administrative cost of private insurance and public programs, research, and construction.

Health care expenditures. (Delmar Publishers, Inc. Reproduced by permission.)

is nation-wide and benefits remain constant throughout the entire United States. It is administered through the Department of Veteran’s Affairs.

The Indian Health Service is an agency within the U.S. Department of Health and Human Services. The IHS is responsible for providing federal health services to Alaska natives and other native Americans. IHS maintains comprehensive health care delivery system of hospitals and clinics nationwide for approximately 1.5 million members of the 550 federally recognized Indian tribes and their descendants.

Viewpoints

Health care financing is the point of much disagreement and dissension on many fronts. While many advances are being made in health care, the number of people who are not covered by private health policies is growing. Even though federal funds provide health care financing programs, many children and disabled people

continue to be under-insured and under-served by the medical community.

Professional implications

The cost of health care financing by the federal government is likely to continue growing for several reasons.

- The large, aging “baby boomer” population will soon be eligible for Medicare benefits.
- Advanced medical technology keeps people alive and living longer with disabilities.
- Longer life expectancy increases need for medical care and long term care.
- Improved preventive practices are covered by health care financing.
- An increasing number of people are living longer with chronic diseases.

KEY TERMS

DHHS—Department of Health and Human Services, formerly the Department of Welfare.

HCFA—Health Care Financing Administration.

Medicaid—A jointly-funded, federal-state health insurance program that provides health care for the aged and the financially needy.

Medicare—A federally funded health insurance program for all persons aged 65 or older.

SCHIP—State Children’s Health Insurance Program. It provides health care insurance for children up to the age 18 years do not qualify for Medicaid, but are not covered by private insurance.

- There is a growing trend for employers to not offer medical benefits to employees and their families.

Peggy Elaine Browning

Health care, quality of

Definition

There is no single, universally accepted definition of health care quality. This is because health care quality involves descriptions of many different, complex aspects of care from several different perspectives. Quality may be measured in terms of outcomes, the end results of care and treatment, or it may be evaluated in terms of process, the way in which the care is delivered. The definition also depends on who is describing quality. Researchers, health care providers, government, and consumers may all assess health care quality differently.

Description

During the early 1980s, Donabedian described high quality care as “...care which is expected to maximize an inclusive measure of patient welfare, after one has taken account of the balance of expected gains and losses that attend the process in all its parts...”

In 1984, the American Medical Association (AMA) characterized high quality care as “care which consistently contributes to the improvement or maintenance of quality and/or duration of life.” The AMA specified the aspects, or features, of care that should be measured to determine quality. These features included:

- attention to evidence-based, scientific medicine
- timely and efficient use of resources
- emphasis on disease prevention and health promotion
- informed participation of patients

Another more concise definition, offered by the Institute of Medicine in 1990, stated that quality is the “degree to which health outcomes are consistent with current professional knowledge.”

Today, health care quality is understood to involve many dimensions of care. Measuring quality of care requires relating disease-specific outcome measures to assessments of general, physiological, mental, physical, and social health along with patient preferences and level of satisfaction. Effective measurement of quality enables researchers, practitioners, payors (health plans, insurance companies, government, employers, and health care coalitions) and other stakeholders to identify aspects of quality care and medical practice. It also enables comparisons to be made between institutions, health plans and providers.

Though definitions of quality and how to best measure it vary, there is agreement about the goal of measuring and monitoring health care quality; it is to evaluate and improve both the processes and outcomes of care. Hospitals, health plans, medical groups, and managed care organizations devote resources and personnel to quality assurance and quality improvement initiatives.

Quality assurance and quality management programs include data, utilization, and case management activities. Data management is used to measure and monitor outcomes and identify best practices; it is the foundation for quality improvement efforts. Examples of data used to evaluate the quality of health care delivered to a patient population include:

- rates of immunization
- disease-specific hospital lengths of stay

- rates of health screening tests performed, such as **mammography**, **hypertension** (high **blood pressure**) screening
- percentage of patients with congestive **heart failure** who receive ACE inhibitors
- results of patient satisfaction surveys

Utilization management is the process of evaluating the necessity, appropriateness, and efficiency of health care services. Case management is patient-centered action aimed at improving health care delivery and outcomes. Quality management enables health care organizations and providers to identify deviations from accepted standards of clinical practice, measure outcome standards, and support opportunities for improvement.

The most beneficial use of health care quality data is as inspiration and incentive to systematically improve care. When evidence of quality problems is identified, health care providers, professionals, and organizations are better prepared to address and promptly resolve problems.

Viewpoints

The American health care system delivers some of the finest, most sophisticated services and treatment available. Nonetheless, it is possible to identify areas of health care delivery that need improvement. A 1998 U.S. Department of Health Services report, *The Challenge and Potential for Assuring Quality Health Care for the 21st Century*, described existing problems and successful efforts to address these problems. The report described four key quality of care issues: underuse of services; overuse of services; misuse of services; and variation of services.

Underuse of services, when patients do not receive needed medical care, clearly contributes to higher rates of morbidity (illness) and mortality (death). Overuse of services, when patients receive unnecessary care, can be just as dangerous. For example, prescribing **antibiotics** to treat viral illnesses, such as colds, not only creates antibiotic resistance but also results in adverse drug reactions and excess costs. Misuse of services refers to errors in health care delivery. These errors range from minor mistakes that have virtually no impact on patients' health to misread laboratory results that delay diagnosis and incorrect administration of medications that may even result in patient deaths.

Variation of services refers to the ways in which medical practice differs between communities and even within a community. For example, studies have found significant geographical differences in the rates of surgical procedures such as Cesarean section. The use of med-

ical practice guidelines, written plans detailing diagnosis and treatment of specific conditions, is considered an effective strategy for reducing variation of services.

All health care providers face pressure not only to demonstrate their ability to effectively deliver health care services but also to document and communicate measures of clinical quality and fiscal accountability. Providers, employers, accreditors (agencies such as the Joint Commission on the Accreditation of Healthcare Organizations and the National Committee for Quality Assurance), and consumers are demanding substantial evidence of quality health care.

Publication of medical outcomes report cards, disease and procedure-specific morbidity and mortality rates has attracted media attention and sparked controversy. Advocates of the public release of clinical outcomes and other health care performance measures believe that despite their limitations, these studies offer consumers a useful way to compare providers.

Others argue that measures such as surgical mortality (death rates resulting from a specific surgical procedure) are incomplete indicators of quality. They feel that the data are often misleading, and unreliable guides for health care decisions. Critics cite problems with data collection that compromise the utility and validity of published reports.

Despite concern about the reliability, validity, and interpretation of data, there is consensus that investigation and disclosure of health care quality data will intensify. Recently, consumer interest has focused on individual providers, such as local hospitals and physicians. Employers, choosing between **managed care plans** involving the same group of participating hospitals and physicians, are requesting plan-specific information to guide contracting decisions. Companies and employer-driven health care coalitions seeking to compare and choose provider networks rely on physician and hospital-specific quality data during the selection process.

The impact of increasingly frequent, public release of clinical performance measures on consumer and provider decision-making, utilization, and the delivery of health care is not yet fully understood.

Professional implications

Traditionally, researchers, health care professionals, and practitioners tend to view quality in technical terms, such as the skills of the practitioners, the appropriateness of care, and the outcomes (results) of treatment. Health care consumers are more likely to focus on process measures such as waiting time for a scheduled appointment, whether they are treated courteously, the extent to which

KEY TERMS

Outcomes—Results or consequences of care or treatment.

Process—The steps, actions, or operations used to bring about the desired outcome.

they feel health care practitioners have answered their questions, and the nature of the interpersonal relationships they have with their providers.

Today, there is increasing awareness and appreciation among health care professionals of the importance of patient satisfaction with care. It is generally accepted that when patients are satisfied with the quality of care they have received, they are more likely to adhere to prescribed treatment, return for necessary follow-up, and recover more quickly and completely.

Health history

Definition

The health history is a current collection of organized information unique to the individual patient. Relevant aspects of the history include biographical, demographic, physical, mental, emotional, sociocultural, sexual, and spiritual data.

Purpose

The history aids the patient and health care provider by supplying essential information that will assist with diagnosis, treatment decisions, and establishment of trust and rapport between patient and medical professional. The information also helps determine the patient's baseline, or what is normal and expected for the patient.

Description

The clinical interview is the most common method for obtaining a health history. When the patient or a designated representative of the patient can communicate effectively, the clinical interview is a valuable means of soliciting information.

The information that comprises the health history may be obtained from the patient's previous records, the patient, or in some cases the patient's significant others or caretakers. The depth and length of the history-taking process is affected by factors such as the purpose of the visit, the urgency of the complaint or condition, the patient's willingness or ability to contribute information, and the environment. When circumstances allow, a history may be holistic and comprehensive, but at times only a cursory review of the most pertinent facts is possible. In cases where the history-gathering process needs to be abbreviated, the history focuses on the patient's medical experiences.

Health histories can be organized in a variety of ways. Often an organization such as a hospital or clinic will provide a form or computer database that serves as a guide and documentation tool for the history. Generally the first aspect covered by the history is identifying data.

Identifying data includes facts such as:

- name
- gender
- age
- date of birth
- occupation
- family/social situation

HEALTH HISTORY		
Name _____	Date _____	Time _____
Demographic Data: Date of birth _____ Gender _____ Marital status _____		
Reason for Seeking Health Care: _____

Health history form. (Delmar Publishers, Inc. Reproduced by permission.)

KEY TERMS

Holistic—Pertaining to all aspects of the patient, including biological, psychosocial, and cultural factors.

Subjective—Influenced by the perspective of the information provider; potentially biased.

- source of referral

Once the identifying data is collected, the history addresses the reason for the current visit in expanded detail. The reason for the visit is sometimes referred to as the chief complaint or the presenting complaint. Once the reason for the visit is established, additional data is solicited by asking for details that provide a full picture of the current clinical situation. For example, in the case of **pain**, aspects such as location, duration, intensity, precipitating factors, aggravating factors, relieving factors, and associated symptoms would need to be recorded. The full picture or “story” that accompanies the chief complaint is often referred to as the history of present illness (HPI).

The review of systems is a useful method for gathering medical information in an orderly fashion. This review is a series of questions about the patient’s current and past medical experiences that follows a head-to-toe pathway.

The names for categories in the review of systems may vary but generally consist of variations on the following list:

- head, eyes, ears, nose, throat (HEENT)
- cardiovascular
- respiratory
- gastrointestinal
- genitourinary
- integumentary
- joint/muscular
- endocrine
- central nervous system (includes psychiatric)

An orderly and thorough review of systems is often completed by asking the patient about each system in a head-to-toe fashion, moving from current to past and from general to specific information. A thorough record of relevant dates is important in determining relevance of past illnesses or events to the patient’s current condition.

Past and current medical history includes details on medicines taken by the patient, as well as **allergies**, ill-

ness, hospitalizations, procedures, pregnancies, environmental factors such as exposure to toxins or carcinogens, and health maintenance habits such as self breast examination or immunizations.

An example of a line of questioning might be:

- How are your ears?
- Are you having any trouble hearing?
- Have you ever had any trouble with your ears or with your hearing?

If the patient indicates a history of auditory difficulties, this would prompt further questions about medicines, surgeries, procedures, or associated problems related to their current or past condition.

In addition to identifying data, chief complaint, and review of systems, a comprehensive health history also includes factors such as the patient’s family and social life, family medical history, mental or emotional illnesses or stressors, detrimental or beneficial habits such as smoking or **exercise**, and aspects of culture, sexuality, and spirituality that are relevant to the individual patient. The clinician also tailors his or her interviewing style to the age, culture, educational level, and attitudes of the patient whom they are interviewing.

Preparation

Because the information obtained from the interview is subjective, it is important that the interviewer assess the patient’s level of understanding, education, communication skills, potential biases, or other information that may affect accurate communication. Thorough training and practice in techniques of interviewing such as asking open-ended questions, listening effectively, and approaching sensitive topics such as substance abuse, domestic violence, or sexual practices assists the clinician in obtaining a maximum amount of information without upsetting the patient or disrupting the interview. The interview should be preceded by a review of the chart and an introduction by the clinician. The clinician should explain the scope and purpose of the interview and provide privacy for the patient. Others should only be present with the patient’s consent.

Health care team roles

Physicians, physician assistants, nurses, nurse practitioners, and many allied health professionals are trained to obtain a patient’s health history. The clinician primarily responsible for this task may vary according to the clinical setting.

Health information management

Definition

Health information management is a phrase used to describe the process of collecting and using data gathered by many different people in different places about services provided to individual patients or groups. Health information management describes both a process and a career choice in that people who are hired to manage health information are employed in a wide variety of health and health related settings.

Description

People who choose to work in health related fields must have a working knowledge of the way health information is gathered, stored, retrieved, and used in today's marketplace. When a patient is seen by a health care agency, regardless of type, for the first time, basic demographic information is gathered by having the patient fill out a paper form, or by interview. Demographic information includes many things such as age, sex, marital status, address, phone number, social security number, insurance carrier, employer name and address, and next of kin. Each agency collects particular information for a reason. This data is then entered, saved, and stored in a computer. The computer is often networked or connected by a line that transmits the data to other computers within the

agency or facility. The data can also be stored on a disk or in a special file, similar to a drawer in a filing cabinet, so the information can be used to collect facts and figures about the services provided by the agency at a later date. This data can be automatically sent to computers within the same building or at remote sites via telephone lines. The computer information can be accessed by other computers that are part of the network (shared function, software, and computer applications).

After the initial paper work or interview is completed, the patient is then directed to a diagnostic center, where a test is done to help the provider make a diagnosis, or to a therapeutic treatment center, where a particular treatment is given. It is usual that some additional personal information is collected at the center itself. This additional information will include particulars needed to provide a service to that patient in that specific center. As an example, if a patient is sent to a hospital for a chest radiology or x ray by a private physician, the patient fills out demographic information at the ambulatory admission desk. Then the patient is sent to the radiology department, where the technician enters the height and weight of the patient so the proper amount of energy is used to take the chest radiology x-ray correctly. The radiology x-ray machine takes the chest radiology x ray (a picture of the **heart** and **lungs** and the underlying structures) and puts the picture onto a film similar to the negative of a picture taken by a camera. The film is printed to a hard copy and/or the image is stored on a computer. The radiologist (a physician with special training) reads or interprets the chest x-ray and dictates the result of the film to a report. The report is printed and stored in the files in the computer. The results of the radiology x ray are also printed by the computer to a piece of paper that is mailed or transmitted to the patient's primary physician. The radiology department then initiates a request that the insurance company be billed for the cost of the service.

Data retrieval describes the process of accessing the stored information and then using the data for a specific purpose. In the example provided above, the billing department can access all of the different types of radiology x rays done in a day, and then issue a request for payment for these services. The payment can be sought from the individual patient, the private insurance company, **Medicare** for patients over the age of 65, or from **Medicaid** for patients who are on state public assistance. The radiology department can total up the number of radiology x rays of each type, for each day, to develop a report that identifies the volume of each particular service rendered for a specific period of time such as quarterly (every three months) or annually at the end of the year. The charge of the individual radiology x-ray can be handled in the same way.

This is a specific example of health information management. Although this is a brief description of how health information is managed, it does represent a rudimentary introduction to the process.

Viewpoints

To expand on the concept of health information and how it is managed, the above example stated basic information is collected and stored. However, health information management includes evaluating the process of collecting and storing data, so that cost-effective and efficient changes can be made to improve outcomes or profits. The process can also be the transformation of a paper-based system into a high-tech computer database. Innovative approaches that might improve the system include developing a series of computer screens that are easy for the average patient or staffer to use. Computer screens modeled after those used by banks such as when people use an automatic teller machine (ATM) to get money out of their bank accounts are very easy to use. If the computer screens are carefully developed, the clerk in the admissions department is no longer needed to input the data about the individual patient, and thus a salary can be saved, or the staffer's time put to better use. Putting patient information into a database software package that can also be used to track billing charges allows manipulation of the data to provide more meaningful information to the facility or person using the data.

Professional implications

Within health care organizations, health information management is a task completed by assorted computer-literate individuals whose goal is to track costs, research, or services. Health information management professionals are people with advanced education, often at the master's degree level, who possess some knowledge of clinical medicine, patient records, national coding and classification systems, database software, and computer applications. The management professional integrates skills and knowledge to provide the agency, organization, or individual researcher with exact information. Thus, the way data is processed, analyzed, and reported back to users changes the overall outcomes for the agencies.

Health information management requires technical skills so that data manipulation provides useful reports. This means that a working knowledge of the integration of the data with database storage software and statistical analysis of the data is needed. The reports generated must serve as a communication link between many different individuals. Providers use information to make health care decisions, and health care facilities and organiza-

tions use it to make business decisions. Health information includes tracking data with the intent to make improvements in the system in some way, or to provide solutions to problems such as those related to research, planning, provision of care, and the evaluation of health care services. Thus the process of collecting and disseminating information must have a positive end goal, such as improving patient care. Outcomes that support quality patient care, medical research, health planning, health care evaluation, and financial reimbursement are a required component of the job. In the modern world of health care, an individual who develops and uses innovative approaches to solve problems, save money, or redesign work habits is highly sought.

The individual who is hired to manage health care information is required to have a working knowledge of **medical ethics** and the legal ramifications of inappropriate use of personal data. For example, the federal government is very clear about the rights of an individual patient, especially in medical research. It is imperative to store data in a way that protects the anonymity of the individual and his or her privacy rights when the data is accessed for research purposes. In addition, data must be stored to insure that confidentiality is maintained, and that access is denied to those individuals who have no need for the specific information about the individual patient. Data must be stored so that it can be used to compare a patient's care with standards of care and quality indicators, which are needed for evidence-based practice.

Those working with health information may be asked to produce a needs analysis, complete a systems analysis, or redesign the existing system, addressing quality of care, costs, care delivery processes, and financial questions. Tying reports to the volume of services, charges, costs, and reimbursements are current and future expectations. Managers of health information work in a wide variety of settings, such as with private physicians; in hospitals or **nursing homes**; with insurance companies, law firms, and government agencies; and for companies who specialize in information technology. In summary, the entire process of health information management is focused on securing, analyzing, and integrating the information so that it can be used for a specific purpose.

Resources available about health information management are extensive. Universities, the world wide web, local hospitals, newspapers, and government agencies are resources that can be tapped to provide more specific information to the reader.

Health promotion and education

Definition

Health promotion and education is the exchange of ideas and the dissemination of facts about illness and disease. These ideas and facts serve to help people make decisions that affect their health care and well-being. Local government programs, universities, hospitals, health clinics, public and private associations and agencies, and the workplace are some of the places where health promotion and education take place.

Description

When managed care emerged within the American health care system in the 1990s, the focus shifted from treating illness to preventive medicine. Insurance compa-

nies began using words like "wellness," and encouraged individuals to have routine check-ups, and workplaces began to offer incentives to employees to quit bad habits, such as smoking. Because the emphasis turned to prevention of illness, injury, and disease—rather than cure, or healing—there has been an influx of health education programs aimed at giving people the information they need to be proactive and responsible for their own well-being.

The Association of State and Territorial Directors of Health Promotion and **Public Health** Education (AST-DHPPHE) was created in 1946. The agency's mission is to promote health education and provide a clearinghouse through which local health education leaders could disseminate and gather information on methods and techniques for education programs. The ASTDHPPHE offers programs in the prevention of chronic disease, injury, the human **immunodeficiency** virus (HIV) and the acquired immunodeficiency syndrome (**AIDS**), and tobacco use. The emphasis turned to good **nutrition**, physical activity, and healthy schools and workplaces.

The U.S. Department of Health and Human Services' Office of Disease Prevention and Health Promotion created "Healthy People 2010," a set of initiatives and health objectives for Americans to focus on achieving optimum health. Ten high priority areas of focus were identified: physical activity, **obesity**, tobacco use, substance abuse, responsible sexual behavior, mental health, injury and violence, environmental quality, immunization, and access to health care. Focus areas within each of those 10 priorities include community-based health education programs, family planning, medical product safety, occupational safety and health, sexually transmitted diseases, immunization and infectious diseases, and physical activity and fitness.

The goal of "Healthy People 2010" is not only to increase the quality of life for people and help them to live longer, but also to eliminate the disparity in health care delivery. The life expectancy of Americans has increased more than 30 years since 1900, with many older Americans living well into their 70s, 80s, and even 90s. Physical health, as well as mental health, has become more and more important as many older adults want to "age in place," and not be forced to live in long-term-care facilities. Older adults are concerned about their quality of life (QOL). It is with good health education that all individuals can become empowered to take care of themselves.

Helping Americans maintain a good QOL is only part of the "Healthy people 2010" effort. Disparities still exist among minority groups; minorities have not enjoyed the same health improvement progress as other

Americans. Minority Americans have higher rates of diabetes, HIV and AIDS, infant mortality, and **heart** disease. Life expectancy for these populations is less than that of others, and minority groups living in poverty often do not have access to adequate health care.

The Cooperative Actions for Health Program (CAHP) is a collaborative grant program that is co-sponsored by the American Public Health Association and the American Medical Association (AMA). Its purpose is to build, support, and strengthen state and local collaboration between medical and public health professionals to improve the public's health. The program fosters collaboration through grant funding, developing a communication network to share ideas and coordinate policy-making efforts between the APHA and the AMA.

Viewpoints

There is some debate among health insurance companies and policy makers on whether health education programs are a cost-effective means of preventing illness and disease. For example, although a smoking cessation program offered in the workplace is believed to be an effective means of helping employees quit smoking, not many of these programs are covered by company insurance policies; the increase in premiums is often not very cost-effective. These health care organizations are seeking research-based evidence that proves that health education and promotion are effective and contribute to maintaining, rather than increasing, the cost of health care.

With the explosion of the information age, however, and the ease with which individuals can access information through computers and the World Wide Web, it has become much easier for the heads of health education programs to reach consumers with information. Still, the concern remains that Internet-based information does not reach poor minority consumers, as they are less likely to own a computer or hold a professional job in which they have computer access. In addition, some sites may not contain accurate health information; consumers and health professionals alike need to make sure that online sources are credible.

Professional implications

The implications for health care professionals is huge, particularly for primary care physicians (PCPs), who are on the front lines of health care for many Americans. Under most **managed care plans**, an individual must first see a primary care doctor regarding almost any problem prior to being referred to a specialist. Further, the referral must be written by the PCP. Primary

care physicians must be well-rounded in general health education and have knowledge in many disciplines in physical and mental health. Physicians must be prepared to address a multitude of questions regarding general health care.

Health services administration

Definition

Health services administration is a phrase that describes the career opportunities for individuals with a college education—often a master's degree—who choose to work in a health-related arena as a manager or administrator.

Description

The roles of individuals in health services administration are most commonly site specific but in general include skills in leadership, financial management, health informatics, marketing, and human resources. Because the health field is so diverse, an individual can choose to specialize in one division of a hospital, for example surgery, or in a specialty area in outpatient services such as managing an independent primary care center. An individual who is hired as a surgical health services adminis-

trator would function under the direction of either a hospital administrator or a surgeon. Coordination of services for surgical patients, acquisition of supplies, scheduling of surgical procedures, financial billing, and evaluation of quality outcomes would likely be job expectations. For the individual who is hired as a manager of a primary care center, responsibilities might include coordination of the hiring and firing of clerical staff, instituting community outreach, marketing the services of the center within the community, financial planning, and overseeing the billing sequence. In both these examples, the roles are site specific in that the needs of the different types of health services determine what responsibilities logically belong to the administrator.

Leadership skills needed for success in health service administration are centered around effective communication and understanding the principles of many theories used to characterize organization management. Situational leadership is a theory that states an individual in a leadership position varies the response to employees and the publics served by gathering data, fully analyzing the incident or occurrence, and then adapting the leadership style to the event. As an example, in a fire, a leader is not democratic but must use the situation (the fire) and then becomes autocratic and directive to avoid injury or harm to staff, patients, and the facility. As an another example, if the organization wanted to expand services in an unknown area of the city, the administrator might choose to use a *laissez faire* leadership style to elicit information from employees who live in the area of interest. *Laissez faire* leadership means that the administrator identifies the task (the seeking of information about the new area in the city) and does not direct the group but waits and watches as the group interacts to achieve the goal of identifying information. The administrator then simply records the information gleaned from the group meeting. Management by objectives is another commonly used management theory. This theory states that the best way for any individual to manage the performance of others is to make sure the overall goal is clear to everyone and that knowledge of the objectives helps all employees meet expected outcomes. The health services administrator is responsible for choosing the objectives (along with a Board of Trustees) and then defining and explaining these objectives to all employees.

Financial management includes the ability to develop and assess a budget, to determine where monies are best spent, to set up systems to monitor and evaluate the outcomes, to complete a cost benefit analysis of the service provided, and the ability to write up the needed reports. A meaningful budget that avoids overpayment of anything is a must in today's marketplace. Thus, health services administration is focused on insuring that costs

(output) are offset by income through budgetary and fiduciary oversight. Health informatics is a phrase used to describe the management of all types of data that compose computerized health records. It includes setting up, modifying, manipulating, and evaluating systems and the output from the systems using appropriate statistics to determine the cost of the service provided. The health services administrator combines knowledge of financial management and informatics to direct and oversee the organization as a whole.

Marketing is a word that is used to identify the skill needed to interact with employees and the public in an articulate way to achieve a favorable perception about the organization. This includes good verbal communication skills and a positive outlook about the organization when interacting with the media, multiple levels of professionals employed by the organization, and patients and their families. The health services administrator uses both knowledge and information as marketing tools to drive the agenda for the organization forward. Marketing includes developing networks with other organizations to maximize something of value for the establishment. As an example, the administrator might want to develop a local network to enhance buying power for the equipment and disposable supplies used for care. In addition, the administrator would be responsible for assessing the market relevance before any planned organizational change was implemented.

Human resources deals with the personnel component of any organization. For a health services administrator, the responsibilities would include developing policy for hiring, discipline, and termination of personnel through direct management or as a supervisor of the individual assigned to these services. Adherence to state employment law is an integral part of this responsibility. In a unionized setting it includes overseeing that all unionized personnel adhere to the union contract. In a non-unionized setting it might include approving the utilization of employee benefits as well as assessing what these benefits are and determining when the employee meets the requirements to earn the benefits. Human resources administrators insure that employee records are kept to meet state and federal regulatory requirements to document who is in the facility on any given day and the type of services provided by all employees on a daily basis.

Strategic planning is a process of working within an organization to develop a master plan that provides for survival and continuity of the organization, with planned growth in selected areas while insuring quality indicators of the services provided are met. This strategic plan provides clear and simple goals and direction to avoid confusion within the organization. Leadership and the strate-

gic directions provided to employees determine whether or not the organization is successful. Overseeing the development of the plan and evaluation of the outcomes are the responsibility of the health services administrator. Avoiding common mistakes such as creating large, unwieldy teams of people to oversee a service or instituting systems that interfere with economic effectiveness are part of the expectations in health services administration. For all organizations positive outcomes are the goal. The strategy for effective leadership in any health care organization is focused on positive outcomes. An old adage that has meaning for anyone choosing a career in health services administration runs something like “a happy customer, makes a happy administrator which leads to happy employees.” Basically when services are provided as promised or as promoted, then all levels of personnel have achieved the desired positive outcome. This also leads to financial success. The focus within the organization remains at all times on cost reduction and quality improvement. The effective strategic plan leads to that outcome.

Work settings

The work sites for individuals who choose health services administration include **public health**, public administration, business administration, allied health administration, or **hospital administration**. Job titles commonly used in the field are supervisor, director, executive director, administrator, executive, superintendent, overseer, governor, steward, and foreman. In the vernacular, the title of the health services administrator usually represents the chief, boss, or head for a division within an organization or for the entire organization. Individuals who select careers in health services administration can choose to work in government, the penal system, public health service, managed care organizations, or in any aspect of health care. In addition, a background in health services administration provides opportunities for selected professionals to work in other service firms such as accounting, law, or management consulting.

At the government level, health services administration is often focused on policy issues. Several ongoing topics that fall in this category include any aspect of health care reform and expansion of the coverage provided by tax levy monies. From a health services administration perspective, fear of expanded government regulation to the point of oppression can have a negative effect on any organization. An example that describes oppressive regulation would be a federal law mandating that the specifics of all health education be documented in the medical record. In this example the health care provider, the nurse or the doctor, would then spend more time doc-

umenting what was taught than the time actually spent teaching patients. The role of the health services administrator is to monitor potential legislation that would have a negative effect on the organization and to then organize appropriate staff to participate in a lobby effort to prevent this type of legislation from becoming law.

Managed care describes a delivery system for health care based on paid insurance coverage that often includes a written plan outlining the specific aspects of care usually provided to patients with a specific medical diagnosis. Managed care refers to the process of regulating care to avoid unnecessary treatments of all kinds and thus limiting costs. If employed by a managed care company, the health services administrator functions as a proponent of the company’s care options and the rules covering services with an overall goal of helping to prevent any further regulation of the insurance provider or the managed care corporation. In the same way, if employed by a hospital or an organization providing health service, the health services administrator is responsible for interpreting the rules and regulations mandated by the managed care organization and helping insure that the hospital or other provider receive maximum reimbursement for allowed services.

The roots of all public health services rest with public education about disease potential and avoidance, and health screening. Health service administrators employed in the public health arena are responsible for the management of many health issues. The role might include employment in centers with specific health functions such as: **asthma** education, services for the homeless, well child care, direct observational treatment for **tuberculosis**, prevention/treatment of sexually transmitted disease, HIV outreach and prevention services, or preventive care for all types of substance abuse, including smoking cessation and alcohol and drug rehabilitation.

Future outlook

The future is extremely positive for individuals who seek careers in health services administration. With the continued movement away from in-patient hospital services, small, independent, stand-alone health service agencies are opening all over the nation. Each of these independent facilities needs an administrator who understands the overall goals of the agency and is willing to join with the professional staff to make the organization a successful venture.

In conclusion, a career in health services administration is a management level position that is focused on achieving positive outcomes, using good internal controls, insuring sound financial management, keeping a pointed focus on the services provided and having over-

all management skills that insure organization survival and success. The National Association of Health Services Executives (NAHSE) offers additional information about this health care career.

Hearing

Definition

Hearing is the ability of the human ear to collect, process, and interpret sound.

Description

Sound vibrations travel through air, water, or solids in the form of pressure waves. When a sound wave hits a flexible object, such as the eardrum, it causes it to vibrate, which begins the process of hearing. The process of hearing involves the conversion of acoustical energy (sound waves) to mechanical, hydraulic, chemical, and finally, electrical energy where the signal reaches the **brain** and is interpreted.

The basis of sound is simple: there is a vibrating source, a medium in which sound travels, and a receiver. For humans the most important sounds are those which

carry meaning, for example, speech and environmental sounds. Sounds can be described in two ways, by their frequency (pitch) or by their intensity (loudness).

Frequency (the number of vibrations or sound waves per second) is measured in Hertz (Hz). A sound that is 4,000 Hz (like the sound the letter 'F' makes) has 4,000 waves per second. Healthy young adults can hear frequencies between 20 and 20,000 Hz. However, the frequencies most important for understanding speech are between 2,000 and 8,000 Hz. As adults age, the ability to hear frequency sounds decreases. An example of a high frequency sound is a bird chirping, while a drum beating is a low frequency sound.

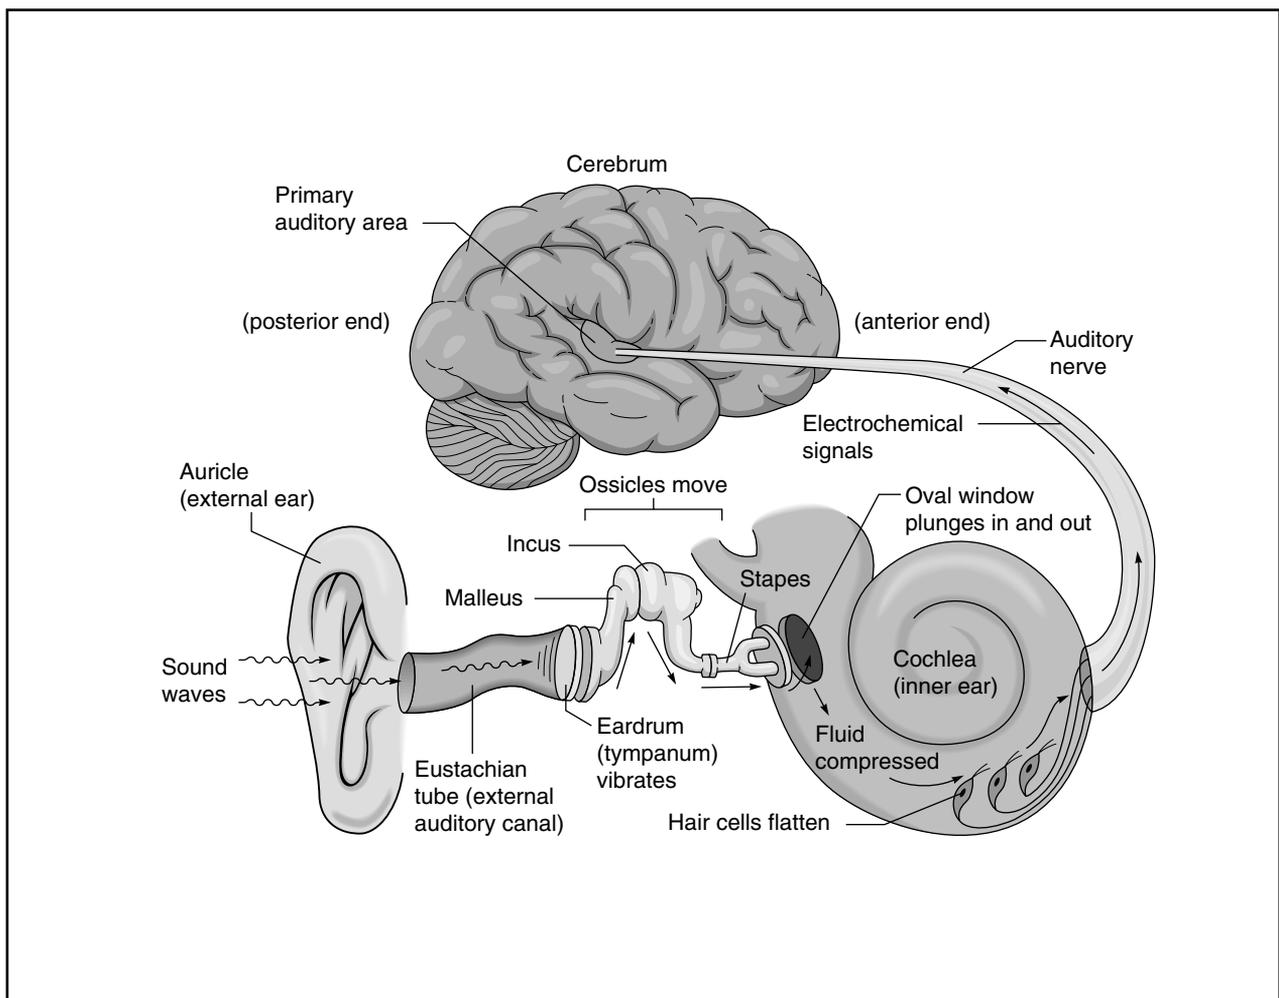

Intensity (loudness) is the amount of energy of a vibration, and is measured in decibels (dB). A zero decibel sound (like leaves rustling in the wind), can barely be heard by young healthy adults. In contrast, a 120 dB sound (like a jet engine at 20 ft [7 m]) is perceived as very loud and/or painful. Extremes in both loudness or pitch may seriously damage the human ear and should be avoided.

The difference between frequency or pitch and intensity or loudness can be illustrated using the piano as an analogy. The piano keyboard contains 88 keys that represent different frequencies or notes. The low frequencies or bass notes are on the left, the higher frequencies or treble notes are on the right. Middle C on the keyboard represents approximately 256 Hz. The intensity or loudness of a note depends on how hard you hit the key. A light touch on middle C may produce a 30 dB, 256 Hz note, while a hard strike on middle C may produce a 55 dB, 256 Hz note. The frequency, or note, stays the same, but the intensity of loudness varies as the pressure on the key varies.

Function

Human hearing involves a complicated process of energy conversion. This process begins with two ears located at opposite sides of the human head. The ability to use two ears for hearing is called binaural hearing. The primary advantages of binaural hearing are the increased ability to localize sounds and the increased ease of listening to a particular sound while having other noises in the background. Sound waves from the world around us enter the ear and are processed and relayed to the brain.

The actual process of sound transmission differs in each of the three parts of the human ear. The three parts of the human ear are the outer ear, middle ear, and inner ear.

The process of hearing. (Delmar Publishers, Inc. Reproduced by permission.)

Role in human health

The outer ear plays an important role in hearing. The pinna of the outer ear gathers sound waves from the environment and transmits them through the external auditory canal and eardrum to the middle ear. In the process of collecting sounds, the outer ear also modifies the sound. The external ear, or pinna, in combination with the head, can slightly amplify or increase as well as attenuate or decrease certain frequencies. The amplification or attenuation is due to individual differences in the dimensions and contours of the head and pinna.

The external auditory canal can also modify sound. This tube-like canal is able to amplify specific frequencies in the 3,000 Hz region. An analogy would be an opened, half-filled soda bottle. If you empty some of the fluid and blow into the bottle again, the frequency of the sound will change. Since the size of the human ear canal is consistent, the specific frequency it amplifies is also

constant. Sound waves travel through the ear canal until they reach the tympanic membrane or eardrum. Together, the head, pinna, and external auditory canal amplify sounds in the 2,000–4,000 Hz range by 10–15 dB. This boost is needed since the process of transmitting sound from the outer to the middle ear requires added energy.

The middle ear is separated from the outer ear by the tympanic membrane or eardrum. The membrane vibrates in response to pressure from sound waves traveling through the external auditory canal. The initial vibration causes the membrane to be displaced (pushed) inward by an amount equal to the intensity of the sound, so that loud sounds push the eardrum more than soft sounds. Once the eardrum is pushed inwards, the pressure within the middle ear causes the eardrum to be pulled outward, setting up a back-and-forth motion that begins the conversion and transmission of acoustical energy (sound waves) to mechanical energy (bone movement).

The three small, connected bones of the middle ear, together called the ossicle, are: the hammer or malleus, the anvil or incus, and the stapes or stirrup. The tiny, interconnected bones move as a unit in a type of lever-like action. The first bone, the malleus, is attached to the tympanic membrane and the back-and-forth motion of the tympanic membrane sets all three bones in motion. The final result of this bone movement is pressure of the foot plate of the last and smallest bone, the stapes, on the oval window. The window is one of two small membranes that allow communication between the middle ear and the inner ear. The lever-like action of the bones amplifies the mechanical energy from the eardrum to the oval window. The energy in the middle ear is also amplified due to the difference in surface size between the tympanic membrane and the oval window, which has been calculated to be a difference of about 14 to one.

The relationship of the eardrum or tympanic membrane to the oval window can be compared to that of a thumbtack. The eardrum would be the head of the thumbtack and the oval window would be the pin point of the thumbtack. The eardrum or the head of the tack would collect and apply pressure and then focus it on the oval window or the pin point, driving it into the surface. The overall amplification in the middle ear is approximately 25 dB. The conversion from mechanical energy or bone movement to hydraulic energy or fluid movement requires added energy since sound does not travel easily through fluids.

The inner ear is the site where hydraulic energy or fluid movement is converted first to chemical energy or hair cell activity and finally to electrical energy or nerve transmission. Once the signal is transmitted to the nerve, it will travel up to the brain to be interpreted.

The bone movements in the middle ear cause movement of the stapes foot plate in the membrane of the oval window. This pressure causes fluid waves or hydraulic energy throughout the entire two-and-a-half turns of the cochlea. The design of the cochlea allows for very little fluid movement, therefore the pressure at the oval window is released by the interaction between the oval and round windows. When the oval window is pushed forward by the stapes foot plate, the round window bulges outward and vice versa. This action permits the fluid wave motion in the cochlea. The cochlea is the fluid-filled, snailshell-shaped, coiled organ in the inner ear that contains the actual sense receptors for hearing. The fluid motion causes a corresponding, but not equal, wave-like motion of the basilar membrane. Internally, the cochlea consists of three fluid filled chambers: the scala vestibuli, the scala timpani, and the scala media. The basilar membrane is located in the scala media portion of the cochlea, and separates the scala media from the scala

timpani. The basilar membrane holds the key structure for hearing, the organ of Corti.

The physical characteristics of the basilar membrane are important, as is its wave-like movement, from its base or originating point to its apex or tip. The basilar wave motion slowly builds to a peak and then quickly dies out. The distance the wave takes to reach the peak depends on the speed at which the oval window is moved. For example, high frequency sounds have short wavelengths, causing rapid movements of the oval window, and peak movements on the basilar membrane near the base of the cochlea. In contrast, low frequency sounds have long wavelengths and cause slower movements of the oval window, and peak movements of the basilar membrane near the apex. The place of the peak membrane movements corresponds to the frequency of the sounds. Sounds can be located or “mapped” on the basilar membrane. High frequency sounds are near the base, middle frequency sounds are in the middle, and low frequency sounds are near the apex. In addition to the location on the basilar membrane, the frequency of sounds can be identified based on the number of nerve impulses sent to the brain.

The organ of Corti lies upon the basilar membrane and contains three to five outer rows (12,000 to 15,000) of hair cells and one inner row (3,000) of hair cells. The influence of the inner and outer hair cells has been widely researched. The common view is that the numerous outer hair cells respond to low intensity sounds below 60 dB. The inner hair cells act as a booster, by responding to high intensity, louder sounds. When the basilar membrane moves, it causes the small hairs on the top of the hair cells or stereo cilia to bend against the overhanging tectorial membrane. The bending of the hair cells causes chemical actions within the cell itself creating electrical impulses in the nerve fibers attached to the bottom of the hair cells. The nerve impulses travel up the nerve to the temporal lobe of the brain. The intensity of a sound can be identified based on the number of hair cells affected and number of impulses sent to the brain. Loud sounds cause a large number of hair cells to be moved, and many nerve impulses to be transmitted to the brain.

Each of the separate nerve fibers join and travel to the lowest portion of the brain, the brain stem. Nerves from the vestibular, or balance, part of the inner ear combine with the cochlear nerves to form the VIII cranial nerve (auditory or vestibulocochlear nerve). Once the nerve impulses enter the brain stem, they follow an established pathway, known as the auditory pathway. The organization within the auditory pathway allows for a large amount of crossover. “Cross-over” means that the sound information or nerve impulses from one ear do not travel exclusively to one side of the brain. Some of the

KEY TERMS

Amplify—To increase.

Attenuate—To decrease.

Bilateral—Both sides of an object.

Binaural—Both ears.

Decibel—Unit of measurement of the intensity of sound, abbreviated dB.

Equilibrium—Balance, the ability to maintain body position.

Frequency—Pitch, the number of vibrations or sound waves per second.

Hertz—Unit of measurement for frequency, abbreviated Hz.

Hydraulic—Fluid in motion.

Intensity—Loudness, the amount of energy of a vibration or sound wave.

Localization—Ability to identify where a sound is coming from.

nerve impulses cross over to the opposite side of the brain. The impulses travel bilaterally on both sides of the brain up the auditory pathway until they reach a specific point in the temporal lobe called Heschl's gyrus. Crossovers act like a safety net. If one side of the auditory pathway is blocked or damaged, the impulses can still reach Heschl's gyrus to be interpreted as sound.

Common diseases and disorders

There are several common diseases, disorders, and conditions that occur in the external ear, middle ear, eardrum, and inner ear that can affect the sense of hearing in humans.

- External otitis (swimmer's ear), an inflammation or **infection** of the external ear.
- Furunculosis or recurring **boils** in the ear canal.
- Exostoses or benign tumors of the ear canal.
- Foreign bodies or anything that gets stuck in the ear. These can range from insects or seeds to earplugs that can't be removed.
- Trauma to the eardrum.
- Bullous myringitis, an inflammation of the eardrum.
- Retracted eardrum or blocked eustachian tube.

- Barotitis media or eardrum retracted by change of atmospheric pressure while the eustachian tube is blocked.
- Otitis media, a middle ear infection.
- Acute mastoiditis, a severely infected mastoid process.
- Otosclerosis or ear bone degeneration.
- Cholesteatoma or epithelial inclusion cyst.
- Meniere's disease or vertigo.
- Acoustic neurinoma, a tumor on the vestibular nerve.
- Presbycusis or sensorineural **hearing loss** due to aging.
- Labyrinthitis, an infection of the inner ear.
- Vestibular neuronitis, a sudden loss of the balance mechanism in one ear.
- Tinnitus or the sensation of sound in the ear when there is no sound.

Hearing aids

Definition

A **hearing aid** is a device that can amplify sound waves in order to help a deaf or hard-of-hearing person hear sounds more clearly. There are two major types of **hearing loss**, conductive hearing loss and sensory hearing loss. Conductive hearing loss is often mechanical in nature, resulting in external or middle ear problems. This type of hearing loss often can be corrected by medicine and/or surgery. Possible causes for conductive hearing loss include otitis media and otosclerosis. Sensory hearing loss is due to a disorder in the inner ear, specifically involving the cochlea. This type of hearing loss may be congenital or the result of an acquired condition, such as meningitis. Hearing aids are primarily used by patients with sensory hearing loss.

Purpose

Recent technology can help most people with hearing loss understand speech better and achieve better communication.

Precautions

It is important that a person being fitted for a hearing aid understand what an aid can and can not do. An aid can help a person hear better, but it will not return hearing to normal levels. Hearing aids boost all sounds, not just those the person wishes to hear. Especially when the source of sound is far away (such as up on a stage), environmental noise can interfere with good speech perception. And, while the aid amplifies sound, it does not necessarily improve the clarity of the sound. A hearing aid is a machine and can never duplicate the true sound that people with normal hearing experience, but it will help the person take advantage of the hearing that remains.

Description

More than one thousand different models of hearing aids are available in the United States. All of them include a microphone (to pick up sound), an amplifier (to boost sound strength), and a receiver or speaker (to deliver sound to the ear). All hearing aids are powered by a battery. Depending on the style, it is possible to add features to filter or block out background noise, minimize feedback, lower sound in noisy settings, or boost power when needed.

Hearing aids are either monaural, a hearing aid for one ear, or binaural, for two ears; more than 65% of all

users have binaural aids. Hearing aids are divided into several different types:

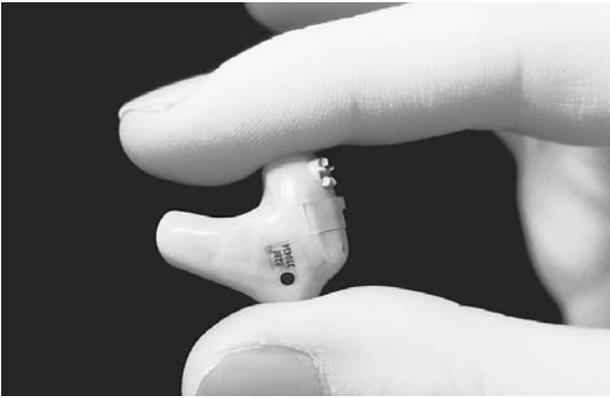

- digital
- in-the-ear
- in-the-canal
- behind-the-ear
- on-the-body

Digital aids are sophisticated, expensive aids that borrow computer technology to allow a person to tailor an aid to a specific hearing loss pattern. Using miniature computer chips, the aids can selectively boost certain frequencies while leaving others alone. This means a person could wear such an aid to a loud party, and screen out unwanted background noise, while tuning in on one-on-one conversations. The aid is programmed by the dealer to conform to the person's specific hearing loss. Some models can be programmed to allow the wearer to choose different settings depending on the noise of the environment.

In-the-ear aids are lightweight devices whose custom-made housings contain all the components; this device fits into the ear canal with no visible wires or tubes. It is possible to control tone but not volume with these aids, so they are helpful only for people with mild hearing loss. Some people find these aids are easier to put on and take off than behind-the-ear aids. However, because they are custom-fit to a person's ear, it is not possible to try on before ordering. Also, some people find them uncomfortable in hot weather.

In-the-canal aids fit far into the ear canal, with only a small bit extending into the external ear. The smallest is the MicroCanal, which fits out of sight down next to the eardrum and is removed with a small transparent wire. These aids are extremely expensive, but they are not visible, offer better acoustics, and are easier to maintain. They can more closely mimic natural sound because of the position of the microphone; this position also cuts down on wind noise. Because of their small size, these aids are harder to handle, and their battery is especially small and difficult to insert. Adjusting the volume may be hard, since a person must stick a finger down into the ear to adjust volume, and this very tiny aid does not have the power of larger aids.

Behind-the-ear aids include a microphone, amplifier, and receiver inside a small curved case worn behind the ear; the case is connected to the earmold by a short plastic tube. The earmold extends into the ear canal. Some models have both tone and volume control, plus a telephone pickup device. Many users think them unattractive and out of date, however, and those who wear glasses find that the glasses interfere with the aid's fit. Others do

Woman holding a cochlear implant by L. Steinmark.
(*Custom Medical Stock Photo. Reproduced by permission.*)

not have space behind the ear for the mold to fit comfortably. They do offer a few advantages.

Behind-the-ear aids:

- do not require as much maintenance
- are easily interchangeable if they need to be serviced
- are more powerful
- are easier to handle than smaller aids
- provide better sound quality
- are more reliable

Eyeglass models are the same as behind-the-ear devices, except that the case fits into an eyeglass frame instead of resting behind the ears. Not many people buy this type of aid, but those who do believe it is less obvious, although there is a tube that travels from the temple of the glasses to the earmold. It can be hard to fit this type of aid, and repairs can be problematic. Also, if the aid breaks, the person also loses the benefit of the glasses.

The crossover system type of hearing aid is often used in conjunction with the eyeglass model. The contralateral routing of signal (CROS) system features a microphone behind the ear that feeds the amplified signal to the better ear, eliminating “head shadow,” which occurs when the head blocks sound from the better ear. This type may help make speech easier to understand for people with a high-frequency loss in both ears.

A BI-CROS system uses two microphones (one above each ear) that send signals to a single amplifier. Sound then travels to a single receiver, which transfers it to the better ear via a conventional earmold.

On-the-body aids feature a larger microphone, amplifier, and power supply inside a case carried inside the pocket or attached to clothing. The receiver attaches directly to the earmold; its power comes through a flexible wire from the amplifier. Although larger than other

aids, the on-the-body aids are more powerful and easier to adjust than other devices. While not popular for everyone, they are often used by those with a profound hearing loss, or by very young children. Some people who are almost totally deaf find they need the extra power boost available only from a body aid.

Cochlear implants, which are implanted through a surgical procedure, are taking hearing technology to a new level. Different from a hearing aid, cochlear implants are composed of an external portion (including a microphone worn behind the ear, a speech processor, and a transmitter) and an internal portion (including an implanted receiver and electrodes), a cochlear implant is designed to bypass damaged sound-sensing cells of the inner ear (cochlear hair cells) and provide electrical stimulation of the auditory nerve. The result is the sensation of sound for individuals who would otherwise be deprived. The best candidates for cochlear implants are individuals with profound hearing loss to both ears who have not received much benefit from traditional hearing aids and are of good general health. Children as young as 14 months have been successfully implanted.

Preparation

The first step in getting a hearing aid is to have a medical exam and a hearing evaluation. (Most states prohibit anyone selling a hearing aid until the patient has been examined by a physician to rule out medical problems.) After performing a hearing evaluation, an audiologist should be able to determine whether a hearing aid will help and which one will do the most good. This is especially important because aids can be very expensive (between \$500 and \$4,000) and are often not covered by health insurance. Hearing aids come in a wide range of styles and types, requiring careful testing to make sure the aid is the best choice for a particular hearing loss.

Some audiologists sell aids; others can make a recommendation, or provide a list of competent dealers in a patient’s area. Patients should shop around and compare prices. In all but three states, hearing aids must be fitted and sold only by licensed specialists called dealers, specialists, dispensers, or dispensing audiologists.

The audiologist or hearing aid dealer will make an impression of the consumer’s ear canals using a putty-like material, from which a personalized earmold will be created. It is the dealer’s job to make sure the aid fits properly. The person may need several visits to find the right hearing aid and learn how to use it. The dealer will help the consumer learn how to put the aid on, adjust the controls, and maintain the device. The dealer should be willing to service the aid and provide information about

what to do if sensitivity to the earmold develops. (Some people are allergic to the materials in the mold.)

Aftercare

Within several weeks, the wearer should return to the dealer to have the aid checked and to discuss the progress in wearing the aid. About 40% of all aids need some modification or adjustment in the beginning.

Within the first month of getting an aid, the patient should make an appointment for a full hearing examination to determine if the aid is functioning properly.

Complications

While there are no medical complications to hearing aids, there is a risk associated with hearing aids: many people end up not wearing their aids because they say everything seems loud when wearing them. This may be because they have lived for so long with a hearing problem that they have forgotten how loud “normal” sound can be. Other potential problems with hearing aids include earmold discomfort and a build up of excess ear wax after getting a hearing aid.

Results

A hearing aid boosts the loudness of sound, which can improve a person’s ability to understand speech.

Health care team roles

Physicians, audiologists, and nurses are involved in the diagnosis and treatment of hearing loss. Audiologists prescribe, dispense, and service hearing aids.

KEY TERMS

Audiologist—A person with a degree and/or certification in the areas of identification and measurement of hearing impairments and rehabilitation of those with hearing problems.

Cochlea—A conical bony structure or the inner ear; perforated by numerous openings for passage of the cochlear division of the acoustic nerve.

Conductive hearing loss—Hearing loss resulting from external or middle ear problems.

Eardrum—A paper-thin covering stretching across the ear canal that separates the middle and outer ears.

Middle ear—The small cavity between the eardrum and the oval window that houses the three tiny bones of hearing.

Oval window—A tiny opening at the entrance to the inner ear.

Sensory hearing loss—Hearing loss due to disorders of the inner ear.

Hearing loss

Definition

Hearing loss is any degree of impairment of the ability to comprehend sound.

Description

Sound can be accurately measured. The term decibel (dB) refers to an amount of energy moving sound from its source to the ears of one or more listeners or to a microphone. A decrease of more than 10 dB in the level of sound a person can hear is significant.

Sound travels through a medium, such as air or water, as waves of compression and rarefaction. These waves are collected by the external ear and cause the tympanic membrane (ear drum) to vibrate. The chain of ossicles connected to the ear drum—the incus, malleus, and stapes—carries the vibrations to the oval window, increasing their amplitude 20 times along the way. There, the energy creates a standing wave in the watery liquid (endolymph) inside the organ of Corti. (A standing wave is one that does not move. A vibrating cup of coffee will demonstrate standing waves.) The shape of the standing wave is determined by the frequency of the sound. Many thousands of tiny nerve fibers detect the highs and lows of the standing wave. Motions in the nerve endings are converted into electrical impulses. These are transmitted to the **brain** via a nerve. Specialized areas of the brain interpret the signals as sound.

To summarize, sound energy passes through the air of the external ear, the bones of the middle ear, and the liquid of the inner ear. It is then translated into nerve impulses, sent to the brain through the acoustic nerve, and understood there as sound. It follows that there are five steps in the hearing process:

- air conduction through the external ear to the ear drum
- bone conduction through the middle ear to the inner ear
- water conduction inside the organ of Corti
- nerve conduction into the brain
- interpretation by the brain

Causes and symptoms

Hearing can be interrupted in several ways at each of the five steps noted above.

The external ear canal can be blocked with ear wax (cerumen), foreign objects, **infection**, and tumors. Overgrowth of the bone, a condition that occurs when the ear canal has been flushed with cold water repeatedly for years, can also narrow the passageway, making blockage and infection more likely. This condition occurs often among northern Californian surfers and is aptly called “surfer’s ear.”

The ear drum is so thin that a physician can see through it, into the middle ear. Sharp objects, pressure from an infection in the middle ear, or even a firm cuff-

ing or slapping of the ear, can rupture the ear drum. The eardrum is also susceptible to pressure changes, such as those that occur when one is scuba diving.

Several conditions can diminish the mobility of the ossicles (small bones) in the middle ear. Otitis media (an infection in the middle ear) occurs when fluid cannot escape into the throat because of blockage of the eustachian tube. The fluid that accumulates, whether it is pus or mucus, dampens the motions of the ossicles. A disease called otosclerosis can bind the stapes in the oval window, thereby cause deafness.

All of the problems and conditions that occur in the external and middle ear are causes of conductive hearing loss. The second category, sensory hearing loss, refers to damage to the organ of Corti, or the acoustic nerve. Prolonged exposure to loud noise is the leading cause of sensory hearing loss. More than a million people have been identified as having this condition. The cause is often believed to be prolonged exposure to loud music. Occupational noise exposure is the other leading cause of noise induced hearing loss (NIHL) and is an ample reason for wearing ear protection on the job. Jobs in construction and loud offices may contribute to ear damage, as may noises of recreation, such as loud music or the engine of a motorcycle. Both types of noises may lead to loss of hairs in one’s inner ear. Thousands of these tiny hairs are attached to nerve cells in the cochlea (a snail-shaped structure in the inner ear). These tiny hairs aid the conversion of sound vibrations into electrical signals, which are then transmitted to the brain. When hairs become broken or bent, the transmission of the electric signals isn’t as good, and sound may become muffled. Words may become difficult to distinguish against background noises.

One-third of people over 65 have presbycusis (gradual loss of hearing that occurs as one ages) and one-half of those older than age 75 have a hearing impairment. Both NIHL and presbycusis are primarily high frequency losses. The human speech frequencies are in relatively low ranges. People with presbycusis hear noise but cannot easily make sense of it. They have particular trouble distinguishing speech from background noise. Brain infections, such as **meningitis**, drugs such as the aminoglycoside **antibiotics** (e.g., streptomycin, kanamycin, tobramycin), and Menière’s disease may also cause permanent sensory hearing loss. Menière’s disease combines attacks of hearing loss with attacks of vertigo. The symptoms may occur together or separately. High doses of salicylates, like aspirin and quinine, can cause a temporary high-frequency loss. Prolonged high doses can lead to permanent deafness. There is an hereditary form of sensory deafness and a congenital form most often caused by rubella (German measles).

DECIBEL RATINGS AND HAZARDOUS LEVELS OF NOISE

<i>Decibel Level</i>	<i>Example Of Sounds</i>
30	Soft whisper
35	Noise may prevent the listener from falling asleep
40	Quiet office noise level
50	Quiet conversation
60	Average television volume, sewing machine, lively conversation
70	Busy traffic, noisy restaurant
80	Heavy city traffic, factory noise, alarm clock
90	Cocktail party, lawn mower
100	Pneumatic drill
120	Sandblasting, thunder
140	Jet airplane
180	Rocket launching pad
<p>Above 110 decibels, hearing may become painful</p> <p>Above 120 decibels is considered deafening</p> <p>Above 135 decibels, hearing will become extremely painful and hearing loss may result if exposure is prolonged</p> <p>Above 180 decibels, hearing loss is almost certain with any exposure</p>	

Source: FDA Consumer, *Gale Encyclopedia of Psychology*, 1996. (Illustration by Standley Publishing. Courtesy of Gale Group.)

Sudden hearing loss—at least 30dB in less than three days—is most commonly caused by cochleitis, an inflammation of the cochlea. The source of this process is thought to be viral, but as of 2001, no causative virus has been identified.

The final category of hearing loss is neural. Damage to the acoustic nerve and the parts of the brain that integrate and interpret sounds are the most likely to produce permanent hearing loss. Strokes, **multiple sclerosis**, and acoustic neuromas are all possible causes of neural hearing loss.

Hearing can also be diminished by extra sounds generated by the ear, most of them from the same kinds of disorders that cause hearing loss. These sounds are referred to as tinnitus and can be ringing, blowing, clicking, or anything else that no one but the affected person hears.

Diagnosis

An examination of the ears and nose, combined with simple hearing tests that can be conducted in a physician's office, detect many common causes of hearing loss. Analysis of an audiogram often concludes the evaluation, since these simple imaging often enables a diag-

nosis. If the defect is in the brain or the acoustic nerve, further neurologic testing and imaging will be required.

An audiogram has many uses in diagnosing hearing deficits. The pattern of hearing loss across the audible frequencies gives clues to the cause. Several alterations in the testing procedure can give additional information. For example, speech is perceived differently than pure tones. Adequate perception of sound, combined with inability to recognize words, indicates a brain problem rather than a sensory or conductive deficit. Loudness perception is distorted by disease in certain areas of the brain, but not in others. Acoustic neuromas often distort the perception of loudness.

Treatment

Conductive hearing loss can almost always be restored to some degree, if not completely.

- Matter in the ear canal can be easily removed. This results in a dramatic improvement in hearing. In cases of earwax blockage, wax may be removed by the physician, who may loosen it and drain the ear, scoop it out, or use a suction device to removed softened wax.

An Oto-Acoustic Emission (OAE) hearing test being performed on a newborn baby. The probe emits harmless sound into the baby's ear, and the response of the inner ear is detected and registered on a computer. Early diagnosis of a hearing disorder is important in young children, who may experience difficulties in speech and language development. (Photograph by James King-Holmes, Photo Researchers, Inc. Reproduced by permission.)

- Surfer's ear gradually regresses if cold water is avoided or a special ear plug is used. In advanced cases, excess bone can be ground away by surgeons.
- Middle ear infection with fluid is also relatively easy to treat. If medications do not work, surgical drainage of the ear is accomplished through the ear drum, which heals completely after treatment.
- Traumatically damaged ear drums can be repaired with a tiny skin graft.
- Surgical repair of otosclerosis through an operating **microscope** is one of the most intricate procedures available, and substitutes tiny, artificial parts for the original ossicles.

Sensory and neural hearing loss, on the other hand, cannot readily be cured. Fortunately, the loss is not often complete, so that **hearing aids** can fill the deficit.

In-the-ear hearing aids can boost the volume of sound by up to 70 dB. (Normal speech is about 60 dB.) Federal law now requires that they be dispensed only with a physician's prescription. For complete conduction

hearing loss, there are now bone conduction hearing aids available, as well as devices that can be surgically implanted in the cochlea.

Tinnitus can sometimes be relieved by adding white noise (like the sound of wind or waves crashing on the shore) to the environment.

Decreased hearing is such a common problem that there are many organizations that provide assistance. Special language training, both in lip reading and signing, and special schools and camps for hearing-impaired children are all available in most regions of the United States.

Conductive hearing loss can be treated with alternative therapies that are specific to the particular condition. Sensory hearing loss may be helped by homeopathic therapies. Oral supplementation with essential fatty acids such as flax oil and omega-3 oil can help alleviate the accumulation of wax in the ear.

Prognosis

The prognosis for conductive hearing loss is quite good. Since there is no cure for sensory or neural hearing loss, the prognosis is poor.

Health care team roles

Hearing examinations are usually conducted by physicians. Audiologists are trained to evaluate hearing. Speech language specialists are trained to provide treatment and rehabilitation for persons with impaired hearing.

Prevention

Prompt treatment and attentive follow-up of middle ear infections in children will prevent this cause of conductive hearing loss. Control of infectious childhood diseases, such as measles, has greatly reduced sensory hearing loss as a complication of epidemic diseases. Laws that require protection from loud noise in the workplace have achieved substantial reduction in noise induced hearing loss. Wearing specially designed earmuffs that resemble earphones may be of use where the noise is still too loud. Surfers should use the right kind of ear plugs.

One should have his or her hearing tested on a regular basis if a noisy environment cannot be avoided. Early detection will enable one to take steps to prevent further hearing loss. Avoiding exposure to loud noise and using hearing protection are the best ways to prevent hearing loss and slow the onset of presbycusis.

KEY TERMS

Compression—Narrower than average distances between wave peaks.

Decibel—A unit of the intensity of sound, a measure of loudness.

Meniere's disease—The combination of vertigo and decreased hearing caused by abnormalities in the inner ear.

Multiple sclerosis—A progressive disease of brain and nerve tissue.

Otosclerosis—A disease that scars and limits the motion of the small conducting bones in the middle ear.

Rarefaction—Wider than average distances between wave peaks.

Stroke—A sudden loss of blood supply to part of the brain.

Heart-lung machines

Definition

The heart-lung machine is medical equipment that provides cardiopulmonary bypass or mechanical circulatory support of the **heart** and **lungs**. The machine may consist of venous and arterial cannula, polyvinyl chloride (PVC) or silicone tubing, reservoir (open or closed system), bubbler or membrane oxygenator, cardiotomy, heat exchanger(s), arterial line filter, pump(s) (usually centrifugal or roller-head), flow meter, inline **blood** gas and electrolyte analyzer, and pressure monitoring devices. Treatment provides removal of carbon dioxide from the blood, oxygen delivery to the blood, blood flow to the body, and/or temperature maintenance. Pediatric and adult patients both benefit from this technology.

Purpose

In the operating room the heart-lung machine is used primarily to provide blood flow and respiration for the patient while the heart is clinically arrested. Surgeons are able to perform coronary artery bypass grafting (CABG), open-heart surgery for valve repair or repair of cardiac anomalies, and aortic aneurysm repairs, along with treatment of other cardiac related diseases.

The heart-lung machine provides the benefit of a motionless heart in an almost bloodless surgical field. Cardioplegia solution is delivered to the heart by a dedicated pump resulting in cardiac arrest. The heart-lung

machine is invaluable during this time since the patient is unable to maintain blood flow to the lungs or the body.

In critical care units and **cardiac catheterization** laboratory the heart-lung machine is used to support and maintain blood flow and respiration. The diseased heart or lungs are replaced by this technology providing time for the organ(s) to heal. Venoarterial extracorporeal membrane oxygenation (ECMO) is used primarily in the treatment of lung disease. Cardiopulmonary support is useful during percutaneous transluminal coronary **angioplasty** (PTCA) and stent procedures performed in the cardiac catheterization lab. Both treatments can be instituted in the critical care unit when severe heart or lung disease is no longer treatable by less invasive conventional treatments such as pharmaceuticals, intra-aortic balloon pump (IABP), and mechanical ventilation with a respirator.

Use of this treatment in the emergency room is not limited to patients suffering heart or lung failure. In severe cases of hypothermia, patient body temperature can be corrected by extracorporeal circulation with the heart-lung machine. Blood is warmed as it passes over the heat exchanger. The warmed blood returns to the body, gradually increasing the patients body temperature to normothermia.

Tertiary care facilities are able to support the staffing required to operate and maintain this technology. Level I trauma centers have access to this specialized treatment and equipment. Being that this technology serves both adult and pediatric patients specialized children's hospitals may provide treatment with the heart-lung machine for Venoarterial ECMO.

Description

The pump oxygenator developed by Dr. Gibbons saw its first success on May 6, 1953. A patient placed on the heart-lung machine survived an open-heart atrial septal defect repair. Continued research and design has allowed the heart-lung machine to become a standard of care in the treatment of heart and lung disease, while supporting other non-conventional treatments.

Foreign surfaces of the heart-lung machine activate **blood coagulation proteins** and platelets, which lead to clot formation. In the heart-lung machine, clot formation would block the flow of blood. As venous and arterial cannulas are inserted, pharmaceuticals are administered to provide anticoagulation of the blood. Clot formation is prevented and blood will flow through the heart-lung machine.

Large vessels, venous and arterial, are required for cannulation, to insert the tubes (cannulas) that will carry

A heart-lung machine. (Photograph by Albert Paglialunga. Phototake NYC. Reproduced by permission.)

the blood away from the patient to the heart-lung machine and return the blood from the heart-lung machine to the patient. Cannulation sites for venous access can include the inferior and superior vena cava, the right atrium, the femoral vein, or internal jugular vein. Oxygen rich blood will be returned to the aorta, femoral artery or carotid artery. By removing oxygen poor blood from the right side of the heart and returning oxygen rich blood to the left side, heart-lung bypass is achieved.

The standard heart-lung machine typically includes up to five pump assemblies. A centrifugal or roller head pump can be used in the arterial position for extracorporeal circulation of the blood. The four remaining pumps are roller pump in design to provide fluid, gas, and liquid for delivery or removal to the heart chambers and surgical field. Left ventricular blood return is accomplished by roller pump, drawing blood away from the heart. Surgical suction created by the roller pump removes accumulated

fluid from the general surgical field. The cardioplegia delivery pump is used to deliver a high potassium solution to the coronary vessels. The potassium arrests the heart so that the surgical field is motionless during surgical procedures. An additional pump is available for emergency backup of the arterial pump in case of mechanical failure.

A pump is required to produce blood flow. Pump technology has advanced from the Sigmamotor pump, a fingerlike contraction that uses peristalsis to propel blood, through tubing, from the oxygenator to the body. This technology was abandoned for more reliable roller pump technology. Currently roller and centrifugal pump designs are the standard of care. Both modern designs can provide pulsatile or non-pulsatile blood flow to the systemic circulation.

The roller assembly rotates and engages the tubing, PVC or silicone, which is then compressed against the pump's housing, propelling blood ahead of the roller

head. Rotational frequency and tubing inner diameter determine blood flow. Because of its occlusive nature the pump can be used to remove blood from the surgical field by creating negative pressure on the inflow side of the pump head.

The centrifugal pump also has a negative inlet pressure. As a safety feature this pump becomes inefficient when gaseous emboli are introduced. The centrifugal force draws blood into the center of the device. Blood is propelled and released to the outflow tract tangential to the pump housing. Rotational speed determines the amount of blood flow, which is measured by a flowmeter placed adjacent to the pump housing. If rotational frequency is too low, blood may flow in the wrong direction since the system is non-occlusive in nature. Magnetic coupling links the centrifugal pump to the control unit.

A reservoir collects blood drained from the venous circulation. Tubing connects the venous cannulae to the reservoir. Reservoir designs include open or closed systems. The open system displays graduated demarcations corresponding to blood volume in the container. The design is open to atmosphere allowing blood to interface with atmospheric gasses. The pliable bag of the closed system eliminates the air blood interface, while still being exposed to atmospheric pressure. Volume is measured by weight or by change in radius of the container. The closed reservoir collapses when emptied as an additional safety feature.

Bubble oxygenators use the reservoir for ventilation. When the reservoir is examined from the exterior the blood is already oxygen rich and appears bright red. As blood enters the reservoir gaseous emboli are mixed directly with the blood. Oxygen and carbon dioxide are exchanged across the boundary layer of the blood and gas bubbles. The blood will then pass through a filter that is coated with an antifoam solution, which helps to remove fine bubbles. As blood pools in the reservoir it has already exchanged carbon dioxide and oxygen. From here tubing carries the blood to the rest of the heart-lung machine.

In opposition to this technique is the membrane oxygenator. Tubing carries the oxygen poor blood from the reservoir through the pump to the membrane oxygenator. Oxygen and carbon dioxide cross a membrane that separates the blood from the ventilation gasses. As blood leaves the oxygenator it is oxygen rich and bright red in color.

As blood is ready to be returned from the heart-lung machine to the patient the arterial line filter will be encountered. This device is used to filter microemboli that may have entered, or been generated by the heart-lung machine. After this filter tubing completes the blood

path as it returns the blood to the arterial cannula to enter the body.

Fluid being returned from the left ventricle and surgical suction require filtration before the blood is reintroduced to the heart-lung machine. Blood enters a filtered reservoir, called a cardiotomy, which is connected with tubing to the venous reservoir. Other fluids, such as blood products and pharmaceuticals are also added in the cardiotomy for filtration, of particulate.

Heat exchangers allow body and organ temperature to be adjusted. The simplest heat exchange design is a bucket of water. As the blood passes through the tubing placed in the bath the blood temperature will change. A more sophisticated system separates the blood and water interface with a metallic barrier. As the water temperature is changed so is the blood temperature, which enters the body or organ circulation changing the tissue temperature. Once the tissue temperature reaches the desired value the water temperature is maintained. Being able to cool the blood helps to preserve the organ and body by metabolizing fewer energy stores.

Because respiration is being controlled, and a machine is meeting metabolic demand, it is necessary to monitor the patient's blood chemical makeup. Chemical sensors placed in the blood path are able to detect the amount of oxygen bound to hemoglobin. Other, more elaborate sensors can constantly trend the blood pH, partial pressure of oxygen and carbon dioxide, and electrolytes. This constant trending can quickly analyze the metabolic demands of the body.

Sensors that communicate system pressures are also a necessity. These transducers are placed in areas where pressure is high, after the pump. Readings outside of normal ranges often alert the operator to obstructions in the blood flow path. The alert of high pressure must be corrected quickly as the heart-lung machine equipment may disengage under the stress of abnormally elevated pressures. Low-pressure readings can be just as serious alerting the user to faulty connections or equipment. Constant monitoring and proper alarms help to protect the integrity of the system.

Constant scanning of all components and monitoring devices is required. Normal values can quickly change due to device failure or sudden mechanical constrictions. The diagnosis of a problem and quick troubleshooting techniques will prevent additional complications.

Operation

The perfusionist or ECMO specialist monitors hemodynamic parameters associated with the patient and the device. Therefore, they are able to use the relation-

ship of pressure, flow and resistance to make the appropriate changes to maintain adequate blood flow to vital organ beds. The standing orders from the physician, along with specific requests during the procedure are met by controlling the flow, temperature, **gas exchange**, pharmaceutical delivery and blood gas and electrolyte values. All requests and changes from protocol require documentation on the patient record.

Patient blood is drawn at 30-minute intervals to document arterial or venous blood gasses along with electrolytes and anticoagulation status. Decisions are made about device operation and pharmaceutical delivery based on these parameters. Abnormal values may indicate mechanical device failure.

Maintenance

Biannual preventive maintenance ensures proper device operation. The preventive maintenance as determined by the manufacturer should be followed. Electrical leakage tests are performed biannually on electrical components. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires documentation of these activities. A pre-bypass checklist is also completed before each procedure for review of the following categories: patient, sterility, pump, electrical, gas supply, lines/pump tubing, cardioplegia, safety mechanisms, monitoring, temperature control, supplies, anticoagulation and backup. Documentation of a completed checklist is kept with the patient record, and must be signed with date and time, by the device operator.

Health care team roles

At the sterile field the physician must react with the perfusionist or ECMO specialist in correcting problems that may interfere with the proper operation of the heart-lung machine. At the termination of device support the perfusionist or ECMO specialist must communicate clearly to the physician all changes in support status. This allows the entire team to assess changes in patient parameters that are consistent with the patient becoming less dependent on the device, while the native heart and lungs meet the metabolic demands of the body.

It is the responsibility of the perfusionist or ECMO specialist to be at the device controls at all times. Continuous scanning of all patient monitors is necessary for proper treatment and troubleshooting. Documentation of patient status is acquired every 15 to 30 minutes. This information allows the physician and nursing staff to follow trends that will help better manage the patient once treatment is discontinued.

KEY TERMS

Anticoagulant—Pharmaceuticals to prevent clotting proteins and platelets in the blood to be activated to form a blood clot.

Cannula—Tubes that provide access to the blood once inserted into the heart or blood vessels

Cardiopulmonary bypass—Diversion of blood flow away from the right atrium and return of blood beyond the left ventricle, to bypass the heart and lungs.

Extracorporeal—Circulation of blood outside of the body.

Training

A perfusionist earns a certificate of completion from a program accredited by the Commission on Accreditation of Allied Health Education Programs (CAAHEP). A bachelor's degree is required before entering the certificate program, or is received at the time of completion of the certificate-granting program. Professional certification can be earned from the American Board of Cardiovascular Perfusion or the International Board of Circulation Technologists. Licensure is required in some states.

Perfusionists, nurses, and respiratory therapists can receive additional training, as ECMO specialists, in the operation of ECMO equipment and institution specific protocols to operate venoarterial ECMO. The institution, in accordance with the guidelines established by the Extracorporeal Life Support Organization (ELSO), performs the training.

Heart

Definition

The heart is a muscular organ of the **cardiovascular system** that contracts to cause movement of the **blood** throughout the body.

Description

The heart is approximately fist-sized and located in the chest between the two **lungs** and behind the ribs and breastbone (sternum). It rests at a slight tilt from vertical, which makes it appear to be on the left side of the body. The walls of the heart are made up of three layers of tissue: epicardium, myocardium, and endocardium. The epicardium is a thin layer on the outer surface of the heart. The myocardium is the muscular layer, made up of cardiac muscle that contracts to do the work of the heart moving the blood. The endocardium is the smooth inner lining of the heart.

The entire structure of the heart is enclosed in a fibrous sac called the pericardium. A small amount of liquid is normally found in the space between the heart and the pericardium, which helps reduce the friction between the epicardial and pericardial membranes.

The heart is divided by a central wall (or septum) into its right and left sides. Each of these sides contains a smaller, upper chamber known as an atrium, and a lower, larger chamber known as a ventricle. The atria and ventricles are separated by a valve made of flaps of tissue that prevent blood flow in the wrong direction. The valve on the left side of the heart is the mitral (or bicuspid) valve, which has two flaps. The right atria and ventricle are separated by the tricuspid valve, which has three flaps.

There are five great vessels branching off from the heart that are responsible for carrying blood into or out of the organ. These five vessels are the aorta, the pulmonary artery and vein, and the superior and inferior venae cavae. The aorta is the main artery, carrying oxygenated blood from the heart out into the body. The pulmonary artery carries blood away from the heart to the lungs, and the pulmonary vein carries blood from the lungs to the

heart. The superior and inferior venae cavae carry deoxygenated blood from the upper and lower parts of the body back to the heart.

Unidirectional valves separate two of the great vessels from the chambers of the heart. The pulmonic (or pulmonary valve) separates the right ventricle and the pulmonary artery. The aorta and left ventricle are separated by the aortic valve.

The coronary arteries are two vessels that divide off the aorta and branch out over the entire surface of the heart. These vessels bring oxygenated blood to the heart tissue itself.

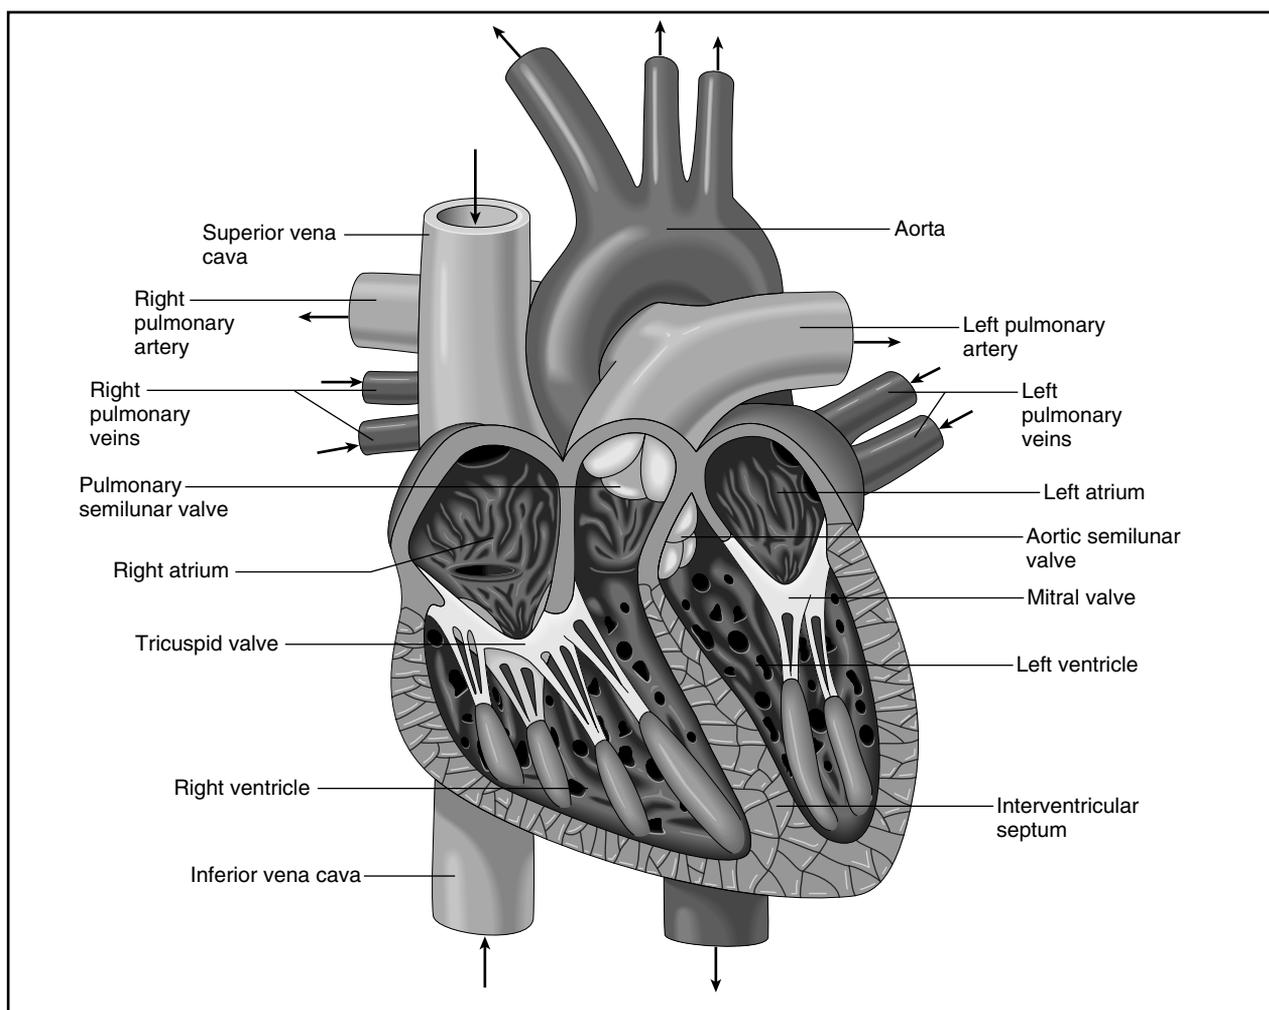

Function

The heart functions as a strong, four-chambered muscular pump. It can move more than five quarts of blood through the body each minute, the equivalent of about 2,000 gallons per day. At a typical heart rate of 72 beats per minute, the heart contracts on average 100,000 times per day. This adds up to more than 2.5 billion beats in a 70-year lifetime.

One key to the functioning of the heart is the unique characteristics of its muscular tissue. Cardiac muscle differs from other muscles of the body in that its normal function is a rhythmic contraction, which is the basis for the tissue's ability to respond to the electrical impulses that govern the beating of the heart. The natural pacemaker of the heart, the sinoatrial (SA) node, is located in the right atrium. Cardiac muscle cells that naturally contract at the fastest rate when compared to the other cells of the heart surround this cluster of nerve cells. This area of the heart therefore has the ability to initiate the contraction by sending wavelike electrical signals throughout the organ.

First, the electrical signal causes the two atria to contract, when sends the blood from those chambers into the two ventricles. Then the signal passes down through a group of nerve cells known as the atrioventricular (AV) node. This nerve cluster is located near the center of the heart. The travel through this area slows down the signal so that it reaches the ventricles after the atria have finished their contraction. Then the ventricles contract, moving the blood out of the heart, and the cycle starts again. The heart's electrical activity can be measured using **electrocardiography**.

The physical functions of the full heartbeat is known as the **cardiac cycle**. The cycle can be divided into two phases: diastole and systole. Diastole occurs when the heart relaxes and the myocardial fibers lengthen. As the heart dilates, the cavities fill with blood. Diastole of the atria occurs slightly before the diastole of the ventricles.

Cross section of the heart. Arrows indicate the direction of blood flow. (Delmar Publishers, Inc. Reproduced by permission.)

Systole happens when the part of the heart is in contraction and the myocardial fibers shorten. Again, systole of the atria precedes systolic phase of the ventricles. Systole of the ventricles cause blood to surge out of the heart and into the aorta and pulmonary artery.

Over time, the cardiac cycle occurs as follows. It begins with the diastole of the atrium, where both the left and right atria relax and fill with blood. The right atria fills with deoxygenated blood from the superior and inferior venae cavae. The pulmonary artery fills the left atria with newly oxygenated blood from the lungs. The SA node signals the beginning of systole and the atrium contract, sending blood through the tricuspid and mitral valves into the right and left ventricles, respectively. During ventricle filling, the valves of the great vessels are closed so blood already pumped out of the heart does not leak back.

The electrical signal has now reached the ventricles and they contract, sending the deoxygenated blood of the right ventricle into the pulmonary artery to the lungs and the oxygenated blood of left ventricle into the aorta to the body. During contraction, the tricuspid and mitral valves close to prevent flow back into the atrium. This cycle is repeated continuously.

Role in human health

The heart is the centerpiece of the elaborate and extensive human cardiovascular system. Responsible for moving the blood throughout the body, this system transports the necessities for life—oxygen, nutrients, hormones, immune functions—to the cells. The system also transports wastes such as carbon dioxide away from the cells to the organs responsible for their elimination from the body. The heart is the driving force behind this essen-

KEY TERMS

Diastole—Phase of the heartbeat where the ventricles relax and fill with blood.

Endocardium—The thin, innermost layer of the heart.

Epicardium—The outermost layer of the heart.

Myocardium—The middle, working layer of the heart containing the heart muscle cells.

Regurgitation—A defect of the heart valves that interferes with its ability to close completely, allowing blood to leak in the direction opposite of circulation.

Septum—A physical divider between chambers, found between the atria and the ventricles.

Stenosis—A stiffening of the heart valves, which narrows its opening and can interfere with function.

Systole—Phase of the heartbeat where the ventricles contract and force blood from the heart.

tial transport. Therefore it is not surprising that a healthy heart is necessary for a healthy body.

There are several risk factors for heart problems that can be controlled through preventative measures. These include lowering blood cholesterol levels with diet, **exercise**, or in extreme cases, medications. Lower cholesterol levels lower the probability of **coronary artery disease** (clogging of the arteries that bring oxygenated blood to the heart), a major cause of **heart failure**. Keeping **blood pressure**, blood sugar levels, and body weight within normal levels also greatly decreases the chance for heart problems. Other controllable risk factors include a sedentary lifestyle, **stress** and anger, and smoking.

Common diseases and disorders

According to 1999 estimates, approximately 58.8 million Americans have one or more types of heart disease, as it is most broadly defined. Although the cause and effect of various heart diseases can be examined in a particular patient, it is difficult to make generalizations about different diseases and disorders. Often one disease of the cardiovascular system will contribute or even cause another. In any case, the various symptoms of an unhealthy heart, whatever the cause, are quite common.

Several diseases of the heart are related to atherosclerosis, the accumulation of cholesterol in the arteries.

When this problem occurs in the coronary arteries, it is known as coronary artery disease. Three conditions which can follow from the loss of blood flow to the heart due to the clogged arteries are angina pectoris, a severe chest **pain**, **myocardial infarction** (commonly called a heart attack), or congestive heart failure, where the heart is unable to efficiently pump the blood throughout the body.

Angina pectoris is the result of temporary deprivation of oxygen and often occurs after stress or exertion. Heart attacks occur because a portion of the heart is permanently deprived of blood and the cells become damaged. Congestive heart failure involves a cascade reaction of the body to inefficient heart action that results in accumulation of fluids in the outer reaches of the body. In each of these cases, the trigger cause of the condition was the blockage of the arteries that supply the heart.

A second set of heart diseases involves an abnormality in the electrical system of the heart. Called arrhythmias, these diseases occur when the heart no longer beats in the standard pattern. Altered beat function can greatly reduce the efficiency of the heart and can result in fainting (due to lack of blood to the **brain**), palpitations (an unpleasant awareness of the beating of the heart), shortness of breath, and chest pain. Some common types of arrhythmia include bradycardia (slow heart beat), atrial fibrillation, and ventricular fibrillation.

Bradycardia is commonly treated using **pacemakers**, an implanted device that keeps the heart's rhythm steady. Fibrillations are very fast, inefficient beats of the atrium or ventricles. Fibrillation can be treated with medication or an implanted cardiac defibrillator (ICD) that delivers a shock to the heart to restart normal beating. Arrhythmias can be caused by coronary heart disease, high blood pressure, or a previous heart attack, emphasizing the interrelation of the various heart diseases.

A third kind of heart disease involves damage to one of the four valves of the heart. The frequency of damage to these structures is related to the work that they do—with the structures undergoing the greatest amount of pressure having the highest frequency of disease. Thus, valve problems occurs most frequently with the mitral valve, then the aortic, tricuspid, and pulmonic. Mitral valve prolapse is the most common condition, where excess valve tissue prevents it from closing properly. Surgery may not be necessary, however, until leaking of the valve, known as valve regurgitation, accompanies the prolapse. Regurgitation is a symptom of stenosis, a condition where the valve has become too stiff to function properly.

Untreated rheumatic **fever**, a bacterial **infection**, is the most prevalent cause of valve problems. The use of

antibiotics to treat **strep throat** has greatly reduced the incidence of this disease in the United States. Congenital defects are the second most common cause of heart valve conditions.

Congenital heart defects, in the valves and other structures, occur when the heart or its vessels do not develop normally before birth. The most common congenital heart defect is a combination of four problems called the tetralogy of Fallot. With this problem the ventricular septum is incomplete, there is an obstruction to blood flow beneath the pulmonary artery, the aorta is shifted rightward, and the right ventricular wall is thickened.

A final kind of heart disease is cardiomyopathy. This disorder occurs when the muscle of the heart degenerates. There are multiple causes of cardiomyopathy and it is the number one reason people undergo heart transplants. Categorized by the type of muscle damage, there are three general types of cardiomyopathy: dilated, hypertrophic, and restrictive. Dilated cardiomyopathy refers to the enlargement of the heart that is a response to the overall myocardial weakness. Many problems can cause dilated cardiomyopathy including viral infections, excessive alcohol intake, and myocarditis (inflammation of the heart).

Hypertrophic cardiomyopathy is an abnormal overgrowth of the heart muscle. An inherited disease, the overgrown muscle blocks the movement of blood both into and out of the heart. Restrictive cardiomyopathy is due to a stiffening of the heart muscle that prevents it from fully relaxing during diastole. This problem is a symptom of other diseases such as hemochromatosis (a defect in **iron** use by the body) or amyloidosis (overproduction of antibodies by the bone marrow that cannot be broken down).

Heart failure

Definition

"Heart failure" is a broad term—often used interchangeably with "congestive **heart failure**" (CHF)—to describe the heart's inability to consistently pump enough **blood** to the body's organs and tissues. Heart failure occurs either from a structural or a functional abnormality. Since blood carries oxygen and vital nutrients to cells throughout the body, a decrease in blood supply interferes with the ability of organs and other tissues to function properly.

Description

According to the American College of Cardiology, approximately 4.8 million Americans live with CHF. Patients ages 65 and older are hospitalized for complications from CHF more often than for any other medical condition, accounting for about 875,000 hospital admissions each year. Anywhere between 400,000 and 700,000 cases of CHF are discovered annually, bringing the cost of treating patients in the United States between \$10 billion and \$30 billion. CHF is either a direct or contributing cause of death for as many as 250,000 people per year. As the population ages, the incidence of heart failure increases.

The term "congestive heart failure" describes its course of action. When the heart fails for some reason to deliver adequate blood supply to the body's tissues, **edema** (swelling, or fluid buildup) develops. Where the edema occurs in the body depends on the part of the heart that is failing in some way. For example, when the left ventricle (lower left chamber of the heart) is damaged, blood fails to get out to other parts of the body as quickly as it returns from the **lungs**. When blood cannot get back to the heart, it backs up inside **blood vessels** in the lungs. Some of the fluid in the blood is then forced into the breathing space of the lungs, causing pulmonary

edema. Pulmonary edema causes varying degrees of breathing difficulty. The degree of severity depends on the amount of excess fluid in the lungs and can be life-threatening in severe cases. Abnormalities in heart structure or rhythms can also cause left-ventricular CHF. Patients often complain of feeling very tired, due to the lack of circulating oxygen and nutrients caused by an inadequate blood supply.

When the right side of the heart fails, the right ventricle (lower right chamber of the heart) cannot pump blood to the lungs as quickly as blood returns from areas throughout the body, via the veins. The blood then engorges the right side of the heart and veins. Fluid begins to back up in the veins and pushes out into the tissues, causing edema, most often in the feet, ankles, and lower legs. Abnormalities of the heart valves and lung disorders often cause right-ventricular CHF.

The failing heart keeps pumping, but not as efficiently as it should. Sometimes the heart tries to compensate for its lack of pumping ability by becoming hypertrophic (larger). When this happens the heart chamber grows larger and the muscle in the wall of the heart thickens, sometimes helping to improve the pumping ability of the heart. Another way in which the damaged heart tries to compensate for declining pumping ability is by stepping up the frequency of heartbeats to improve blood output and circulation. Eventually the **kidneys** join the fight to compensate for the failing heart; they hold on to more salt and water in order to increase blood volume. But this extra fluid can also cause edema. This can further complicate the situation and make treatment even more difficult. As the condition worsens over time, these compensatory measures are not enough to keep the heart pumping enough blood to meet the body's demand.

For most people, heart failure is a chronic disease with no real cure. However, depending on the individual circumstances, heart transplantation is considered in some cases when all other treatment options fail. While there is no cure, heart failure can often be managed and treated effectively using medications, proper diet, modified **exercise**, and other lifestyle changes as needed.

Causes and symptoms

The most common causes of heart failure are:

- coronary artery disease (CAD)
- heart attack (which may be “silent”)
- cardiomyopathy
- high **blood pressure** (HBP, or **hypertension**)
- heart valve disease
- **infection** of the heart valves or heart muscle
- congenital structural abnormality
- alcohol and drug abuse

CAD is the most common cause of heart failure. The arteries that supply the heart muscle with blood begin to narrow over time. Eventually they may become completely blocked. When the blood cannot reach a specific area of the heart, a heart attack occurs. Some heart attacks are so slight that they go unrecognized, while others prove lethal. The heart muscle is damaged when the blood supply is greatly reduced or blocked entirely. If the damage markedly impairs the heart's pumping ability, heart failure follows.

Cardiomyopathy is a general term describing disease of the heart-muscle tissue. It can be caused by CAD, an inherited abnormality, severe **alcoholism** or drug abuse, or a viral infection. When the cause of the condition cannot be identified, it is termed idiopathic cardiomyopathy. Some types of **cancer** treatments have been associated with the development of cardiomyopathy. Cardiomyopathy brought on by anthracycline or other cardiotoxic agents is termed toxic cardiomyopathy. Regardless of the cause of the condition, the heart muscle weakens and eventually fails.

Sustained and uncontrolled high blood pressure is another common cause of heart failure. The persistent high pressure exerted on arterial walls makes them thicker and less pliable, and resistant to normal blood flow. As a result, the heart compensates by pumping harder, in an attempt to regain normal blood flow. Eventually the heart cannot keep up with the increased demand and heart failure results.

Defective heart valves, congenital heart diseases, severe alcohol and drug abuse, cardiotoxic cancer treatments, and specific **viruses** can cause the heart to fail.

The patient with heart failure can experience any number of the following symptoms:

- swollen, prominent veins in the neck area
- shortness of breath (causing crackling noises in the lungs)
- frequent coughing, especially when lying down
- swollen feet, ankles, and legs (edema)
- abdominal swelling (acites) and **pain** (caused by organ engorgement)
- fatigue
- dizziness or fainting
- increased exercise intolerance
- sudden death

The person with left-sided heart failure may experience shortness of breath and increased episodes of coughing caused by fluid buildup in the lungs. Pulmonary edema often causes a patient to cough up bubbly, blood-tinged phlegm. In right-sided heart failure, fluid builds up in the veins and tissues, causing swelling of the lower extremities and the abdomen. When body tissues fail to get the oxygen and nutrients they require, they begin to lose their efficiency, causing increased dizziness and fatigue.

Diagnosis

Physicians base their diagnosis of heart failure on the results of the following evaluations:

- symptoms
- medical history
- **physical examination**
- blood work
- **chest x ray**
- electrocardiogram (ECG; also called EKG)
- metabolic exercise testing (**stress test** with gas-exchange measurement)
- **cardiac catheterization**

A person's symptoms can provide important clues to the presence of heart failure. Patients who come to see a doctor, whether at the office or in an emergency room, will be examined by a physician, and in some cases also by a physician's assistant, a nurse, nurse practitioner, or nurse clinician. A patient who complains of shortness of breath while performing activities of daily living (ADL) and/or episodes of shortness of breath that wakes him or her from sleep is exhibiting classic symptoms of heart failure.

The health care professional who first examines the patient will also write down the patient's medical history. Often, something in the patient's medical history, such as a history of rheumatic **fever** or sustained hypertension, can help support the diagnosis of heart failure.

The physician will complete a thorough physical examination. He or she will listen to the heart and the lungs using a **stethoscope**, looking and listening for signs of heart failure. Irregular heart sounds (gallops), rapid heartbeats, and murmurs of the heart valves may be heard. A crackling sound in the lungs tells the physician that fluid is present in the lungs. Quick or shallow breathing may be present, along with a rapid pulse.

The physician will palpate (press down firmly with the fingertips of both hands) the patient's abdomen to feel if the **liver** is enlarged. He or she will also check the skin

and nail beds on fingers and toes, looking for a bluish tint and a feeling of coolness to the skin. The bluish tint and coolness reflect a lack of oxygen in those regions.

At least one, but preferably two different views of the patient's chest will be taken in the upright position, by a licensed radiologic technologist, to determine whether there is fluid in the lungs and/or the heart is enlarged. Some heart-valve or other structural abnormalities can also be identified on plain chest films. A radiologist (a physician who specializes in radiology) reads the x ray and gives the report to the patient's doctor. If the patient is in distress, the radiologist may call the ordering physician with a "wet" (immediate) reading; otherwise, the chest films will be read and dictated, and the patient's doctor will receive a transcribed report the next day.

Routine blood work can sometimes give insight into both the cause of the heart failure and the extent of damage to the heart. For example, an abnormally low level of sodium can indicate advanced heart failure with a poor prognosis. Conversely, a high creatinine (used to assess kidney function) level can reflect kidney malfunction that either is contributing to the heart failure or is caused by the failing heart. Medical assistants, phlebotomists, medical technicians, and nurses are all trained to draw blood from veins. The blood samples are evaluated in the laboratory by laboratory technicians, medical technologists, pathologists, and/or other trained and licensed medical-laboratory professionals.

An electrocardiogram gives information about heart rhythm and size. It can demonstrate an enlarged heart chamber and whether or not damage to the heart muscle is caused by narrowing or blocked arteries.

Besides a chest x ray, the physician may order an echocardiogram or an ultrasound of the heart to help reach a diagnosis. **Echocardiography** uses sound waves to make images of the heart. These images can show whether the heart wall or chambers are enlarged, or if there are any abnormalities of the heart valves. An echocardiogram can also be used to find out how much blood the heart is pumping. It helps determine the amount of blood the ventricle pumps each time the heart beats (called the ejection fraction). A healthy heart pumps at least one half the amount of blood in the left ventricle with each heartbeat. A test called a radionuclide ventriculography is sometimes ordered to measure the ejection fraction. It uses very low doses of an injected radioactive substance and is imaged as it travels through the heart.

Cardiac catheterization involves threading a small tube (catheter) into either the arm or groin area and up into the heart. The test is used to measure pressure in the heart and the amount of blood pumped by the heart. It

can detect abnormalities of the coronary arteries, heart valves, heart muscle, and other blood vessels. Cardiac catheterization is not always necessary in diagnosing heart failure, but when used in concert with echocardiography and other tests, it can help to pinpoint the cause of the condition.

Chest x rays, echocardiography, cardiac catheterization, and radionuclide ventriculography are all performed by radiologic technologists and radiologists who are specifically trained in these specialty areas. The chest x ray and echocardiogram can be performed using a portable bedside unit if the patient is too ill to travel to the x-ray department.

Metabolic exercise testing provides a noninvasive method for getting a lot of information about the patient in heart failure. It not only gives the physician a good idea of the functional capacity of the heart, but also demonstrates the patient's maximal oxygen consumption during peak exercise. The test offers insight into any functional disability that the patient is experiencing, so that the physician can discuss individualized plans for rehabilitation in light of any physical limitations. This test is often performed by a cardiologist with a nurse, physical therapist, medical assistant, or technician present to assist.

Treatment

Heart failure is most often treated with different medications and lifestyle changes. In some cases, surgery is performed to correct abnormalities of the heart or heart valves. Heart transplantation is a last resort, considered only in certain cases.

Dietary changes designed to help the patient reach and maintain a proper weight and to reduce salt intake to reduce fluid buildup may be required (reducing salt intake helps decrease swelling in the lower extremities and abdomen). An individualized exercise program may be recommended, but only after a full evaluation by the physician. The physician works with cardiac-rehabilitation nurses, physical therapists, and the patient to determine what each patient can tolerate safely. The patient performs the exercise regimen in the cardiac-rehabilitation department for a number of weeks under the careful supervision of staff. The patients are hooked up to monitors, their **vital signs** taken at intervals throughout their program, to ensure their safety. Once exercise tolerance is established, the patient is encouraged to follow the program consistently and is cautioned not to change it in any way once he or she returns home, in order to avoid complications. The patient is also reminded to report any unusual symptoms to his or her physician. Depending on the patient's specific limitations and exercise needs,

walking, bicycling, swimming, or even low-impact aerobic exercises may be recommended. Homebound patients will work with home health care nurses, therapists, and aides in much the same way to help manage their symptoms. Most medium- to larger-size hospitals in the United States have good cardiac-rehabilitation programs.

Other lifestyle changes that may reduce the severity of symptoms associated with heart failure include quitting smoking or other tobacco use, eliminating or reducing alcohol consumption, and not using certain drugs.

One or more of the following types of medications may be prescribed for heart failure:

- diuretics
- digitalis
- vasodilators
- beta blockers
- angiotensin-converting enzyme inhibitors (ACE inhibitors)
- angiotensin-receptor blockers (ARBs)
- calcium-channel blockers

Diuretic medication helps eliminate excess salt and water from the kidneys by making patients urinate more often. This increased flushing action helps reduce the swelling caused by fluid buildup in the tissues. It is important to monitor patients for electrolyte imbalance when they used diuretics regularly. Digitalis gives the heart muscle stronger pumping ability. Vasodilators, ACE inhibitors, ARBs, and calcium-channel blockers all help to lower blood pressure via different methods, expanding the blood vessels so that blood can move more freely through them. This expansion makes it easier for the heart to pump blood through the vessels.

Surgery is used to correct certain heart conditions that cause heart failure. Congenital heart defects and abnormal heart valves may be repaired with surgery. Narrowing or completely blocked coronary arteries can be effectively treated with **angioplasty** or coronary-artery bypass surgery.

In patients with severe heart failure, the heart muscle itself may become so damaged that available treatments cannot help. Patients in this condition are said to be in end-stage heart failure. The only available treatment option for patients in end-stage heart failure and for which all other treatments are no longer working is heart transplantation. However, the patient's age and a number of other health-related issues are taken into account in the decision-making process.

Support staff, including pharmacists, dieticians, physicians' assistants, nurses, technicians, physical ther-

apists, respiratory therapists, and nurses' aides can play an important role in the effective management of the patient with heart failure. In communicating responsibly with one another and with the patient and his or her caregivers, many complications can be avoided and quality of life improved.

Prognosis

Most patients in mild or moderate heart failure can be successfully managed with a combination of dietary and exercise programs and the right medications. Many patients are able to participate in normal daily activities and lead relatively active lives. However, the patient's success with any treatment program depends a great deal on effective communication among members of the health care team and the patient's compliance with treatment recommendations.

Patients in severe heart failure may eventually have to consider heart transplantation. About 50% of patients diagnosed with CHF live for at least five years with the condition. Women who have heart failure often live longer than men with the same condition. However, survival statistics continue to improve some with newer and more advanced treatments.

Health care team roles

Each professional in the health care team plays an important role in helping to diagnose and treat a patient in any stage of heart failure. From the person who writes down the patient's medical history to the pharmacist who explains the patient's medications, attention to detail, effective communication, and a positive attitude are key to the patient's ability to realize good outcomes.

Cardiac-rehabilitation nurses—registered nurses who see the patient either in the hospital or at the doctor's office—will be responsible for assessing the patient's condition from the time the patient first presents with symptoms and complaints, and throughout return visits. All nurses take vital signs and monitor the patient's compliance with medications, diet, and exercise regimens. Nurses are expected to document their findings thoroughly in progress notes and to communicate any problems with the physician or other appropriate health care professional. Nurses explain and teach patients about their disease and different aspects of their treatment programs, and serve as the pipeline between the patient and the physician. They are also the patient's advocate. Nurses spend more time with patients than the other members of the health care team do, so they get a better opportunity to gain insight into the patient's total health picture.

Radiologic technologists are responsible for performing certain diagnostic procedures, either directly or by assisting a radiologist or cardiologist. Prior to the exam, the technician is responsible for explaining any procedure to the patient and for getting a consent form signed whenever contrast material will be injected into the body. The technician needs to ask whether the patient has any known **allergies** and communicate those findings to the radiologist before any contrast material is injected.

Respiratory therapists and physical therapists are required to explain any procedures or therapy they administer to patients. Dieticians explain different diet plans with patients and family caregivers to help patients get used to buying and preparing foods in ways that reduce both salt and caloric intake.

Patient education

Each member of the health care team is responsible for explaining the connection between his or her specific discipline and the patient's condition. For example, if breathing treatments are ordered by a physician to help keep a patient from getting **pneumonia**, the therapist needs to explain the procedure and the reason for the procedure to the patient. When a patient gets a chest x ray, the radiologic technologist should tell the patient that he or she will need to take in a deep breath and hold it in, so that the lungs fully expand and the radiologist can determine whether the lungs are clear and get an accurate measurement of heart size.

Nursing staff teach patients about the signs and symptoms of heart failure, treatment interventions, and expected outcomes. They are required to teach the patient about his or her specific heart failure and why certain interventions are necessary. For example, if a patient tells the nurse that he or she gets very short of breath walking from one end of the house to the other, the nurse can suggest that the patient choose a point in between to sit down for a few moments to rest. Nursing staff look for physical signs and symptoms of heart failure, chart assessments and vital signs, and review treatments with patients, keeping an eye out for compliance issues and whether treatment appears effective.

Patients who undergo cardiac catheterization are asked a number of questions before the procedure takes place, and then are asked to sign a consent form. Contrast material will be injected into the patient through a small catheter that may require a small incision in the groin or elbow area. The radiologist or technologist explains what physical sensations to expect while the contrast media is being injected, as well as any allergic-reaction potential, including symptoms and side effects.

KEY TERMS

Angioplasty—A technique used for treating blocked coronary arteries by inserting a catheter with a tiny balloon at the tip into the artery and then inflating it.

Angiotensin-converting enzyme (ACE) inhibitor—A drug that relaxes blood-vessel walls and lowers blood pressure.

Arrhythmia—Abnormal heartbeat.

Atherosclerosis—Buildup of a fatty substance called a plaque inside blood vessels.

Calcium-channel blocker—A drug that relaxes blood vessels and lowers blood pressure.

Cardiac catheterization—A diagnostic test for evaluating heart disease; a catheter is inserted into an artery and passed into the heart.

Cardiomyopathy—Disease of the heart muscle.

Catheter—A thin, hollow tube.

Congenital heart defects—Abnormal formation of structures of the heart or of its major blood vessels, present at birth.

Congestive heart failure—A condition in which the heart cannot pump enough blood to supply the body's tissues with sufficient oxygen and nutrients; backup of blood in vessels and the lungs causes buildup of fluid (congestion) in the tissues.

Coronary arteries—Arteries that supply blood to the heart muscle.

Coronary artery bypass—A surgical procedure to reroute blood around a blocked coronary artery.

Coronary artery disease—Narrowing or blockage of coronary arteries by atherosclerosis.

Diuretic—A type of drug that helps the kidneys eliminate excess salt and water.

Edema—Swelling caused by fluid buildup in tissues.

Ejection fraction—A measure of the portion of blood that is pumped out of a filled ventricle.

Heart valves—Valves that regulate blood flow into and out of the heart chambers.

Hypertension—High blood pressure.

Hypertrophic—Enlarged.

Idiopathic cardiomyopathy—Cardiomyopathy without a known cause.

Pulmonary edema—Buildup of fluid in the tissue of the lungs.

Vasodilator—Any drug that relaxes blood-vessel walls.

Ventricles—The two lower chambers of the heart.

Patients who undergo metabolic exercise testing will be monitored carefully throughout the procedure and asked to let the doctor know immediately if they feel any chest pain or dizziness during the procedure.

Prevention

Heart failure is usually caused by the effects of some type of heart disease. The best way to try to prevent heart failure is to eat a healthy diet and get regular exercise, but many causes of heart failure cannot be prevented. People with risk factors for coronary disease (such as high blood pressure and high cholesterol levels) should work closely with their physician to reduce their likelihood of heart attack and heart failure.

Heart failure can sometimes be avoided by identifying and treating any conditions that might lead to heart disease. These include HBP, alcoholism or drug abuse, **obesity**, and CAD. Regular blood-pressure checks and seeking immediate medical care for symptoms of CAD,

such as chest pain, will help to get these conditions diagnosed and treated early, before they progress and damage the heart muscle.

Finally, diagnosing and treating heart failure before the heart becomes severely damaged can improve the prognosis. With proper treatment, many patients may continue to lead active lives for a number of years.

Heat disorders

Definition

Heat disorders are a group of physically related illnesses caused by prolonged exposure to hot temperatures, restricted fluid intake, or failure of temperature regulation mechanisms of the body. Disorders of heat exposure include heat cramps, heat exhaustion, and heat stroke (also called sunstroke). Hyperthermia is the general name given to heat-related illnesses. The two most common forms of hyperthermia are heat exhaustion and heat stroke. Heat stroke is especially dangerous and requires immediate medical attention.

Description

Heat disorders are harmful to people of all ages, but their severity is likely to increase as people age. Heat cramps in a 16-year-old may be heat exhaustion in a 45-year-old and heat stroke in a 65-year-old. The body's temperature-regulating mechanisms rely on the thermal-

regulating centers in the **brain**. Through these complex centers, the body tries to adapt to high temperatures by adjusting the amount of salt in the perspiration. Salt helps the cells in body tissues retain water. In hot weather, a healthy body will lose enough water to cool the body while generating the minimum level of chemical imbalance. Regardless of extreme weather conditions, a healthy human body keeps a steady temperature of approximately 98.6°F (37°C). In hot weather, or during vigorous activity, the body perspires. As perspiration evaporates from skin, the body is cooled. If the body loses too much salt and fluids, the symptoms of **dehydration** can occur.

Heat cramps

Heat cramps are the least severe of the heat-related illnesses. This heat disorder is often the first signal that a body is having difficulty with increased temperature. Individuals exposed to excessive heat should think of heat cramps as a warning sign to a potential heat-related emergency.

Heat exhaustion

Heat exhaustion is a more serious and complex condition than heat cramps. Heat exhaustion can result from prolonged exposure to hot temperatures, restricted fluid intake, or failure of temperature regulation mechanisms of the body. It often affects athletes, firefighters, construction workers, factory workers, and anyone who wears heavy clothing in hot or humid weather.

Heat stroke

Heat exhaustion can develop rapidly into heat stroke, which can be life threatening. Heat stroke, like heat exhaustion, is also a result of prolonged exposure to hot temperatures, restricted fluid intake, or failure of temperature regulation mechanisms of the body. However, the severity of impact on the body is much greater with heat stroke.

Causes and symptoms

Heat cramps

Heat cramps are painful muscle spasms caused by the excessive loss of salts (electrolytes) due to heavy perspiration. This disorder occurs more often in the legs and abdomen than in other areas of the body. Muscle tissue becomes less flexible, causing **pain**, difficult movement, and involuntary tightness. Heavy exertion in extreme heat, restricted fluid intake, or failure of temperature regulation mechanisms of the body may lead to heat cramps. Individuals at higher risk are those working in extreme

KEY TERMS

Convulsions—Also termed seizures; a sudden violent contraction of a group of muscles.

Electrolytes—An element or compound that when melted or dissolved in water dissociates into ions and is able to conduct an electrical current. Careful and regular monitoring of electrolytes and intravenous replacement of fluid and electrolytes are part of the acute care in many illnesses.

Rehydration—The restoration of water or fluid to a body that has become dehydrated.

heat, elderly people, young children, people with health problems, and those who are unable to naturally and properly cool their bodies. Individuals with poor circulation and who take medications to reduce excess body fluids can be at risk when conditions are hot and humid.

Heat exhaustion

Heat exhaustion is caused by exposure to high heat and humidity for many hours, resulting in excessive loss of fluids and salts through heavy perspiration. The skin may appear cool, moist, and pale. An individual may complain of headache and nausea with a feeling of overall weakness and exhaustion. Dizziness, faintness, and mental confusion are often present, as is rapid and weak pulse. Breathing becomes fast and shallow. Fluid loss reduces **blood** volume and lowers **blood pressure**. Yellow or orange urine is often a result of inadequate fluid intake, along with associated intense thirst. Insufficient water and salt intake or a deficiency in the production of sweat can place an individual at high risk for heat exhaustion.

Heat stroke

Heat stroke is caused by overexposure to extreme heat, resulting in a breakdown in the body's heat-regulating mechanisms. The body's temperature reaches a dangerous level, as high as 106°F (41.1°C). An individual with heat stroke has a body temperature higher than 104°F (40°C). Other symptoms include mental confusion with possible combativeness and bizarre behavior, staggering, and faintness.

The pulse becomes strong and rapid (between 160 and 180 beats per minute) with the skin taking on a dry and flushed appearance. There is often very little perspiration. An individual can quickly lose consciousness or have convulsions. Before heatstroke, an individual suf-

fers from heat exhaustion and the associated symptoms. When the body can no longer maintain a normal temperature, heat exhaustion becomes heatstroke. Heat stroke is a life-threatening medical emergency that requires immediate initiation of life-saving measures.

Diagnosis

The diagnosis of heat cramps usually involves the observation of individual symptoms such as muscle cramping and thirst. Diagnosis of heat exhaustion or heat stroke, however, may require a physician to review the medical history, document symptoms, and obtain a blood pressure and temperature reading. The physician may also take blood and urine samples for further laboratory testing. A test to measure the body's electrolytes can also give valuable information about chemical imbalances caused by the heat-related illness.

Treatment

Heat cramps

The care for heat cramps includes placing an individual at rest in a cool environment, while giving cool water with a teaspoon of salt per quart, or a commercial sports drink. Usually, rest and liquids are all that is needed for a person to recover. Mild stretching and massaging of the muscle area follows once the condition improves. An individual should not take salt tablets, since this may actually worsen the condition. When the cramps stop, a person can usually start activity again if there are no other signs of illness. An individual needs to continue drinking fluids and should be watched carefully for further signs of heat-related illnesses.

Heat exhaustion

An individual suffering from heat exhaustion should stop all physical activity and move immediately to a cool place out of the sun, preferably a cool, air-conditioned location. The person should then lie down with feet slightly elevated, loosen or remove clothing, and drink cold (but not iced), slightly salty water or a commercial sports drink. Rest and replacement of fluids and salt are usually all the treatment that is needed; hospitalization is rarely required. Following rehydration, the person usually recovers rapidly.

Heat stroke

Simply moving an individual afflicted with heat stroke to a cooler place is not enough to reverse the internal overheating. Emergency medical assistance should be called immediately. While waiting for help to arrive,

move the person to a cool place, loosen or remove clothes, and allow air to circulate around the body. The next important step is wrapping the individual in wet towels or clothing, and placing ice packs in those areas with the greatest blood supply, such as the neck, under the arm and knees, and in the groin. Once the person is under medical care, **cooling treatments** may continue as appropriate. The person's body temperature will be monitored constantly to guard against overcooling. Breathing and **heart** rate will be monitored closely, and fluids and electrolytes will be replaced intravenously. Anti-convulsant drugs may be given. After severe heat stroke, bed rest may be recommended for several days.

Prognosis

Prompt treatment for heat cramps is usually very effective, allowing an individual to return to activity soon thereafter. Treatment of heat exhaustion usually brings full recovery in one to two days. Heatstroke is a very serious condition, and its outcome depends upon general health and age. Due to the high internal temperature of heat stroke, permanent damage to internal organs is possible.

Health care team roles

Persons trained in **first aid** may provide initial treatment. **Emergency medical technicians** may be necessary, if additional treatment is required. Physicians provide treatment in hospitals. Nurses assist and provide supportive care.

Prevention

Because heat cramps, heat exhaustion, and heat stroke have a cascade effect on each other, the prevention of the onset of all heat disorders is similar. Avoid strenuous **exercise** when it is very hot. Individuals exposed to extreme heat conditions should drink plenty of fluids, and not wait until thirst develops. Wearing light and loose-fitting clothing in hot weather is important, regardless of the activity. If perspiration is excessive, fluid intake should be increased. When urine output decreases, fluid intake should increase. Eating lightly salted foods can help replace salts lost through perspiration. Ventilation in any working areas in warm weather must be adequate.

Heat exhaustion see **Heat disorders**

Heat treatments

Definition

Heat treatments are therapeutic applications of superficial or deep-heating agents to areas of the body.

Purpose

Thermal agents are used therapeutically to:

- decrease **pain**
- decrease muscle spasm
- decrease muscle tightness and increase flexibility
- prepare joints and muscles for **exercise**
- increase local **blood** flow to the area, thus promoting tissue healing

Precautions

Therapeutic heat treatments should not be used in individuals who have bleeding or recent hemorrhage, an acute inflammatory process, or local **infection** near the point of application. Furthermore, heat treatments should not be used over areas of malignancy, decreased sensation, or vascular disease. Heat treatments also should be used with caution on individuals with **heart**, lung, or kidney diseases. Deep heat treatments should not be used on areas above the eye, heart, or on a pregnant patient. Deep heat treatments over areas with metal surgical implants should be avoided in case of rapid temperature increase and potential for injury.

Description

There are two type of heat treatments: superficial and deep. Superficial treatments are applied to the skin over the involved area. Depth of heat depends on types of tissue and ranges from 0.19 in (0.5 cm) to 0.39–0.78 in (1–2 cm). Heat depth also depends on amount of fat in the area, as fat is an insulator. There are four different ways to convey heat:

- Conduction is the transfer of heat between two objects in direct contact with each other.

- Conversion is the transition of one form of energy to heat.
- Radiation involves the transmission and absorption of electromagnetic waves to produce a heating effect.
- Convection occurs when a liquid or gas moves past a body part creating heat.

Hot packs, water bottles, and heating pads

Hot packs are a very common form of heat treatment using conduction as a form of heat transfer. Moist heat packs are readily available in most hospitals, **physical therapy** centers, and athletic training rooms. Treatment temperature should not exceed 131°F (55°C). The pack is used over multiple layers of toweling to achieve a comfortable warming effect for approximately 30 minutes. More recently, several manufacturers have developed packs that may be warmed in a microwave prior to use.

Hot-water bottles are another form of superficial heat treatment. The bottles are filled half way with hot water between 115–125°F (46.1–52°C). Covered by a protective toweling, the hot-water bottle is placed on the treatment area and left until the water has cooled off.

Electrical heating pads continue to be used as a home treatment, but safety and convenience issues limit their use in healthcare settings.

Paraffin

Paraffin, a conductive form of superficial heat, is often used for heating uneven surface of the body such as the hands. It consists of melted paraffin wax and mineral oil. Paraffin placed in a small bath unit becomes solid at room temperature, and is used as a liquid heat treatment when heated at 126–127.4°F (52–53°C). The most common form of paraffin application is called the dip and wax method. In this technique, the patient will dip eight to 12 times and then the extremity will be covered with a plastic bag and a towel for insulation. Most treatment sessions last about 20 minutes.

Hydrotherapy

Hydrotherapy is used in a form of heat treatment for many musculoskeletal disorders. The hydrotherapy tanks and pools are all generally set at warm temperatures. Because the patient often performs resistance exercises while in the water, higher water temperatures become a concern as the treatment becomes more physiologically draining. Because of this, many hydrotherapy baths are now being set at 95–110°F (35–43.3°C). There are also units available with moveable turbine jets that provide a light massage effect. Hydrotherapy is helpful as a warm-up prior to exercise.

Fluidotherapy

Fluidotherapy is a form of heat treatment developed in the 1970s. It is a dry heat modality consisting of cellulose particles suspended in air. Units come in different sizes and some are restricted to only treating a hand or foot. The turbulence of the gas-solid mixture provides thermal contact with objects that are immersed in the medium. Temperatures of this treatment range from 110–123°F (43.3–50.5°C). Fluidotherapy allows the patient to exercise the limb during the treatment and also massages the limb, increasing blood flow.

Ultrasound

Ultrasound heat treatments penetrate the body to provide relief to inner tissue, thus it is a deep heating agent. Ultrasound energy comes from the acoustic or sound spectrum and is undetectable to the human ear. By using conducting agents such as gel or mineral oil, the ultrasound transducer warms tissue by conversion of sound waves to heat. Some areas of the musculoskeletal system absorb ultrasound better than others. Muscle tissue and other connective tissue such as ligaments and tendons absorb this form of energy very well, but fat absorbs to a much lesser degree. Ultrasound has a relatively long lasting effect, continuing up to one hour.

Diathermy

Diathermy is another deep heat treatment. An electrode drum is used to apply heat to an affected area. It consists of a wire coil surrounded by dead space and other insulators such as a plastic housing. Both short-wave and microwave frequencies have been used in therapeutic deep-heating devices. Prior to ultrasound technology, diathermy was a popular heat therapy of the 1940s–1960s.

Preparation

Before administering any form of heat treatment, nurses and allied health professionals need to assess a patient's sensation and sensitivity to heat. The skin over the area to be heated should be clean. When a patient is undergoing any form of heat treatment supervision should always be present, especially in the treatment of hydrotherapy.

Aftercare

Once the heat treatment has been completed, any symptoms of dizziness and nausea should be noted and documented along with any skin irritations or discoloring not present prior to the heat treatment. A one hour inter-

val between treatments should be adhered to in order to avoid restriction of blood flow.

Complications

All heat treatments have the potential of tissue damage resulting from excessive temperatures. Proper insulation and treatment duration should be carefully administered for each method. Overexposure during a superficial heat treatment may result in redness, blisters, **burns**, or reduced blood circulation. During ultrasound therapy, excessive treatment over bony areas with little soft tissue (such as hand, feet, and elbow) can cause excessive heat resulting in pain and possible tissue damage. Diathermy may produce hot spots, and is contraindicated for patients with metal implants.

Health care team roles

Nurses and allied health care professionals must realize that there are metabolic, vascular, and connective tissue effects secondary to therapeutic heat treatments. When heat is required to deep structures such as deep into a joint, deep heat is appropriate. Superficial heating is variable and depends on area and goal of the heat treatment.

Patient education

Nurses and allied health care professionals may need to provide patients with instructions on home therapeutic treatments. There are many heating agents available commercially which operate either electrically, heated in a microwave, or heated in hot water. Nurses and allied health care professionals need to educate patients on precautions, heating times per day, duration of heating, proper positioning, and any specific instructions related to pathology.

Heimlich maneuver

Definition

The Heimlich maneuver is an emergency procedure for removing a foreign object lodged in the airway that is preventing a person from breathing.

Purpose

Each year, approximately 3,000 adults die in the United States because they accidentally inhale rather than swallow food. The food gets stuck and blocks their trachea (windpipe), making breathing impossible. Death follows rapidly unless the food or other foreign material can be displaced from the airway. This condition is so common it has been nicknamed the “café coronary.”

In 1974, Dr. Henry Heimlich first described an emergency technique for expelling foreign material blocking the trachea. This technique, now called the Heimlich maneuver or abdominal thrust, is simple enough that it can be performed immediately by anyone trained in the maneuver. The Heimlich maneuver is a standard part of all **first aid** courses.

The theory behind the Heimlich maneuver is that by compressing the abdomen below the level of the diaphragm, air is forced out of the **lungs** under pressure. This air dislodges the obstruction in the trachea and brings the foreign material back up into the mouth.

The Heimlich maneuver is used mainly when solid materials such as food, coins, vomit, or small toys are blocking the airway. There has been some controversy about whether the Heimlich maneuver is appropriate to use routinely on **near-drowning** victims. After several studies of the effectiveness of the Heimlich maneuver on reestablishing breathing in near-drowning victims, the American Red Cross and the American **Heart Association** both recommend that the Heimlich maneuver be used only as a last resort after traditional airway clearance techniques and **cardiopulmonary resuscitation (CPR)** have been tried repeatedly and failed; or if it is clear that a solid foreign object is blocking the airway.

Precautions

Incorrect application of the Heimlich maneuver can damage the chest, ribs, heart or internal organs of the person on whom it is performed. People may also vomit after being treated with the Heimlich maneuver. It is important to prevent aspiration of the vomitus.

Description

The Heimlich maneuver can be performed on all people. Modifications are necessary if the person choking is very obese, pregnant, a child, or an infant.

Indications that a person’s airway is blocked include:

- inability to speak or cry out
- face turning blue from lack of oxygen
- desperate grabbing at the throat
- weak cough with labored breathing producing a high-pitched noise
- all of the above, followed by unconsciousness

Performing the Heimlich maneuver on adults

To perform the Heimlich maneuver on a conscious adult, the rescuer stands behind the affected person, who may be either sitting or standing. The rescuer makes a fist with one hand and places it, thumb toward the person choking, below the rib cage and above the waist. The rescuer encircles the other person’s waist, placing the other hand on top of the fist.

In a series of six to 10 sharp and distinct thrusts upward and inward, the rescuer attempts to develop enough pressure to force the foreign object back up the trachea. If the maneuver fails, it is repeated. It is important not to give up if the first attempt fails. As the choking person is deprived of oxygen, the muscles of the trachea relax slightly. Because of this loosening, it is possible that a foreign object may be expelled on a second or third attempt.

If the individual choking is unconscious, the rescuer should place the person supine on the floor; bend the chin forward; make sure the tongue is not blocking the airway; and feel in the mouth for any foreign objects, being careful not to push them further into the airway. The rescuer kneels astride the choking person’s thighs and places the fists between the bottom of the choking person’s breastbone and navel. The rescuer then executes a series of six to 10 sharp compressions by pushing inward and upward.

After the abdominal thrusts, the rescuer repeats the process of lifting the chin, moving the tongue, feeling for and possibly removing any foreign material. If the airway is not clear, the rescuer repeats the abdominal thrusts as

often as necessary. If the foreign object has been removed, but the victim is not breathing, the rescuer starts CPR.

Performing the Heimlich maneuver under special circumstances

OBVIOUSLY PREGNANT AND VERY OBESE PEOPLE.

The main difference in performing the Heimlich maneuver on this group of people is in the placement of the fists. Instead of using abdominal thrusts, chest thrusts are used. The fists are placed against the middle of the breastbone (sternum), and the motion of the chest thrust is in and downward, rather than upward. If the person choking is unconscious, the chest thrusts are similar to those used in CPR.

CHILDREN. The technique in children over one year of age is the same as in adults, except that the amount of force used is less than that used with adults, in order to avoid damaging a child's ribs, breastbone, and internal organs.

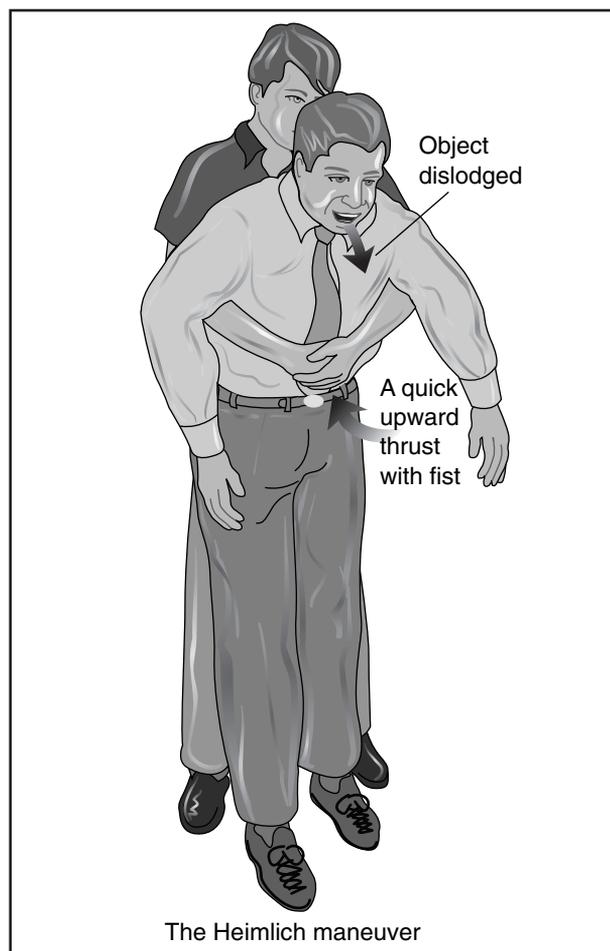

INFANTS UNDER ONE YEAR OLD. The rescuer sits down and positions the infant along the rescuer's forearm with the infant's face pointed toward the floor and at a lower level than the infant's chest. The rescuer's hand supports the infant's head. The forearm rests on the rescuer's own thigh for additional support. Using the heel of the other hand, the rescuer administers four or five rapid blows to the infant's back between the shoulder blades.

After administering the back blows, the rescuer sandwiches the infant between both arms. The infant is turned over so that it lies face up, supported by the rescuer's opposite arm. Using the free hand, the rescuer places the index and middle finger on the center of the breastbone and makes four sharp chest thrusts. This series of back blows and chest thrusts is alternated until the foreign object is expelled.

SELF-ADMINISTRATION OF THE HEIMLICH MANEUVER. To apply the Heimlich maneuver to oneself, a choking person should make a fist with one hand and place it in the middle of the body at a spot above the navel and below the breastbone, then grasp the fist with the other hand and push sharply inward and upward. If this fails, the choking person should press the upper abdomen over the back of a chair, edge of a table, porch railing or something similar, and thrust up and inward until the object is dislodged.

Preparation

Any person can be trained to perform the Heimlich maneuver. Knowing how to perform it may save someone's life. Before doing the maneuver, it is important to

To perform the Heimlich maneuver on a conscious adult (as illustrated above), the rescuer stands behind the victim and encircles his waist. The rescuer makes a fist with one hand and places the other hand on top, positioned below the rib cage and above the waist. The rescuer then applies pressure by a series of upward and inward thrusts to force the foreign object back up the victim's trachea. (Illustration by Electronic Illustrators Group.)

determine if the airway is completely blocked. If the choking person can talk or cry, the Heimlich maneuver is not appropriate. If the airway is not completely blocked, the choking person should be allowed to try to cough up the foreign object without assistance.

Aftercare

Once the obstruction is removed, most persons who experience an episode of choking recover without any further care. Persons who have an obstruction that cannot be dislodged but are able to breathe should be taken to an emergency room for treatment.

KEY TERMS

Diaphragm—The thin layer of muscle that separates the chest cavity, which contains the lungs and heart, from the abdominal cavity, which contains the intestines and digestive organs.

Sternum—The breastbone. The sternum is located over the heart, is the point of attachment for ribs at the front of the body and provides protection to the heart beneath it.

Trachea—The windpipe. A tube extending from below the voice box into the chest where it splits into two branches, the bronchi, that lead to each lung.

Complications

Many people vomit after being treated with the Heimlich maneuver. Depending on the length and severity of the choking episode, the person may need to be taken to a hospital emergency room. Occasionally, one or more ribs of the choking person may be broken during administration of the Heimlich maneuver. Applying the Heimlich maneuver too vigorously may result in an injury to the internal organs of the choking person. There may be some local **pain** and tenderness at the point where the rescuer's fist was placed. In infants, a rescuer should never attempt to sweep the baby's mouth without looking to remove foreign material. This is likely to push the material farther down the trachea. If the foreign material is not removed, the person choking will die from lack of oxygen.

Results

The Heimlich maneuver usually results in the expulsion and removal of an obstruction in the throat. The choking person suffers no permanent effects from the episode.

Health care team roles

Anyone can be trained to successfully apply the Heimlich maneuver. Most of the applications each year are provided by trained volunteers. Health professionals may become involved. Paramedics may apply the Heimlich maneuver to a choking person. Physicians, physician assistants and nurses may provide additional treatment in a hospital emergency room. Nurses may provide some follow-up care.

Hematocrit

Definition

The hematocrit is a test that measures the volume of **blood** by the percentage that is comprised of red blood cells. The hematocrit is also called the packed red cell volume because classically it is measured by centrifuging the blood in a capillary tube.

Purpose

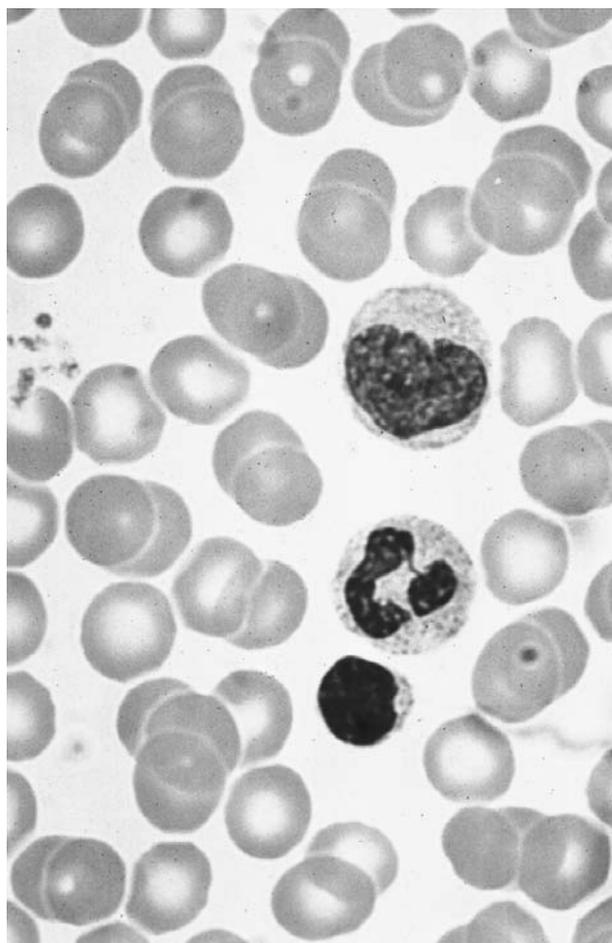

The hematocrit is used to screen for anemia, or is measured on a person to determine the extent of anemia. An anemic person has fewer or smaller than normal red blood cells. A low hematocrit, combined with other abnormal blood tests, confirms the diagnosis. The hematocrit is decreased in a variety of common conditions including chronic and recent acute blood loss, some cancers, kidney and **liver** diseases, malnutrition, **vitamin B₁₂** and **foliac acid** deficiencies, **iron** deficiency, **pregnancy**, systemic lupus erythematosus, rheumatoid arthritis and peptic ulcer disease. An elevated hematocrit is most often associated with severe **burns**, **diarrhea**, **shock**, Addison's disease, and **dehydration**. These conditions reduce the volume of plasma water causing a relative increase in RBCs or hemoconcentration. An elevated hematocrit may also be caused by an absolute increase in blood cells called polycythemia. This may be secondary to hypoxia or the result of a proliferation of blood forming cells in the bone marrow (polycythemia vera).

Transfusion decisions are based upon the results of laboratory tests, including the hematocrit. Generally, transfusion is not considered necessary if the hematocrit is below 21%. The hematocrit is also used as a guide to how many transfusions are needed. Each unit of packed red blood cells administered to an adult is expected to increase the hematocrit by approximately 4%.

Precautions

Fluid volume in the blood affects hematocrit values. Accordingly, the blood sample should not be taken from an arm receiving IV fluid or during hemodialysis. It should be noted that pregnant women have extra fluid, which dilutes the blood, decreasing the hematocrit. Dehydration concentrates the blood, which increases the hematocrit.

In addition, care should be taken to avoid hemolysis, as this will invalidate test results. Certain drugs such as penicillin and chloramphenicol may decrease the hematocrit, while glucose levels above 400 mg/dL are known to elevate results. Blood should be collected in heparin or

Red blood cells. (Photograph by Biophoto Associates. Photo Researchers, Inc. Reproduced by permission.)

EDTA (edetic acid) and measured within six hours to avoid RBC (red blood cell) swelling. Prolonged use of the tourniquet during collection will increase the hematocrit. Excess EDTA caused by an incomplete filling of the tube will falsely lower the hematocrit. Blood for hematocrit may be collected either by finger puncture or venipuncture. When performing a finger puncture, the first drop of blood should be wiped away because it dilutes the sample with tissue fluid. A nurse or phlebotomist usually collects the sample following standard precautions for the prevention of transmission of blood-borne pathogens.

Description

Blood is made up of red blood cells, white blood cells (WBCs), platelets, and plasma. A decrease in the number or size of red cells also decreases the amount of space they occupy, resulting in a lower hematocrit. Conversely, an increase in the number or size of red cells

KEY TERMS

Anemia—A lack of oxygen carrying capacity commonly caused by a decrease in red blood cell number, size, or function.

Hematocrit—The volume of blood occupied by the red blood cells expressed in percent.

increases the amount of space they occupy, resulting in a higher hematocrit. Thalassemia minor is an exception in that it usually causes an increase in the number of red blood cells, but because they are small, it results in a decreased hematocrit.

The hematocrit may be measured manually by centrifugation. A thin capillary tube called a microhematocrit tube is filled with blood and sealed at the bottom. The tube is centrifuged at 10,000 RPM (revolutions per minute) for five minutes. The RBCs have the greatest mass and are forced to the bottom of the tube. The WBCs and platelets form a thin layer between the RBCs and the plasma called the buffy coat, and the liquid plasma rises to the top. The height of the red cell column is measured as a percent of the total blood column. The higher the column of red cells, the higher the hematocrit. Most commonly, the hematocrit is measured indirectly by an automated blood cell counter. The counter measures the RBCs by impedance. A RBC displaces electrolyte in the counting aperture causing a voltage pulse proportional to the cell size. The instrument calculates the mean cell volume (MCV) from the voltage pulses. The MCV is multiplied by the RBC count to give the hematocrit. Whole blood electrolyte analyzers measure the hematocrit using a conductivity electrode. The electrical conductivity of the sample is inversely related to the hematocrit after correcting for the sodium concentration. It is important to recognize that different results may be obtained when different measurement principles are used. For example, the microhematocrit tube method will give slightly higher results than the electronic methods when RBCs of abnormal shape are present because more plasma is trapped between the cells.

Aftercare

Discomfort or bruising may occur at the puncture site. Pressure to the puncture site until the bleeding stops reduces bruising; warm packs relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be treated accordingly.

Complications

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with this test.

Results

Normal values vary with age and sex. Some representative ranges are:

- at birth: 42-60%
- six to 12 months: 33-40%
- adult males: 42-52%
- adult females: 35-47%

Health care team roles

Laboratory scientists perform hematocrit tests using manual or automated procedures. Critically high or low levels should be immediately called to the attention of the patient's nurse or doctor. Nurses should bring high or low hematocrit levels to the attention of the patient's physician, and should also report any signs and symptoms that could be associated with the increase or decrease such as medications, excessive thirst, tachycardia, low **blood pressure**, weakness, etc.

Hemodialysis shunt, graft, and fistula care

Definition

A hemodialysis shunt, graft, or fistula provides vascular access for hemodialysis, a treatment that cleans the

blood by removing wastes and excess water from the body.

Purpose

Kidneys remove wastes from the blood through the urine, regulate the amount of water and **minerals** needed by the body, and produce hormones. When the kidneys lose their ability to filter wastes and excess water from the blood, hemodialysis is required. During hemodialysis, the blood is circulated through a hemodialysis (artificial kidney) machine. Hemodialysis cleans blood similar to the way kidneys do. A vascular site, such as an arteriovenous (AV) fistula or graft, provides access for the removal and return of blood during hemodialysis. The patient's blood is removed and circulated through a machine that contains a dialyzer. The wastes and excess water from the patient's blood pass through the dialysis machine's membrane into the dialysate, and are then discarded. The dialyzed (cleaned) blood is returned to the patient's bloodstream.

Description

The patient is attached to the hemodialysis machine through several means. The most common method of providing permanent access to the bloodstream for hemodialysis is an arteriovenous (AV) fistula. An AV fistula is created surgically by connecting an artery to a vein, usually in the forearm. An AV fistula requires planning more than other kinds of access because it takes two to six months to develop. During this time, the stronger blood flow from the artery causes the vein to become larger. This allows the fistula to take repeated needle insertions, and for blood to flow quickly to the dialyzer. Another way to provide vascular access to the bloodstream is through an internal graft surgically connecting an artery to a vein with a synthetic or bovine graft placed under the skin. A hemodialysis graft does not need to develop as a fistula does and so can be used soon after it has been placed. Other types of vascular access, such as catheters and shunts, are temporary forms of access.

Complications

The primary complications of vascular access are clotting and **infection**. After an AV fistula has developed, it is less likely to form clots or get infected. Grafts typically have more problems with infection and clotting and need revisions or replacement sooner than fistulas. Proper hemodialysis depends on fistulas and grafts that work well.

To preserve and protect AV access:

KEY TERMS

Arteriovenous (AV) fistula—Surgical connection of an artery to a vein.

Bovine graft—Transplanted vein from a cow.

Dialysate—The cleansing solution used in hemodialysis.

Dialyzer—A part of the hemodialysis machine that contains two sections, one for the dialysate and one for the patient's blood.

Hemodialysis—The use of a machine to clean wastes from the blood when the kidneys cannot do it.

Hormone—A natural chemical produced by a part of the body to trigger or regulate particular functions.

Kidneys—Two bean-shaped organs that filter wastes from the blood and create urine.

Nephrologist—Physician who specializes in diseases of the kidney.

Nephropathy—Disease of the kidney.

Renal—Having to do with the kidneys.

- Keep the access site clean at all times to prevent infection.
- Avoid injections, intravenous (IV) needles or fluids, or taking blood samples in the access site arm.
- Needle insertions for hemodialysis treatments should be rotated so that one spot is not repeatedly stuck and weakened.
- Do not take **blood pressure** or put pressure on the access arm.
- Advise patients to avoid wearing jewelry or tight clothing, sleeping on, or lifting heavy objects with the access arm.
- Check the temperature and color of the fingers and the pulse of the access arm for adequate circulation.
- Check for signs of infection at the access site.

Results

AV fistulas usually last longer and have less complications than other kinds of vascular access.

Health care team roles

The health care team can help patients prepare and maintain their vascular access. The type of vascular access selected for patients depends on their individual needs such as vein size. The health care team provides the information and support for patients and families on how to preserve and protect their vascular access.

Hemoglobin test

Definition

Hemoglobin is a protein inside red **blood** cells that carries oxygen. A hemoglobin test reveals how much hemoglobin is in a person's blood. This information can be used to help physician's diagnose and monitor anemia and polycythemia vera, a condition in which the bone marrow produces too many blood cells.

Purpose

A hemoglobin test is performed to determine the amount of hemoglobin in a person's red blood cells (RBCs). This is important because the amount of oxygen available to tissues depends upon how much oxyhemoglobin is in the RBCs, and local perfusion of the tissues. Without sufficient hemoglobin, the tissues lack oxygen and the **heart** and **lungs** must work harder to compensate.

A low hemoglobin measurement usually means the person has anemia. Anemia results from a decrease in the number, size, or function of RBCs. Common causes include excessive bleeding, a deficiency of **iron**, **vitamin B₁₂**, or **follic acid**, destruction of red cells by antibodies or mechanical trauma, and structurally abnormal hemoglobin. Hemoglobin levels are also decreased due to **cancer**, kidney diseases, and excessive IV fluids. An elevated hemoglobin may be caused by **dehydration**, hypoxia, or polycythemia vera. Hypoxia may result from high altitudes, chronic obstructive lung diseases, and congestive **heart failure**. Hemoglobin levels are also used to determine if a person needs a blood transfusion. Usually a person's hemoglobin must be below 8 g/dL before a transfusion is considered. The hemoglobin concentration is also used to determine how many units of packed red blood cells should be transfused. A common rule of thumb is that each unit of red cells should increase the hemoglobin by approximately 1.5 g/dL.

Precautions

Fluid volume in the blood affects hemoglobin values. Accordingly, the blood sample should not be taken from an arm receiving IV fluid. It should also be noted that pregnant women and people with cirrhosis have extra fluid, which dilutes the blood, decreasing the hemoglobin. Dehydration concentrates the blood, which may cause an increased hemoglobin result.

Certain drugs such as **antibiotics**, aspirin, antineoplastic drugs, doxapram, indomethacin, sulfonamides, primaquine, rifampin, and trimethadione, may also decrease the hemoglobin level.

A nurse or phlebotomist usually collects the sample by venipuncture or fingerstick following standard precautions for the prevention of transmission of bloodborne pathogens.

Description

Hemoglobin is a complex protein composed of four subunits. Each subunit consists of a polypeptide chain that enfolds a heme group. Each heme contains iron

(Fe²⁺) which can bind a molecule of oxygen. The iron gives blood its red color. After the first year of life, 95-97% of the hemoglobin molecules contain two pairs of polypeptide chains designated alpha and beta. This form of hemoglobin is called hemoglobin A.

Hemoglobin is most commonly measured by the cyanmethemoglobin method. Whole blood is mixed with a buffered solution of potassium ferricyanide and potassium cyanide. The potassium ferricyanide oxidizes the heme iron forming methemoglobin (Fe³⁺). This reacts with potassium cyanide forming cyanmethemoglobin which is orange-red. The absorbance of the solution measured at 540 nm is proportional to the hemoglobin concentration. Hemoglobin is most often performed as part of a **complete blood count** (CBC), a test that includes counts of the red blood cells, white blood cells, and platelets (thrombocytes).

Some people inherit hemoglobin with an abnormal structure. The abnormal hemoglobin results from a point mutation in one or both genes that code for the alpha or beta polypeptide chains. Examples of abnormal hemoglobins resulting from a single amino acid substitution in the beta chain are sickle cell and hemoglobin C disease. Most abnormal hemoglobin molecules can be detected by hemoglobin electrophoresis. This procedure separates hemoglobin molecules with different net charges.

Preparation

No special preparation is required. Blood is collected by venipuncture in a tube containing EDTA anticoagulant after disinfecting the puncture site.

Aftercare

Discomfort or bruising may occur at the puncture site. Pressure to the puncture site until the bleeding stops reduces bruising; warm packs relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be treated accordingly.

Complications

Other than potential bruising at the puncture site, and/or dizziness, there are no complications associated with this test.

Results

Normal values vary with age and sex, with women generally having lower hemoglobin values than men. Normal results for men range from 13.6-17.2 g/dL. For women the normal range is 12-15 g/dL. Critical limits

KEY TERMS

Anemia—A diminished oxygen carrying capacity caused by a decrease in the size, number, or function of red blood cells.

Hemoglobin—A protein inside red blood cells that carries oxygen to body tissues.

Polycythemia vera—A disease in which the bone marrow makes too many blood cells.

(panic values) for both males and females are below 5.0 g/dL or above 20.0 g/dL.

A low hemoglobin value usually indicates the person has anemia. Further tests are done to discover the cause and type of anemia. Dangerously low hemoglobin levels put a person at risk of a heart attack, congestive heart failure, or stroke. A high hemoglobin value indicates the body is making too many red cells. Further tests are performed to differentiate the cause.

Health care team roles

Laboratory scientists perform hemoglobin tests using automated laboratory equipment. Critically high or low levels should be immediately called to the attention of the patient's nurse or doctor. Nurses should bring high or low hemoglobin levels to the attention of the patient's physician, and should also report any signs and symptoms that could be associated with an abnormal hemoglobin: medications, excessive thirst, tachycardia, low **blood pressure**, weakness, etc.

Hemophilia

Definition

Hemophilia is a genetic disorder of the mechanism of **blood** clotting that is usually inherited. Depending on the degree of the disorder present in an individual, excess bleeding may occur only after specific, predictable events (such as surgery, dental procedures, or injury), or occur spontaneously, with no known initiating event.

Description

The normal mechanism for blood clotting is a complex series of events involving the interaction of injured blood vessels, blood cells (called platelets), and over 20 different **proteins** that also circulate in the blood.

When a blood vessel is injured in a way that causes bleeding, platelets collect over the injured area, and form a temporary plug to prevent further bleeding. This temporary plug, however, is too disorganized to serve as a long-term solution. A series of chemical events occur, resulting in the formation of a more reliable plug. The final plug involves tightly woven fibers of a material called fibrin. The production of fibrin requires the interaction of several chemicals, in particular a series of proteins called clotting factors. At least thirteen different clotting factors have been identified.

The clotting cascade, as it is called, is the series of events required to form the final fibrin clot. The cascade uses a technique called amplification to rapidly produce the proper sized fibrin clot from the small number of molecules initially activated by an injury.

In hemophilia, certain clotting factors are either decreased in quantity, absent, or improperly formed. Because the clotting cascade uses amplification to plug a bleeding area rapidly, absence or inactivity of just one clotting factor can greatly increase bleeding time and slow the formation of a clot.

Hemophilia A is the most common type of bleeding disorder and involves decreased activity of factor VIII. There are three levels of factor VIII deficiency: severe, moderate, and mild. This classification is based on the percentage of normal factor VIII activity present:

- Individuals with less than 1% of normal factor VIII activity level have severe hemophilia. Half of all people with hemophilia A fall into this category. Such individuals frequently experience spontaneous bleeding, most frequently into their joints, skin, and muscles. Surgery or trauma can result in life-threatening hemorrhage, and must be carefully managed.

- Individuals with 1-5% of normal factor VIII activity level have moderate hemophilia, and are at risk for heavy bleeding after seemingly minor traumatic injury.
- Individuals with 5-40% of normal factor VIII activity level have mild hemophilia, and must prepare carefully for any surgery or dental procedures.

Individuals with hemophilia B have symptoms very similar to those of hemophilia A, but the deficient factor is factor IX. This type of hemophilia is also known as Christmas disease.

Hemophilia C involves factor XI, is very rare, and much more mild than hemophilia A or B.

Hemophilia A and B are both caused by a genetic defect present on the X chromosome. (Hemophilia C is inherited in a different fashion.) About 70% of all people with hemophilia A or B inherited the disease. The other 30% develop the disease as a result of a spontaneous genetic mutation.

The following concepts are important to understanding the inheritance of these diseases. All humans have two chromosomes determining their gender: females have XX, males have XY. Because the trait is carried only on the X chromosome, it is termed sex-linked. The chromosomes are comprised of units referred to as genes.

Both factors VIII and IX are produced by genes located on the X chromosome, so hemophilia A and B are both sex-linked diseases. Because a female child always receives two X chromosomes, she nearly always will receive at least one normal X chromosome. Therefore, even if she receives one abnormal X chromosome, she will still be capable of producing a sufficient quantity of factors VIII and IX to avoid the symptoms of hemophilia. Such a person who has one abnormal chromosome, but does not actually experience disease symptoms, is called a carrier. She carries the abnormal gene that causes hemophilia and can pass it on to her offspring. If, however, she has a son who receives her abnormal X chromosome, he will be unable to produce the right quantity of factors VIII or IX, and he will have some degree of hemophilia. (Males inherit one X and one Y chromosome, and therefore have only one X chromosome.)

In rare cases, a hemophiliac father and a carrier mother can pass on the right combination of parental chromosomes to result in a hemophiliac female child. This situation, however, is rare. The vast majority of people with hemophilia A or B are male.

About 30% of all people with hemophilia A or B are the first member of their family to ever have the disease. These individuals have had the unfortunate occurrence of a spontaneous mutation; meaning that in their early development, some random genetic accident befell their

X chromosome, resulting in the defect causing hemophilia A or B. Once such a spontaneous genetic mutation takes place, offspring of the affected person can inherit the newly-created, abnormal chromosome.

Hemophilia A affects between one in 5,000 to one in 10,000 males in most populations.

One recent study estimated the prevalence of hemophilia to be 13.4 cases per 100,000 U.S. males (10.5 hemophilia A and 2.9 hemophilia B). By race or ethnicity, the prevalence was 13.2 cases per 100,000 among white, 11.0 among African-American, and 11.5 among Hispanic males.

Causes and symptoms

In the case of severe hemophilia, the first bleeding event usually occurs prior to 18 months of age. In some babies, hemophilia is suspected immediately when a routine circumcision (removal of the foreskin of a penis) results in unusually heavy bleeding. Toddlers are at particular risk because they fall frequently, and may bleed into the soft tissue of their arms and legs. These small bleeds result in bruising and noticeable lumps but usually don't need treatment. As a child becomes more active, bleeding may occur into the muscles. This is a much more painful and debilitating problem. Such muscle bleedings result in **pain** and pressure on the nerves in the area of the bleeding. Damage to nerves can cause numbness and decreased ability to use the injured limb.

Some of the most problematic and frequent bleeds occur into the joints, particularly into the knees and elbows. Repeated bleeding into joints can result in scarring within the joints and permanent deformities. Individuals may develop arthritis in joints that have suffered continued irritation from the presence of blood. Mouth injuries can result in compression of the airway, and, therefore, can be life-threatening. A blow to the head, which might be totally insignificant in a normal individual, can result in bleeding into the **skull** and **brain** in someone with hemophilia. Because the skull has no room for expansion, a hemophiliac individual is at risk for brain damage due to blood taking up space and exerting pressure on the delicate brain tissue.

People with hemophilia are at very high risk of hemorrhage (severe, heavy, uncontrollable bleeding) from injuries such as motor vehicle accidents and also from surgery.

Some other rare clotting disorders such as Von Willebrand disease present similar symptoms but are not usually called hemophilia.

Diagnosis

Various tests are available to measure, under very carefully controlled conditions, the length of time it takes to produce certain components of the final fibrin clot. Tests called assays can also determine the percentage of factors VIII and IX present compared to normal percentages. This information can help in demonstrating the type, as well as the severity, of hemophilia present.

Individuals with a family history of hemophilia may benefit from **genetic counseling** before deciding to have a baby. Families with a history of hemophilia can also have tests done during a **pregnancy** to determine whether the fetus has hemophilia. The test, called chorionic villous sampling, examines proteins for the defects that lead to hemophilia. This test, which is associated with a 1% risk of **miscarriage**, can be performed at 10-14 weeks of gestation. The test called **amniocentesis** examines the DNA of fetal cells shed into the amniotic fluid for genetic mutations. Amniocentesis, which is associated with a one in 200 risk of miscarriage, is performed at 15-18 weeks of gestation.

Treatment

The most important thing that individuals with hemophilia can do to prevent complications of their disease is to avoid injury. Those individuals who require dental work or any surgery may need to be pre-treated with an infusion of factor VIII to avoid hemorrhage. Also, hemophiliacs should be vaccinated against hepatitis. Medications or drugs that promote bleeding, such as aspirin, should be avoided.

Various types of factors VIII and IX are available to replace a person's missing factors. These are administered intravenously (directly into a person's veins by needle). These factor preparations may be obtained from a single donor, by pooling the donations of as many as thousands of donors, or by laboratory creation through highly advanced genetic techniques.

The frequency of treatment with factors depends on the severity of a person's disease. People with relatively mild disease will only require treatment in the event of injury, or to prepare for scheduled surgical or dental procedures. Individuals with more severe disease will require regular treatment to avoid spontaneous bleeding.

While appropriate treatment of hemophilia can both decrease discomfort and be life-saving, complications associated with treatment can also be quite serious. About 20% of all people with hemophilia A begin to produce chemicals in their bodies that rapidly destroy infused factor VIII. The presence of such a chemical may

KEY TERMS

Amplification—A process by which something is made larger. In clotting, only a very few chemicals are released by the initial injury; they result in a cascade of chemical reactions which produces increasingly larger quantities of different chemicals, resulting in an appropriately-sized, strong fibrin clot.

Factors—Coagulation factors are substances in the blood, such as proteins and minerals, that are necessary for clotting. Each clotting substance is designated with roman numerals I through XIII.

Fibrin—The final substance created through the clotting cascade, which provides a strong, reliable plug to prevent further bleeding from the initial injury.

Hemorrhage—Very severe, massive bleeding which is difficult to control. Hemorrhage can occur in hemophiliacs after what would be a relatively minor injury to a person with normal clotting factors.

Mutation—In genetic inheritance, a permanent change in part of a chromosome.

Platelets—Blood cells involved in the clotting process.

Trauma—Injury.

greatly hamper efforts to prevent or stop a major hemorrhage.

Individuals who receive factor prepared from pooled donor blood are at risk for serious infections that may be passed through blood. Hepatitis, a severe and potentially fatal viral **liver infection**, may be contracted from pooled factor preparations. Recently, much concern has been raised about the possibility of hemophiliacs contracting a fatal slow virus infection of the brain (CJD or **Creutzfeldt-Jakob disease**) from blood products. Unfortunately, pooled factor preparations in the early 1980s were contaminated with human **immunodeficiency virus (HIV)**, the virus that causes **AIDS**. A large number of hemophiliacs were infected with HIV and some statistics show that HIV is still the leading cause of death among hemophiliacs. Currently, careful methods of donor testing, as well as methods of inactivating **viruses** present in donated blood, have greatly lowered this risk.

The most exciting new treatments currently being studied involve efforts to transfer new genes to hemo-

philiacs. These new genes would have the ability to produce the missing factors. As yet, these techniques are not being performed on humans, but there is great hope that eventually this type of **gene therapy** will be available.

Prognosis

Prognosis is very difficult to generalize because there are so many variations in the severity of hemophilia, and because much of what befalls a person with hemophilia will depend on issues such as physical activity level and accidental injuries. Statistics on prognosis are not generally available.

Health care team roles

Hemophilia is usually diagnosed by a pediatrician or family physician. These doctors, assisted by a hematologist, usually also provide care. Nurses may provide supportive care.

Prevention

People who know that their family includes hemophiliacs should receive careful genetic counseling before deciding to have a baby. There is no way to prevent the 30% of hemophilia cases that are caused by new, spontaneous mutations.

Hepatitis virus tests

Definition

Viral hepatitis is any type of **liver** inflammation caused by a viral **infection**. The three most common **viruses** now recognized to cause liver disease are hepatitis A (infectious hepatitis), hepatitis B (serum hepatitis), and hepatitis C (non-A, non-B hepatitis). Several other types of viral hepatitis have been recognized recently, including hepatitis D (delta hepatitis), hepatitis E (epidemic hepatitis), and hepatitis G. A seventh type called transfusion-transmitted virus (TTV), a single-stranded DNA virus, has been implicated in post transfusion hepatitis. Commercial tests are not yet available to screen for HGV, and TTV infections. All **blood** and blood products donated for transfusion in the United States are screened for hepatitis B and hepatitis C.

Purpose

The different types of viral hepatitis produce similar symptoms, but they differ in terms of transmission, clinical course, and prognosis. Common symptoms are **jaundice**, malaise, nausea, and anorexia. It is estimated that approximately 600,000 cases of viral hepatitis occur in the United States each year, about half being caused by hepatitis B virus (HBV). Viral hepatitis infection is diagnosed by identifying specific viral antigens and/or anti-

Hepatitis A virus, magnified x225,000. (Custom Medical Stock Photo. Reproduced by permission.)

bodies associated with each type of viral hepatitis. An antigen is a substance, usually a protein, that is foreign to the body. An antibody is a protein manufactured by lymphocytes, a type of white blood cell, to neutralize the antigen. Hepatitis testing is also used to monitor the course of viral hepatitis.

Precautions

False negative and positive test results may occur in a small number of persons tested. Fibrin deposits, heterophile antibodies, sample carryover, and autoantibodies such as rheumatoid factor have been reported to cause false positive results for some hepatitis tests. Repeat testing of reactive samples eliminates most false positives. False negatives may be caused when antigen or antibody levels are too low to detect, as in the “window phase” of infection. This is defined as the period between initial infection and the appearance of IgG antibodies.

Hepatitis B vaccine is recommended for health care workers who may be exposed to blood or body fluids. Health care workers should be familiar with procedures for post-exposure prophylaxis. Standard (universal) precautions for prevention of exposure to bloodborne pathogens should be followed at all times. Healthcare staff working in hemodialysis and other high prevalence environments should request education regarding more strict precautions.

Description

There are five major types of viral hepatitis. The diseases, along with the tests available to aid in diagnosis, are described below.

Hepatitis A

Hepatitis A infection, formerly called infectious hepatitis, is caused by the hepatitis A virus (HAV), a single-stranded RNA virus. It is usually a mild disease, most often spread by food and water contamination with fecal material containing the virus. HAV can also be spread by sexual contact. Virus can be detected in stool samples prior to symptoms and for approximately three months thereafter. However, the virus cannot be isolated from the blood. Two types of antibodies to HAV can be detected. IgM antibody (anti-HAV/IgM), appears approximately three to four weeks after exposure and returns to normal within three to six months. IgG (anti-HAV/IgG) appears approximately two weeks after the IgM begins to increase, remains positive for years, and can often be detected for life. A diagnosis of infection with hepatitis A virus is usually made when symptoms including jaundice occur along with elevated levels of transaminases and a positive test for either IgM or total anti-HVA. Transaminases are enzymes released into the plasma in large amounts in necrotic liver diseases. If anti-HAV/IgG is elevated without anti-HAV/IgM, a convalescent stage of HAV infection or prior infection is presumed. Enzyme immunoassay (EIA) and radioimmunoassay (RIA) are the methods used to measure anti-HAV. Molecular diagnostic assays for the detection of HAV in stools and tissues have been developed but are not available commercially.

Hepatitis B

Hepatitis B infections, formerly known as serum hepatitis, are caused by the hepatitis B virus (HBV), a double stranded DNA virus. The disease can be mild or severe, and it can be acute (of limited duration) or chronic (ongoing). It is usually spread by sexual contact with another infected person, or through contact with infected blood. It is also transmitted from mother to child at birth (vertical transmission).

The incubation period for HBV is longer than for HAV (six to 25 weeks versus two to six weeks). The disease ranges from mild (asymptomatic) to severe and lasts for one to six months. Mortality from HBV infection is 1-2%. Approximately 10% of adults and 25% of children with acute HBV infection will develop chronic disease. About 90% of infants who are infected at birth will develop chronic hepatitis or become carriers. Chronic hepatitis may last from 1-20 years and varies greatly in severity. It is usually followed by an asymptomatic phase which lasts for many years called the chronic carrier state. Chronic carriers are capable of transmitting the virus to others. Chronic HBV infection results in cirrho-

sis of the liver in about 2%, and hepatic carcinoma in about 40% of cases.

HBV, also called the Dane particle, is composed of an inner protein core surrounded by an outer protein capsule. The outer capsule contains the hepatitis B surface antigen (HBsAg), formerly called the Australia antigen, that is excreted by infected hepatocytes into the bloodstream. The inner core contains HBV core antigen (HBcAg), and HBV e-antigen (HBeAg). Antibodies to these antigens are called anti-HBs, anti-HBc, and anti-HBe. The diagnostic utility of tests for HBV infection is described below:

- Hepatitis B surface antigen (HBsAg). This is the first test for HBV to become abnormal. HBsAg is detected before the onset of clinical symptoms, peaks during the first week of symptoms, and usually disappears by the time the accompanying jaundice (yellowing of the skin and other tissues) begins to subside (three months). In a very small number of cases, HBsAg may disappear from the blood sooner, causing a negative test result before the presence of antibodies can be detected. HBsAg is commonly detected by a double antibody sandwich immunoassay. The presence of HBsAg indicates infection with HBV. The test will be positive in the acute, chronic, or carrier state. A positive test for both HBsAg and anti-HBs/IgM indicates an active HBV infection. A person is considered to be a chronic carrier if HBsAg persists in the blood for six or more months. Carriers test negative for anti-HBs, but test positive for total anti-HBc.
- Hepatitis B surface antibody (anti-HBs). This appears approximately one month after the disappearance of the HBsAg, signaling the end of the acute infection period. Anti-HBs is the antibody that demonstrates immunity after administration of the hepatitis B vaccine. Its presence also indicates immunity to subsequent infection. Failure to detect anti-HBs in a person who is positive for HBsAg signals the development of chronic hepatitis or a carrier state. Tests for anti-HBs use particles coated with HBsAg to bind antibodies in the plasma. The antibodies are detected using an enzyme labeled or radiolabeled anti-human immunoglobulin.
- Hepatitis B DNA (HBV DNA) can be measured in the serum of persons in both the acute and chronic phases. This is accomplished through sensitive DNA hybridization techniques. The viral DNA is amplified using the polymerase chain reaction (PCR), and the amplicon products are detected using an enzyme-conjugated probe. This test measures the amount of virus in the blood and is used to monitor persons receiving antiviral therapy.

Hepatitis testing

Hepatitis test	Appears/disappears	Significance
HBsAg (hepatitis B surface antigen)	2–6 weeks/1–3 months	Indicates active infection. If antigen level persists in blood, patient is considered a carrier.
HBsAb (hepatitis B surface antibody)	2–6 weeks/life	Patient is in convalescent stage. Antigen presence denotes immunity to HBV.
HBcAb (hepatitis B core antibody)	2 weeks/3–6 months	Indicates past infection. Also present in patients with chronic hepatitis.
HBeAg (hepatitis B e-antigen)	3–5 days/2–4 weeks	Its presence correlates with early and active disease and high infectivity in acute HBV infection.
HBeAb (hepatitis B e-antibody)	1–4 weeks/4–6 years	Indicates convalescent stage and denotes decreased infectivity.

SOURCE: Pagana, K.D. and T.J. Pagana. *Mosby's Diagnostic and Laboratory Test Reference*. 3rd ed. St. Louis: Mosby, 1997.

- Hepatitis B core antibody (anti-HBc). There are two tests, anti-HBc/IgM and total anti-HBc. The former detects only the IgM antibody to the core antigen and the latter detects both IgG and IgM antibodies to the core antigen. The IgM component is the first antibody produced in HBV infection. It appears just before acute hepatitis develops and remains elevated for six to 18 months. After this time the IgM anti-HBc will be undetectable. Anti-HBc (owing to the IgM component) will be the only hepatitis test that is positive during the “window phase” of infection. This is the period when HBsAg levels are too low to detect, and IgG antibodies have not yet developed. The IgG component appears shortly after the IgM. Although the level slowly declines, it remains detectable for years and often for life. Therefore, total anti-HBc is a marker that detects both current or prior infection. Total anti-HBc is positive in chronic HBV infection. Anti-HBc/IgM is typically negative in chronic infection. Testing for anti-HBc/IgM and total anti-HBc is similar to that for anti-HBs except that the antigen used is HBc.
- Hepatitis B e-antigen (HBeAg). This test is used as an index of infection, rather than for diagnostic purposes. The presence of this antigen correlates with early and active disease, as well as with high infectivity in patients with acute HBV infection. When HBeAg levels persist in the blood, the development of chronic HBV infection is suspected. This test is also used to determine if antiviral therapy has been effective.

KEY TERMS

Antibody—A protein manufactured by lymphocytes that binds to a specific antigen

Antigen—A protein that is foreign to the body, not part of “self.”

Lymphocyte—A type of white blood cell involved in the immune response.

Hepatitis A—Commonly called infectious hepatitis, caused by the hepatitis A virus (HAV). Most often spread by food and water contamination.

Hepatitis B—Commonly known as serum hepatitis, it is caused by the hepatitis B virus (HBV). The disease can be mild or severe, and it can occur as an acute or chronic disease. Frequently spread by sexual contact with another infected person, contact with infected blood, intravenous drug use, or from mother to child at birth.

Hepatitis C—Hepatitis caused by the hepatitis C virus (HCV). Usually a more mild form of the disease initially, but carries a greater chance to lead to chronic liver disease, possible liver failure, and the eventual need for transplant. Chronic carrier state is also a risk.

Measurement of HBeAg is similar to HBsAg except that the antibody used is anti-HBe.

- Hepatitis B e-antibody (anti-HBe). This antibody rises after anti-HBc and correlates with the disappearance of HBeAg. Therefore, the presence of anti-HBe and disappearance of HBeAg signal recovery and indicate a reduced risk of infectivity in patients who have previously been HBeAg positive. Chronic hepatitis B and carriers can be positive for either HBeAg or anti-HBe, but are less infectious when anti-HBe is present. Anti-HBe can persist for years, but usually disappears earlier than anti-HBs or anti-HBc. Measurement is similar to anti-HBs except that HBeAg is used instead of HBsAg.

Hepatitis C

Hepatitis C, previously known as non-A, non-B hepatitis, is caused by the hepatitis C virus (HCV), a single-stranded RNA virus. Transmission is mainly via contact with blood through contaminated needles, tattoos, and other parenteral means. The incidence of HCV infection by sexual transmission or close contact is much less than for HBV. Vertical transmission occurs in about 5% of cases. The course of acute disease is variable but gener-

ally is mild and often asymptomatic. HCV is more likely than HBV to lead to chronic liver disease, possible liver failure, and the eventual need for a liver transplant. Chronic carrier states develop in more than 80% of patients, and chronic liver disease with cirrhosis develops in approximately 20%. Persons with HCV are also at risk for hepatic carcinoma.

Hepatitis C is detected by demonstrating the presence of anti-HCV in the blood (HCV serology). The test is a sandwich-type enzyme immunoassay and detects the IgG antibody to HCV. The addition of this test to those for HbsAg and anti-HBc has greatly reduced the incidence of post-transfusion hepatitis. Since false positive results do occur with this test, a positive finding is confirmed by a more specific test, the recombinant immunoblot assay (RIBA) which also measures anti-HCV. New tests are available to measure HCV RNA in the blood. These viral load tests make use of the reverse transcription-polymerase chain reaction (RT-PCR) and are helpful in measuring the effect of interferon and other antiviral treatments.

Hepatitis D

Hepatitis D, previously called delta hepatitis, is caused by the hepatitis D virus (HDV). This is a single stranded RNA virus that requires coinfection with HBV in order to enter the hepatocyte. The disease occurs only in those who have HBV surface antigen in the blood from a past or simultaneously occurring infection. Transmission is mainly through intravenous drug use via contaminated needles, and in persons who have received multiple transfusions, but experts believe that transmission may also occur through sexual contact. Infection usually causes severe (fulminant) hepatitis and has a mortality rate of approximately 30%. It is diagnosed by demonstrating IgG antibodies to HDV in plasma of persons with documented HBV infection. Although not available commercially, research methods for IgM anti-HDV and HDV RNA have been developed.

Hepatitis E

Hepatitis E, once called epidemic hepatitis, is caused by hepatitis E virus (HEV), a single stranded RNA virus. It is also called enteric non-A, non-B hepatitis. Infection with HBE is transmitted when water or food becomes contaminated with feces containing the virus. Although not frequent in the United States, epidemic outbreaks have occurred in many other countries worldwide. The incubation time and course of the disease is similar to hepatitis A. Hepatitis E is usually a self-limiting disease, and chronic infection is infrequent. However, it is associated with a high mortality rate (about 20%) when con-

tracted during **pregnancy**. Infection with HEV is diagnosed by demonstrating antibodies to the virus in the plasma of an infected person.

Preparation

Hepatitis virus tests require a blood sample. It is not necessary for the patient to withhold food or fluids before any of these tests, unless requested to do so by the physician. A nurse or phlebotomist usually collects the blood by venipuncture following standard precautions for prevention of exposure to bloodborne pathogens.

Aftercare

Pressure should be applied to the site of venipuncture.

Complications

Complications for these tests are minimal for the patient, but may include slight bleeding from the blood-drawing site, fainting or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

Testing for hepatitis infection requires a panel of tests. A typical screening panel for acute hepatitis consists of tests for anti-HAV/IgM, HBsAg, and anti-HBc/IgM. A positive test for total antibodies to HAV or HBV may indicate current infection, prior infection, or **vaccination** for hepatitis B. Therefore, when positive, these tests are evaluated in conjunction with other tests, the patient's history, and clinical findings. Normal results are as follows:

- hepatitis A antibody (IgM or total): negative
- hepatitis B core antibody (IgM or total): negative
- hepatitis B e antibody: negative
- hepatitis B e-antigen: negative
- hepatitis B surface antigen: negative
- hepatitis C antibody: negative
- hepatitis D antibody: negative
- hepatitis E antibody: negative

Abnormal results

HEPATITIS A. A single positive total anti-HAV test may indicate HAV infection or previous exposure to the virus because these antibodies persist so long in the bloodstream. A positive test for anti-HAV/IgM or evi-

dence of a rising total anti-HAV titer confirms hepatitis A. A negative anti-HAV test rules out hepatitis A.

HEPATITIS B. A positive test for HBsAg indicates acute or chronic infection or a carrier state. High levels of HBsAg that continue for three or more months after onset of acute infection suggest development of chronic hepatitis or carrier status. A positive test for total anti-HBc indicates current infection or previous exposure. A negative test for HBsAg and total anti-HBc rules out hepatitis. A positive test for anti-HBc/IgM indicates acute infection and may be the only HBV marker that is positive during the window phase of infection. Anti-HBc/IgM is not positive in the chronic phase of infection. Detection of anti-HBs signals late convalescence or recovery from infection. This antibody remains in the blood to provide immunity to reinfection. A positive test for HBeAg indicates acute infection and a high state of infectivity. Disappearance of HBeAg and appearance of anti-HBe indicates recovery from HBV infection.

HEPATITIS C. (non-A, non-B hepatitis) Anti-HBc develops after exposure to hepatitis C.

HEPATITIS D. Anti-HDV develops after exposure to hepatitis D.

HEPATITIS E. Anti-HEV develops after exposure to hepatitis E.

Health care team roles

Hepatitis tests are ordered and interpreted by a physician. A phlebotomist, or sometimes a nurse, collects the blood, and a clinical laboratory scientist, CLS(NCA)/medical technologist, MT(ASCP) or clinical laboratory technician CLT(NCA)/medical laboratory technician MLT(ASCP) performs the testing.

Herbalism, Western

Definition

Western herbalism is a form of the healing arts that draws from herbal traditions of Europe and the Americas, and that emphasizes the study and use of European and Native American herbs in the treatment and prevention of illness. Western herbalism is based on physicians' and herbalists' clinical experience and traditional knowledge of medicinal plant remedies preserved by oral tradition and in written records over thousands of years. Western herbalism, like the much older system of traditional Chinese medicine, relies on the synergistic and curative properties of the plant to treat symptoms and disease and maintain health.

Western herbalism is based upon pharmacognosy, the study of natural products. Pharmacognosy includes the identification, extraction methods, and applications of specific plant constituents responsible for specific therapeutic actions, such as the use of digoxin from *Digitalis* leaf for **heart failure**. These constituents are extracted, purified and studied in vitro, in vivo, and in clinical research. They may be concentrated to deliver standardized, set doses. Sometimes, the natural constituent can be synthesized in the lab, or changed and patented. Practitioners may choose to use fresh medicinal plants, simple extracts, or standardized extracts.

In standardized extracts, a specific quantity of a constituent is called a marker compound, and it may or may not be the active constituent(s) in the plant medicine. There are preparations with standardized active constituent quantities, and preparations with greater emphasis on quality of crude plant material and traditional preparation methodology than on finalized total quantity of marker compounds. The preference between the two for precision dosing is philosophical, practical and vari-

able. When using plant extracts in which the active constituents and their cofactors are well established, or the therapeutic and lethal dose are close, standardized products are often preferred. When using plant extracts whose active constituents remain obscure, or the active constituents when purified produce weaker therapeutic results or more undesirable side effects, the products produced under good manufacturing processes and according to the traditional *National Formulary U. S. Dispensatory* or *U. S. Pharmacopeia* are preferred.

Origins

Over 2,500 years ago Hippocrates wrote, "In medicine one must pay attention not to plausible theorizing but to experience and reason together." This Greek physician and herbalist from the fourth century B.C. is considered the father of western medicine. He stressed the importance of diet, water quality, climate, and social environment in the development of disease. Hippocrates believed in treating the whole person, rather than merely isolating and treating symptoms. He recognized the innate capacity of the body to heal itself, and emphasized the importance of keen observation in the medical practice. He recommended simple herbal remedies to assist the body in restoring health.

Ancient Greek medicine around the fifth century B.C. was a fertile ground for contrasting philosophies and religions. Greek physicians were influenced by the accumulated medical knowledge from Egypt, Persia, and Babylon. Medical advances flourished and practitioners and scholars were free to study and practice without religious and secular constraints. In the fourth century B.C., Theophrastus wrote the *Historia Plantarum*, considered to be the founding text in the science of botany.

During the first century A.D., Dioscorides, a Greek physician who traveled with the Roman legions, produced five medical texts. His herbal text, known as the *De Materia Medica* is considered to be among the most influential of all western herbal texts. It became a standard reference for practitioners for the next 1,500 years. This influential book also included information on medicinal herbs and treatments that had been used for centuries in Indian Ayurvedic medicine. Galen of Pergamon, who also lived in the first century A.D., was a Roman physician and student of anatomy and physiology. He authored a recipe book containing 130 antidotes and medicinal preparations. These elaborate mixtures, known as galenicals, sometimes included up to one hundred herbs and other substances. This complex approach to herbal medicine was a dramatic change from the simple remedies recommended by Hippocrates and employed by traditional folk healers. Galen developed a

rigid system of medicine in which the physician, with his specialized knowledge of complex medical formulas, was considered the ultimate authority in matters of health care. The Galenic system, relying on theory and scholarship rather than observation, persisted throughout the Middle Ages. The galenic compounds, along with bloodletting and purging, were among the drastic techniques practiced by the medical professionals during those times; however, traditional herbal healers persisted outside the mainstream medical system.

During the eighth century a medical school was established in Salerno, Italy, where the herbal knowledge accumulated by Arab physicians was preserved. The Arabian Muslims conducted extensive research on medicinal herbs found in Europe, Persia, India, and the Far East. Arab businessmen opened the first herbal pharmacies early in the ninth century. The *Leech Book of Bald*, the work of a Christian monk, was compiled in the tenth century. It preserved important medical writings that had survived from the work of physicians in ancient Greece and Rome.

The Middle Ages in Europe were a time of widespread death by plagues and pestilence. The Black Plague of 1348, particularly, and other health catastrophes in later years, claimed so many lives that survivors began to lose faith in the dominant Galenic medical system. Fortunately, the knowledge of traditional herbal medicine had not been lost. Medieval monks who cultivated extensive medicinal gardens on the monastery grounds, also patiently copied the ancient herbal and medical texts. Folk medicine as practiced in Europe by traditional healers persisted, even though many women herbalists were persecuted as witches and enemies of the Catholic church and their herbal arts were suppressed.

The growing spice trade and explorations to the New World introduced exotic plants, and a whole new realm of botanical medicines became available to Europeans. Following the invention of the printing press in the fifteenth century, a large number of herbal texts, also simply called herbals, became available for popular use. Among them were the beautifully illustrated works of the German botanists Otto Brunfels and Leonhard Fuchs published in 1530, and the Dutch herbal of Belgian physician Rembert Dodoens, a popular work that was later reproduced in English. In 1597, the physician and gardener John Gerard published one of the most famous of the English herbals, still in print today. Gerard's herbal, known as *The Herbal or General Historie of Plantes* was not an original work. Much of the content was taken from the translated text of his Belgian predecessor Dodoens. Gerard did, however, include descriptions of some of the more than one thousand species of rare and exotic plants and English flora from his own garden.

The correspondence of astrology with herbs was taught by Arab physicians who regarded astrology as a science helpful in the selection of medicines and in the treatment of diseases. This approach to western herbalism was particularly evident in the herbal texts published in the sixteenth and seventeenth centuries. One of the most popular and controversial English herbals is *The English Physician Enlarged* published in 1653. The author, Nicholas Culpeper, was an apothecary by trade. He also published a translation of the Latin language *London Pharmacopoeia* into English. Culpeper was a nonconformist in loyalist England, and was determined to make medical knowledge more accessible to the apothecaries, the tradesmen who prescribed most of the herbal remedies. Culpeper's herbal was criticized by the medical establishment for its mix of magic and astrology with botanical medicine, but it became one of the most popular compendiums of botanical medicine of its day. Culpeper also accepted the so-called "Doctrine of Signatures," practiced by medieval monks in their medicinal gardens. This theory teaches that the appearance of plants is the clue to their curative powers. Plants were chosen for treatment of particular medical conditions based on their associations with the four natural elements and with a planet or sign. The place where the plant grows, its dominant physical feature, and the **smell** and taste of an herb determined the plant's signature. Culpeper's herbal is still in print in facsimile copies, and some pharmacognosists and herbalists in the twenty-first century voice the same criticisms that Culpeper's early critics did.

European colonists brought their herbal knowledge and plant specimens to settlements in North America where they learned from the indigenous Americans how to make use of numerous nutritive and medicinal plants native to the New World. Many European medicinal plants escaped cultivation from the early settlements and have become naturalized throughout North America. The first record of Native American herbalism is found in the manuscript of the native Mexican Indian physician, Juan Badianus published in 1552. The American Folk tradition of herbalism developed as a blend of traditional European medicine and Native American herbalism. The pioneer necessity for self-reliance contributed to the perseverance of folk medicine well into the twentieth century.

In Europe in the seventeenth century, the alchemist Paracelsus changed the direction of western medicine with the introduction of chemical and mineral medicines. He was the son of a Swiss chemist and physician. Paracelsus began to apply chemicals, such as arsenic, mercury, sulfur, **iron**, and **copper** sulfate to treat disease. His chemical approach to the treatment of disease was a forerunner to the reliance in the twentieth century on

chemical medicine as the orthodox treatment prescribed in mainstream medical practice.

The nineteenth and twentieth centuries brought a renewed interest in the practice of western herbalism and the development of natural therapies and health care systems that ran counter to the mainstream methods of combating disease symptoms with synthetic pharmaceuticals.

In the late eighteenth century, the German physician Samuel Hahnemann developed a system of medicine known as **homeopathy**. This approach to healing embraces the philosophy of “like cures like.” Homeopathy uses extremely diluted solutions of herbs, animal products, and chemicals that are believed to hold a “trace memory” or energetic imprint of the substance used. Homeopathic remedies are used to amplify the patient’s symptoms with remedies that would act to produce the same symptom in a healthy person. Homeopathy holds that the symptoms of illness are evidence of the body’s natural process of healing and eliminating the cause of the disease.

In 1895, the European medical system known as Naturopathy was introduced to North America. Like homeopathy, this medical approach is based on the Hippocratic idea of eliminating disease by assisting the body’s natural healing abilities. The naturopath uses non-toxic methods to assist the body’s natural healing processes, including nutritional supplements, herbal remedies, proper diet, and **exercise** to restore health.

Western herbalism is regaining popularity at a time when the world is assaulted by the **stress** of overpopulation and development that threatens the natural biodiversity necessary for these valuable medicinal plants to survive. The American herb market is growing rapidly and increasing numbers of individuals are choosing alternative therapies over the mainstream allopathic western medicine. It is projected that by the year 2002 consumers will spend more than seven billion dollars a year on herbal products. An estimated 2,400 acres of native plant habitat is lost to development every day. As much as 29% of all plant life in North America is in danger of extinction, including some of the most important native medicinal plants, according to the 1997 World Conservation Union Red List of Threatened Plants.

Though research into the efficacy and safety of traditional herbal remedies is increasing, it has been limited by the high costs of clinical studies and laboratory research, and by the fact that whole plants and their constituents are not generally patentable (therefore, there is no drug profit after market introduction). Outside the United States, herbalism has successfully combined with conventional medicine, and in some countries is fully integrated into the nations’ health care systems. At the

beginning of the twenty-first century, 80% of the world’s population continues to rely on herbal treatments. The World Health Organization, an agency of the United Nations, promotes traditional herbal medicine for treatment of many local health problems, particularly in the third world where it is affordable and already well-integrated into the cultural fabric.

In the United States, the re-emergence in interest in holistic approaches to health care is evident. Citizens are demanding access to effective, safe, low-cost, natural medicine. Legislative and societal change is needed, however, before natural therapies can be fully integrated into the orthodox allopathic health care system and provide citizens with a wide range of choices for treatment. If the current trend continues, U. S. citizens will benefit from a choice among a variety of safe and effective medical treatments.

Benefits

The benefits of botanical medicine may be subtle or dramatic, depending on the remedy used and the symptom or problem being addressed. Herbal remedies usually have a much slower effect than pharmaceutical drugs. Some herbal remedies have a cumulative effect and work slowly over time to restore balance, and others are indicated for short-term treatment of acute symptoms. When compared to the pharmaceutical drugs, herbal remedies prepared from the whole plant have relatively few side effects. This is due to the complex chemistry and synergistic action of the full range of phytochemicals present in the whole plant, and the relatively lower concentrations. They are generally safe when used in properly designated therapeutic dosages, and less costly than the isolated chemicals or synthetic prescription drugs available from western pharmaceutical corporations.

Description

Herbs are generally defined as any plant or plant part that may be used for medicinal, nutritional, culinary, or other beneficial purposes. The active constituents of plants (if known) may be found in varying amounts in the root, stem, leaf, flower, and fruit, etc. of the plant. Herbs may be classified into many different categories. Some western herbalists categorize herbal remedies according to their strength, action, and characteristics. Categories may include sedatives, stimulants, **laxatives**, febrifuges (to reduce **fever**), and many others. One system of classification is based on a principle in traditional Chinese medicine that categorizes herbs into four classes: tonics, specifics, heroics, or cleansers and protectors. Within these broad classifications are the numerous medicinal

actions of the whole herb which may be due to a specific chemical or combination of chemicals in the plant.

- **Tonics.** Herbs in this classification are also known as alteratives in western herbalism. They are generally mild in their action and act slowly in the body, providing gentle stimulation and **nutrition** to specific organs and systems. Tonic herbs act over time to strengthen and nourish the whole body. These herbs are generally safe and may be used regularly, even in large quantities. These tonic herbs are known as “superior” remedies in traditional Chinese medicine. The therapeutic dose of tonic remedies is far removed from the possible toxic dose. American ginseng is an example of a tonic herb.
- **Specifics.** Herbs in this classification are strong and specific in their therapeutic action. They are generally used for short periods of time in smaller dosages to treat acute conditions. Herbs classified as specifics are not used beyond the therapeutic treatment period. Echinacea is a specific herb.
- **Heroic.** These herbs offer high potency but are potentially toxic, and should not be used in self-treatment. Because the therapeutic dosage may be close to the lethal dosage, these herbs are presented cautiously and closely monitored or avoided by trained clinicians. They should not be used continuously or without expert supervision. Poke (*Phytolacca americana*) is an example of a heroic remedy.
- **Cleansers and protectors.** These herbs, plants, and plant tissues remove wastes and pollutants, while minimally affecting regular body processes. An example of a cleanser is pectin. Pectins are the water soluble substances that bind cell walls in plant tissues, and some believe that they help remove heavy metals and environmental toxins from the body.

Preparations

Herbal preparations are commercially available in a variety of forms including tablets or capsules, tinctures, teas, fluid extracts, douches, washes, suppositories, dried herbs, and many other forms. The medicinal properties of herbs are extracted from the fresh or dried plant parts by the use of solvents appropriate to the particular herb. Alcohol, oil, water, vinegar, glycerin, and propylene glycol are some of the solvents used to extract and concentrate the medicinal properties. Steam distillation and cold-pressing techniques are used to extract the essential oils. The quality of any herbal remedy and the potency of the phytochemicals found in the herb depends greatly on the conditions of weather and soil where the herb was grown, the timing and care in harvesting, and the manner of preparation and storage.

Precautions

Herbal remedies prepared by infusion, decoction, or alcohol tincture from the appropriate plant part, such as the leaf, root, or flower are generally safe when ingested in properly designated therapeutic dosages. However, many herbs have specific contraindications for use when certain medical conditions are present. Not all herbal remedies may be safely administered to infants or small children. Many herbs are not safe for use by pregnant or lactating women. Some herbs are toxic, even deadly, in large amounts, and there is little research on the chronic toxicity that may result from prolonged use. Herbal remedies are sold in the United States as dietary supplements and are not regulated for content or efficacy. Self-diagnosis and treatment with botanical medicinals may be risky. A consultation with a clinical herbalist, Naturopathic physician, or certified clinical herbalist is prudent before undertaking a course of treatment.

Essential oils are highly concentrated and should not be ingested as a general rule. They should also be diluted in water or in a non-toxic carrier oil before application to the skin to prevent contact dermatitis or photo-sensitization. The toxicity of the concentrated essential oil varies depending on the chemical constituents of the herb.

The American Professor of Pharmacognosy, Varro E. Tyler, believes that “herbal chaos” prevails in the United States with regard to herbs and phytomedicinals. In part he blames the herb producers and marketers of crude herbs and remedies for what he terms unproven hyperbolic, poor quality control, deceptive labeling, resistance to standardization of dosage forms, and continued sale of herbs determined to be harmful.

Side effects

Herbs have a variety of complex phytochemicals that act on the body as a whole or on specific organs and systems. Some of these chemical constituents are mild and safe, even in large doses. Other herbs contain chemicals that act more strongly and may be toxic in large doses or when taken continuously. **Drug interactions** are possible with certain herbs when combined with certain pharmaceutical drugs. Some herbs are tonic in a small amount and toxic in larger dosages.

Research and general acceptance

Western herbalism is experiencing a revival of popular and professional interest. The number of training schools and qualified herbal practitioners is growing to meet the demand. Western herbalism is incorporated into the medical practice of licensed Naturopathic doctors, who receive special training in clinical herbalism. Folk

KEY TERMS

In vitro—A biological reaction occurring in a laboratory apparatus.

In vivo—Occurring in a living organism.

Phyto-, as in phytochemical, phytomedicinal, and phytotherapy—Meaning, or pertaining to, a plant or plants.

Wildcrafting—Gathering of herbs or other natural materials.

herbalists, heir to the continuing oral traditions passed from generation to generation in many rural areas, as well as amateur, self-taught herbalists, keep the practice of botanical medicine alive at the grassroots level. Traditional western herbalism relies on traditional use and materia medica, folk wisdom, and recent clinical research and advances in the extraction processes. These advances provide increased quality control on the concentration and potency of the active ingredients. Western physicians, educated in allopathic medicine, typically receive no training in the use of herbs. These doctors rely on pharmaceutical drugs for their patients, and some cite the following reasons for continuing to do so: lack of standardized dosages, lack of quality control in the preparation of herbal medicinals, and the dearth of clinical research verifying the safety and effectiveness of many traditional herbal remedies.

Herbalism is widely practiced throughout Europe, particularly in England, France, Italy, and Germany where phytomedicinals are available in prescription form and as over-the-counter remedies. In Germany, plant medicines are regulated by a special government body known as the Commission E. In the United States, however, despite increasing popularity, traditional herbalism is not integrated into the allopathic medical system. Phytomedicinals are sold as dietary supplements rather than being adequately researched and recognized as safe and effective drugs. The Dietary Supplement Health and Education Act of 1994 circumvented a U. S. Food and Drug Administration (FDA) effort to effectively remove botanicals from the marketplace and implement regulations restricting sale. Massive popular outcry against the proposed regulations on the sale of herbs and phytomedicinals resulted in this Congressional action. In 2000, U.S. President Bill Clinton, by executive order, created the White House Commission on Alternative Medicine in an effort to hold alternative medicine therapies “to the same standard of scientific rigor as more traditional health care interventions.” That Commission is charged

with recommending federal guidelines and legislation regarding the use of alternative medical therapies in the twenty-first century.

Training and certification

In the United States, courses of study in Western herbalism are available in almost all of the fifty states. The study of traditional herbalism is part of the course curriculum in Naturopathic medical colleges that offer four-year degree programs leading to licensure as a Doctor of Naturopathy. The oldest of these institutions is the National College of Naturopathic Medicine, established in 1956. Western clinical herbalism is taught through a growing number of institutions and organizations offering training and certification through residential and apprenticeship programs, and by correspondence. Some programs are comprehensive, with curricula in physiology, clinical diagnosis and treatment, ethnobotany, pharmacognosy, phytotherapy, plant identification, ethical wildcrafting and cultivation, and preparation and application of herbal remedies. Other programs are brief, geared more to the amateur herbalist and gardener. The Southwest School of Botanical Medicine in Bisbee, Arizona, is one of the oldest herbal schools, established in 1978. No licensing body yet exists in the United States to regulate the practice of herbal medicine.

In the United States herbal remedies are sold as dietary supplements. They are not regulated as to content and efficacy, and few are prepared in standardized dosages. Many of the supplements commercially available base claims for efficacy on traditional use and anecdotal evidence that has not been duplicated by clinical studies. In Germany, an expert committee known as the Commission E, was established by that government in 1978 to evaluate the safety and efficacy of the three hundred herbs and herb combinations sold in that country. No equivalent regulatory commission exists in the United States. Permits are required in some states for the wildcrafting of rare and endangered herbs, such as goldenseal and American ginseng, two commercially valuable herbs in high demand in the growing medical botanicals industry.

Herniated disk

Definition

Disk herniation is a rupture of fibrocartilagenous material (annulus fibrosis) that surrounds the intervertebral disk. This rupture involves the release of the disk's center portion containing a gelatinous substance called the nucleus pulposus. Pressure from the vertebrae above and below may cause the nucleus pulposus to be forced outward, placing pressure on a spinal nerve and causing considerable **pain** and damage to the nerve. This condition most frequently occurs in the lumbar region and is also commonly called herniated nucleus pulposus, prolapsed disk, ruptured intervertebral disk, or slipped disk.

Description

The spinal column is made up of 26 vertebrae that are joined together and permit forward and backward bending, side bending, and rotation of the spine. Five distinct regions comprise the spinal column, including the cervical (neck) region, thoracic (chest) region, lumbar (low back) region, sacral and coccygeal (tailbone) region. The cervical region consists of seven vertebrae, the thoracic region includes 12 vertebrae, and the lumbar region contains five vertebrae. The sacrum is composed of five fused vertebrae, which are connected to four fused vertebrae forming the coccyx. Intervertebral disks lie between each adjacent vertebra.

Each disk is composed of a gelatinous material in the center, called the nucleus pulposus, surrounded by rings of a fibrous tissue (annulus fibrosus). In disk herniation, an intervertebral disk's central portion herniates through the surrounding annulus fibrosus into the spinal canal, putting pressure on a nerve root. (There is often a progression of small fissures in the annulus fibrosis before the disk herniates.) Disk herniation most commonly affects the lumbar region between the fifth lumbar vertebra and the first sacral vertebra. However, disk herniation can also occur in the cervical spine. The incidence of cervical disk herniation is most common between the fifth and sixth cervical vertebrae. The second most common area for cervical disk herniation occurs between the sixth and seventh cervical vertebrae. Disk herniation is less common in the thoracic region.

Predisposing factors associated with disk herniation include age, gender, and work environment. The peak age for occurrence of disk herniation is between 20–45 years of age. Studies have shown that males are more commonly affected than females in lumbar disk herniation by a 3:2 ratio. Genetic factors are suspected of playing a role in disk herniation. Prolonged exposure to a bent-forward work posture is correlated with an increased incidence of disk herniation. Pain from a herniated disk is usually greatest when sitting and is lessened when standing.

There are four classifications of disk pathology:

- A protrusion may occur where a disk bulges without rupturing the annulus fibrosis.
- The disk may prolapse where the nucleus pulposus migrates to the outermost fibers of the annulus fibrosis.
- There may be a disk extrusion, which is the case if the annulus fibrosis perforates and material of the nucleus moves into the epidural space.
- The sequestered disk may occur as fragments from the annulus fibrosis and nucleus pulposus are outside the disk proper.

Causes and symptoms

Any direct, forceful, and vertical pressure on the lumbar disks can cause the disk to push its fluid contents into the vertebral body. Herniated nucleus pulposus may occur suddenly from lifting, twisting, or direct injury, or it can occur gradually from degenerative changes with episodes of intensifying symptoms. As individuals age, the intervertebral disk changes in shape and volume. Changes in the chemical and mechanical characteristics of the disk also occur. It is these changes that predispose certain individuals to disk herniation. The annulus may also become weakened over time, allowing stretching or tearing and leading to a disk herniation. Depending on the location of the herniation, the herniated material can also press directly on nerve roots or on the **spinal cord**, causing a shock-like pain (**sciatica**) down the legs, weakness, numbness, or problems with bowels, bladder, or sexual function.

Diagnosis

A variety of non-invasive physical tests can be performed to help diagnose disk herniation. A straight-leg raising test may be performed by the health practitioner. If severe pain is produced in the back of the leg, then it may suggest a lumbar nerve root problem. A crossed straight-leg raising test may also be performed. This involves raising the leg opposite to that with current pain. This test tends to produce a more localized but less intense pain than the straight-leg raising test. Several radiographic tests are useful for confirming a diagnosis of disk herniation and locating the source of pain. These tests also help the surgeon indicate the extent of the surgery needed to fully decompress the nerve. X rays show structural changes of the lumbar spine. **Myelography** is a special x ray of the spine in which a dye or air is injected into the patient's spinal canal. The patient lies strapped to a table as the table tilts in various directions and spot x rays are taken. X rays showing a narrowed dye column in the intervertebral disk area indicate possible disk herniation.

Computed tomography, or computed axial tomography (CT or CAT) scans reveal the details of pathology necessary to obtain consistently good surgical results. **Magnetic resonance imaging** (MRI) analysis of the disks can accurately detect the early stages of disk aging and degeneration. MRI is most useful in assessing how the disk and nerve roots change over time. The MRI has become the standard diagnostic imaging tool for disk herniation. A newer technology called magnetic resonance myelography does not provide a better overall image of the spine than an MRI, but it can improve diagnosis of disk herniation in some cases.

Treatment

Drugs

Unless serious neurologic symptoms occur, herniated disks can initially be treated with pain medication and up to 48 hours of bed rest. There is no proven benefit from resting more than 48 hours. Many patients benefit from lying on a very firm mattress or an ordinary mattress with a board placed underneath. Heat or cold applied to the affected region often helps many patients. Patients are then encouraged to gradually increase their activity. Pain medications, including non-steroidal anti-inflammatory drugs, muscle relaxers, or in severe cases, narcotics, may be continued if needed.

Epidural steroid injections have been used to decrease pain by injecting an anti-inflammatory drug, usually a corticosteroid, around the nerve root to reduce inflammation and **edema** (swelling). This partly relieves the pressure on the nerve root as well as resolves the inflammation. Some physicians are using trigger point injections of lidocaine without epinephrine to provide localized pain relief for extended periods of time. Some of these physicians also use electrical or ultrasound therapy over these localized areas, but these methods have not been scientifically validated.

Physical therapy

Physical therapists are skilled in treating acute back pain caused by disk herniation. The physical therapist can provide noninvasive therapies, such as ultrasound or diathermy to project heat deep into the tissues of the back or administer manual therapy, if mobility of the spine is impaired. They may help improve posture and develop an **exercise** program for recovery and long-term protection. Appropriate exercise can help take pressure off inflamed nerve structures, while improving overall posture and flexibility. Traction can be used to try to decrease pressure on the disk. A lumbar support can be helpful for a herniated disk at this level as a temporary measure to reduce pain and improve posture.

Surgery

Surgery is often appropriate for conditions that do not improve with the usual treatment. In this event, a strong, flexible spine is important for a quick recovery after surgery. There are several surgical approaches to treating a herniated disk, including the classic discectomy, microdiscectomy, or percutaneous discectomy. The basic differences among these procedures are the size of the incision, how the disk is reached surgically, and how much of the disk is removed.

Discectomy is the surgical removal of the portion of the disk that is putting pressure on a nerve causing the back pain. In the classic discectomy, the surgeon first enters through the skin and then removes a bony portion of the vertebra called the lamina, hence the term laminectomy. The surgeon removes the disk material that is pressing on a nerve. Rarely is the entire lamina or disk removed. Often, only one side is removed and the surgical procedure is termed hemilaminectomy.

In microdiscectomy, through the use of an operating **microscope**, the surgeon removes the offending bone or disk tissue until the nerve is free from compression or stretch. This procedure is possible using **local anesthesia**. Microsurgery techniques vary and have several advantages over the standard discectomy, such as a smaller incision, less trauma to the musculature and nerves, and easier identification of structures by viewing into the disk space through microscope magnification.

Percutaneous disk excision is performed on an outpatient basis, is less expensive than other surgical procedures, and does not require a **general anesthesia**. The purpose of percutaneous disk excision is to reduce the volume of the affected disk indirectly by partial removal of the nucleus pulposus, leaving all the structures important to stability practically unaffected. In this procedure, large incisions are avoided by inserting devices that have cutting and suction capability. Suction is applied and the disk is sliced and aspirated.

Arthroscopic microdiscectomy is similar to percutaneous discectomy, however it incorporates modified arthroscopic instruments, including scopes and suction devices. A suction irrigation of saline solution is established through two entry sites. A video discoscope is introduced from one site and the deflecting instruments from the opposite side. In this way, the surgeon is able to search and extract the nuclear fragments under direct visualization.

Laser disk decompression is performed using similar means as percutaneous excision and arthroscopic microdiscectomy, however laser energy is used to remove the disk tissue. Here, laser energy is percutaneously introduced through a needle to vaporize a small volume of nucleus pulposus, thereby dropping the pressure of the disk and decompressing the involved neural tissues. One disadvantage of this procedure is the high initial cost of the laser equipment. It is important to realize that only a very small percentage of people with herniated lumbar disks go on to require surgery. Further, surgery should be followed by appropriate rehabilitation to decrease the chance of reinjury.

Chemonucleolysis

Chemonucleolysis is an alternative to surgical excision. Chymopapain, a purified enzyme derived from the papaya plant, is injected percutaneously into the disk space to reduce the size of the herniated disks. It hydrolyses **proteins**, thereby decreasing water-binding capacity, when injected into the nucleus pulposus inner disk material. The reduction in size of the disk relieves pressure on the nerve root.

Spinal fusion

Spinal fusion is the process by which bone grafts harvested from the iliac crest (thick border of the ilium located on the pelvis) are placed between the intervertebral bodies after the disk material is removed. This approach is used when there is a need to reestablish the normal bony relationship between the vertebrae. A total discectomy may be needed in some cases because lumbar spinal fusion can help prevent recurrent lumbar disk herniation at a particular level.

Alternative treatment

Acupuncture involves the injection of fine needles to relieve pain. An acupuncturist determines the location of the nerves affected by the herniated disk and positions the needles appropriately. Massage therapists may also provide short-term relief from a herniated disk. Following manual examination and x-ray diagnosis, chiropractic treatment usually includes manipulation to correct muscle and joint malfunctions, while care is taken not to place an additional strain on the injured disk. If a full trial of conservative therapy fails, or if neurologic problems (weakness, bowel or bladder problems, and sensory loss) develop, the next step is usually evaluation by an orthopedic surgeon.

Health care team roles

Nurses play an important role in the diagnosis and treatment of disk herniation disease. They assist health care practitioners in performing basic physical testing, such as the straight-leg raising test. They also play an important role in determining the history of the patient and how the patient developed the herniated disk. They also will often assist in procedures such as the steroid or lidocaine injection. Surgical nurses assist in the operative repair of herniated disks.

Physical therapists play an important role in the prevention and treatment of patients with herniated disk disease. They can create an exercise and posture program that can reduce the risk of developing the condition in the

KEY TERMS

Annulus fibrosus—The outer portion of the intervertebral disk made primarily of fibrocartilage rings.

Epidural space—The space immediately surrounding the outer most membrane of the spinal cord.

Excision—The process of excising, removing, or amputating.

Fibrocartilage—Cartilage that consists of dense fibers.

Nucleus pulposus—The center portion of the intervertebral disk that is made up of a gelatinous substance.

Percutaneous—Performed through the skin.

first place as well as generate a course of therapy that will help restore function in those with serious disease.

Radiologic technologists play a critical role in the diagnosis of disk herniation. They are involved in the three most important diagnostic imaging tests: CAT scans, MRI procedures, and x rays.

Patient education

Nurses play a critical role in **patient education** in the prevention and treatment of disk herniation. One of the most important areas in which they educate patients is following disk herniation surgery. These **postoperative care** instructions are vital to the success of the surgery. Pharmacists play a key role in dispensing accurate information about the proper use of drugs, particularly non-steroidal anti-inflammatory agents, **muscle relaxants**, and narcotic-based compounds. They also provide instructions to patients on the proper use of drugs prescribed following surgery. Physical therapists instruct individuals on how to properly lift heavy objects, how to maintain good posture while working and during other activities, and how to perform certain exercises to prevent or treat disk herniation. Occupational therapists provide information to individuals and employers on how to minimize back and neck strain in the workplace. Dietitians can design a weight-loss program in those cases where extra weight helped precipitate and aggravate disk herniation.

Prognosis

Only 5–10% of patients with unrelenting sciatica and neurological involvement, leading to chronic pain of the lumbar spine, need to have a surgical procedure performed. This strongly suggests that many patients with herniated disks at the lumbar level respond well to conservative treatment. For those patients who do require surgery for lumbar disk herniation, the reviewed procedures of nerve root decompression caused by disk herniation is favorable. Results of studies varied from 60–90% success rates. Disk surgery has progressively evolved in the direction of decreasing invasiveness. Each surgical procedure is not without possible complications, which can lead to chronic low back pain and restricted lifestyle.

Prevention

Proper exercises to strengthen the lower back and abdominal muscles are key in preventing excess stress and compressive forces on lumbar disks. Good posture will help prevent problems on cervical, thoracic, and lumbar disks. A good flexibility program is critical for prevention of muscle and spasm that can cause an increase in compressive forces on disks at any level. Proper lifting of heavy objects is important for all muscles and levels of the individual disks. Good posture in sitting, standing, and lying down is helpful for the spine. Losing weight, if needed, can prevent weakness and unnecessary stress on the disks caused by **obesity**. Choosing proper footwear may also be helpful to reduce the impact forces to the lumbar disks while walking on hard surfaces. Wearing special back support devices may be helpful if heavy lifting is required with combinations of twisting.

High-risk pregnancy

Definition

A **pregnancy** that has maternal or fetal complications requiring special medical attention or bed rest is considered to be high-risk. Complications, as used here, mean the risk of illness or death before or after delivery is greater than normal for the mother or baby.

Description

Risk factors in pregnancy are those findings discovered during prenatal assessment that are known to have a potentially negative effect on the outcome of the pregnancy, either for the woman or the fetus. This evaluation determines whether or not the mother has characteristics or conditions that make her or her baby more likely to become sick or die during the pregnancy.

Causes and symptoms

All risk factors do not threaten pregnancy to the same extent. The risk of complications is increased by smoking, poor nutritional habits, drug and alcohol abuse, domestic violence, prepregnancy maternal health status, psychosocial factors, prior health care, the presence of chronic medical problems in the mother, past history of repeated preterm delivery, multiple gestation, and abnormalities of the fetus or placenta. A woman with a high-risk pregnancy may have an earlier labor and delivery depending upon the fetal or maternal complication present and, likewise, present with symptoms dependent upon the condition. Since the placenta supplies the baby with its nutrients and oxygen, any condition that threatens the **blood** supply to it threatens **fetal development**.

The threat of a preterm delivery is the most common reason for a referral to a perinatal center, which is linked to obstetric and newborn services that provide the highest level of care for a pregnant woman and her baby. A preterm delivery may occur because of a premature rupture of membranes (the bag of water surrounding the baby breaks) or **preterm labor**. There is a strong correlation of vaginal or uterine **infection** with the pregnant woman’s water breaking, and there are lab tests that can be predictive of a woman’s risk of experiencing preterm labor.

According to a 2001 report from the U.S. Centers for Disease Control and Prevention, there were 29.6 deaths per 100,000 births among African-American women between 1991 and 1997. The rate for women of Hispanic origin was 10.3, and for white women it was 7.3. The rate for Asian women was unavailable. The second most common causes of death in women are problems related to pregnancy and delivery, including blood clots that travel to the **lungs**, anesthesia complications, bleeding, infection, and high **blood pressure** complications. A baby dies before, during, or after birth in 16 out of 1,000 deliveries in the United States. Almost 50% of these deaths are stillbirths, which are sometimes unexplained. The rest of the deaths occur in babies up to 28 days old, and the leading cause of these is birth defects, followed by prematurity. Risk factors can be present before pregnancy occurs and others develop during pregnancy.

Diagnosis

A risk-scoring sheet is utilized by many healthcare agencies during the prenatal assessment to establish if a woman may be at risk for complications during her pregnancy. This score sheet is implemented at the first prenatal visit, becomes a part of the woman’s record, and is updated throughout the pregnancy as necessary. A

KEY TERMS

Amniocentesis—A procedure that uses ultrasound to guide a needle into the amniotic sac (bag of waters) surrounding the baby and obtain fluid to analyze for genetic abnormalities.

Antepartum—This refers to the time period of the woman's pregnancy from conception and onset of labor.

Perinatal—Refers to the period shortly before and after birth, generally from around the 20th week of pregnancy to one to four weeks after birth.

Perinatologist—A specialist in the branch of obstetrics that deals with the high-risk pregnant woman and her fetus.

Preconceptional—This refers to the time period before pregnancy, i.e., conception, occurs.

Ultrasonographer—The person who performs the radiologic technique of ultrasound in which deep structures of the body are visualized.

woman's age affects pregnancy risk, as girls 15 years old and under are more likely to develop high blood pressure, protein in the urine and fluid accumulation (preeclampsia), or seizures (eclampsia). They also are more likely to have underweight or undernourished babies. A woman 35 or older has a greater risk of developing high blood pressure or diabetes, as well as a much higher risk of having a chromosomal abnormality such as **Down syndrome**. A woman shorter than five feet or a woman weighing less than 100 pounds before pregnancy has a greater risk of having a small or preterm baby.

Lab data and ultrasound are also utilized to determine high-risk pregnancies by specific blood tests and imaging of the baby. A pregnancy may begin as low risk and change to high risk secondary to complications determined from the ongoing assessment of the pregnant woman. Since many of these complications can be managed with proper treatment, it is essential that a pregnant woman keep her obstetric appointments.

Treatment

Treatment will vary, depending upon the maternal or fetal complication present. Generally, a woman with severe high-risk factors in pregnancy should be referred to a perinatal center to obtain the highest level of care for herself and her baby. Interventions to improve health status might include nutritional assessment, **physical**

examination, teaching modalities for smoking cessation, drug and alcohol programs, prescribing medications related to the condition, or changing pre-pregnancy medications (known to cause problems in the fetus), serial ultrasounds to learn fetal status, **amniocentesis**, fetal transfusions, fetal surgery, **antepartum testing**, bed rest, home health care, hospitalization, and early delivery. In a postterm pregnancy (greater than 42 weeks), the death of a baby is three times more likely than that of a normal term pregnancy (37–40 weeks). The treatment in this case would be to induce labor before problems start to occur with an aging placenta.

Prognosis

Advances in the management of complications in high-risk pregnancies have provided women with a means of controlling their risks, which substantially increases the potential for a successful outcome. Since it is impossible to guarantee a good outcome in a normal pregnancy, it is even more difficult to ensure that a high-risk pregnancy will result in a healthy infant and mother. A woman who strictly adheres to the medical regimen established for her, however, will greatly increase her chances of a positive result.

Health care team roles

The pregnant woman's interview at her first visit the health care provider is conducted by the nurse, who obtains the data necessary to begin the high-risk screening. The physician or midwife caring for a pregnant woman should review the prenatal assessment sheet, order lab data, and obtain ultrasounds to determine if any risk factors are present. If it is determined that a woman has a high-risk pregnancy, she should be referred to a perinatologist for advanced care. This is the specialist who establishes and implements the medical regimen needed for the particular maternal/fetal complication and the inter-disciplinary team associated with the perinatal center works in its management. The perinatal team usually comprises a nutritionist, social worker, nurse educators, geneticists, ultrasonographers, and additional nursing staff who are responsible for the monitoring and supervising of ongoing team care of the patient.

Prevention

The early weeks of pregnancy are the most crucial ones for the fetus. Many women do not know they are pregnant until several weeks after conception, so education about the need for preconceptional care is essential. **Preconception counseling** guides a woman in planning

a healthy pregnancy. These are some of the factors to which attention must be paid:

- family history
- medical history
- past pregnancies
- current medications
- lifestyle
- environment
- infections

Cigarette smoking is the most common addiction among pregnant women in the United States, and despite the health hazards of smoking being well-known, only about 20% of these women actually quit during pregnancy. One risk of smoking during pregnancy is having a baby who may die from sudden infant death syndrome (SIDS).

Drugs known to cause birth defects when taken during pregnancy include: alcohol, dilantin (phenytoin), any drug that interferes with the actions of **folic acid**, lithium, streptomycin, tetracycline, thalidomide, warfarin (Coumadin), and isotretinoin (Accutane), which is prescribed for acne. The number one preventable cause of mental retardation in infants is the abuse of alcohol during pregnancy. Alcohol can cause problems ranging from **miscarriage** to severe behavioral problems in the baby or developing child even if no obvious physical birth defects are apparent. **Fetal alcohol syndrome** is seen in about two out of 1000 live births. Infections that may cause birth defects include: herpes simplex, viral hepatitis, the flu, mumps, German measles (rubella), chickenpox (varicella), **syphilis**, toxoplasmosis (occurs from eating undercooked meat and handling kitty litter), listeriosis, and infections from the coxsackievirus or cytomegalovirus (CMV). Many adults have been exposed to coxsackievirus and CMV when they were younger, but there are many who have not been. Those who have not been exposed should pay careful attention to any illnesses they have early in their pregnancy, noting the onset, presence of **fever**, muscle aches and pains, and duration of illness to report to their physician.

Hemolytic disease of the newborn (destruction of the red blood cells) can occur when Rh incompatibility exists between child and mother. The most common cause of incompatible blood types is Rh incompatibility—such as when the mother has Rh-negative blood and the father has Rh-positive blood. The baby may have Rh-positive blood, in which case the mother's body produces antibodies against the baby's blood. Fortunately, the mother can be treated with Rhogam [Rh0(D)immune globulin], which can be given to the mother in the first 72 hours

after delivery and at the twenty-eighth week of pregnancy; it will destroy any antibodies produced by her blood and significantly decrease the risk associated with pregnancies with Rh-factor incompatibilities.

There are, however, other incompatible blood factors during the prenatal assessment period that can cause anemia in the fetus and require ongoing monitoring. The greatest gift a woman gives herself is to plan her pregnancy with preconceptional counseling. Many women are frequently deficient in folic acid, a B vitamin used in the synthesis of ribonucleic acid (RNA) and essential, in large quantities, for optimal protein synthesis in the fetus. This is especially true in the early weeks of pregnancy, when all **cell division** and organ development is occurring. Thus, the best prevention for a high risk pregnancy is good planning.

Hinge joint

Definition

Hinge joints are places in the human skeleton where the ends of bones meet and rotate uniaxially (in a single plane, like a knuckle or elbow). They are lubricated with synovial fluids, secreted by the synovial membrane, to ensure easy, pain-free movement.

Description

Hinge joints, also called ginglymi or ginglymus joints, act like the hinges on a cabinet or door to provide back and forth movement. However, unlike their hardware namesakes, hinge joints provide more movement than just back and forth swing. They have a varying spiral profile that allows some rotation. The interphalangeal (finger) and humeroulnar (elbow) joints are examples of the hinge joint. The knee is also a hinge joint.

Function

The purpose of joints is to provide movement for the body. Different types of joints move in different ways. The hinge joint is shaped to restrict movement to one plane. It has strong collateral ligaments that aid and restrict movement. The ends of the bones are covered with tough cartilage and are lined with the synovial membrane.

Each joint contains a small amount of synovial fluid which lubricates it. Synovial fluid provides protection for the hinge joint and allows for its stress-free movement.

The hinge joint provides a connection that allows articular surfaces to be closely molded together. This molding together permits extensive motion in one plane. The joint has stabilizing ligaments that limit the directions and extent to which the bones can be moved. The hinge joint moves back and forth with some rotation allowed.

Role in human health

Because synovial joints are the most mobile and intricate of all the joints, they are also the most prone to disease. Healthy hinge joints allow effortless, painfree mobility; diseased hinge joints are not only a source of physical **pain**, but also place severe limitations on movement. These limitations, in turn, can have adverse psychological consequences.

Common diseases and disorders

There are many disorders and diseases that can afflict the joints, making the hinge joints vulnerable to pain and discomfort. Degenerative and inflammatory diseases, conditions involving the membranes around the joints, generalized and congenital disorders, and dislocation and **fractures** can all cause damage to the hinge joints.

Arthritis is one of the conditions that causes pain and dysfunction in the hinge joint. There are several types of arthritis, but **osteoarthritis** and rheumatoid arthritis are the most common.

Osteoarthritis is a degenerative disease that affects the cartilage in the joints, and can cause inflammation in the tissues surrounding the affected joint or joints. Degeneration is commonly thought to be caused by stress on the joints or by injury to the joint lining. Osteoarthritis can affect all joints, but it is usually found in the fingers, feet, hips, spine, and knees. It causes joint stiffness and pain. Symptoms of osteoarthritis can be treated, but the disease is irreversible.

Rheumatoid arthritis is an inflammatory disease of the muscles and the membrane linings of cartilage and joints. The areas commonly affected are the hands, hips, knees, legs, and joints. The symptoms include low-grade **fever**, stiffness in the morning, and redness, pain, warmth, and tenderness in the affected joints. Rheumatoid arthritis can cause crippling pain and deformities of the hands and causes painful swelling of the joints.

Bursitis is a common disorder that affects the hinge joints and other joints. It is most often found in the elbow, knee, and shoulders. Bursitis is the inflammation of the bursa, flat sacs that surround the joints. Symptoms of bursitis are swelling, tenderness, pain, and warmth around the joint. The inflammation of the bursa is usually caused by overuse or injury of the joint. Two common types of bursitis are “housemaid’s knee,” which is caused by kneeling on hard surfaces for an extended period of time and “student’s elbow,” which is caused by leaning the arm against a desk or other hard surface.

KEY TERMS

Axis—A central or principal structure about which something turns or is arranged. The hinge joint has one axis.

Bursitis—Inflammation of the bursa—flat sacs that surround the joints—usually caused by overuse or injury of the joint. “Housemaid’s knee” and “student’s elbow” are common forms of bursitis.

Osteoarthritis—A degenerative disease, usually found in the fingers, feet, hips, spine, and knees, that affects cartilage in the joints, and can cause inflammation in the surrounding tissues.

Rheumatoid arthritis—An inflammatory disease, related to a streptococcus infection, that affects muscles and the membrane linings of cartilage and joints. It can cause crippling pain, deformities of the hands, and painful swelling of the joints.

Synovial fluid—A transparent, viscous fluid found in the synovial joints. It lubricates the joint for easier movement.

Uniaxial—Having only one axis. The hinge joint is a uniaxial joint.

Hip fractures rehabilitation

Definition

The hip is a ball and socket type joint that has an influence on the pelvis and lumbar spine. The hip joint helps control and stabilize the lower limb, and plays an

integral part in lower limb mechanics including walking and climbing stairs. The hip joint is formed by the head of the femur and the acetabulum area of the pelvis. The femoral head sits deep into the concave acetabulum and is bound firmly by ligaments, a joint capsule, and muscles. The muscles around the hip act to move the lower limb. An example would be the moving of one’s thigh (femur) forward by contracting the muscles that flex the hip. Muscles act to stabilize the hip but also provide mobility and control (i.e. walking). It is quite apparent that through contraction of muscles and weight-bearing there can be large forces generated on the hip joint. Therefore, it is very important that hip musculature be strong and flexible to resist forces encountered during activities such as walking and stair climbing, resulting in minimized stress on the hip joint.

As individuals age into late adulthood, muscle strength declines. Due to decreased strength in older individuals, the forces on the hip joint once taken up by the surrounding musculature are now placed more on the weight-bearing surface of the hip. **Osteoarthritis (OA)** and **osteoporosis** further compromise the hip joint. Both diseases are common in the elderly adult. As the aging process continues the effects of decreased strength, OA and osteoporosis can lead to a less stable hip joint. With decreased stability, an individual can be at an increased risk for falling. Unfortunately, **fractures** are a possible outcome of falling in older adults. Hip fractures are one of the most common fractures associated with falling.

Purpose

The hip joint is a very stable **ball and socket joint**. Because of this inherent stability, the hip rarely dislocates. There are also numerous muscles around the hip that move the lower limb forward, backward, and to the side. These muscles aid in stabilizing the hip by further compressing or “holding” the femoral head in place. As stated previously, as the age of an individual increases, the stability of the hip joint can decrease. This decreased stability can lead to **gait and balance problems**, thus increasing the risk for falling. Moreover, other factors such as **dementia**, medication, and **vision** can also increase the risk for falling. Barriers in the environment can also make a surrounding place unsafe for the elderly. It becomes quite clear that older adults are at risk for falling, and a serious complication can be fracture.

Precautions

There are disorders that effect the hip, and one of the most common in older adults is hip fracture. There is an area in the hip joint that is located approximately mid-way between the femoral head and the shaft of the femur.

KEY TERMS

Acetabulum—The cup-shaped socket in the pelvis.

Dementia—A deterioration of mentality usually with marked apathy.

Flex—To bend.

Isometric exercises—A mode of exercise where there is contraction of muscle fibers, yet there is no movement of the limb.

Lumbar—Pertaining to the vertebrae in the lower back.

Pelvis—A basin-shaped group of bones that form the pelvic girdle.

Osteoarthritis—Degeneration of cartilage and bone of joints.

Osteoporosis—A condition that is characterized by decrease in bone mass with decreased density and enlargement of bone spaces.

Progressive resistive exercises—The mode of training that involves increasing intensity of exercise over time.

Prosthesis—An artificial implant or device that replaces a part of the body.

This area is called the femoral neck. Within the femoral neck there is a zone of weakness that is inherent to the bony structure. Unfortunately, as aging occurs and OA progresses, this area (or zone of weakness) becomes weaker and loses the ability to handle stress. There is a greater risk for fracture secondary to trauma or degeneration particularly in the area of the femoral neck.

There are many factors that can lead to falling and subsequent hip fracture. There are ways in which older adults can minimize the risk of falling and thus, decrease the possibility of fracturing the hip. Steps that can be taken by the older adult to minimize the risk of falling are:

- Removing slippery or tiled surfaces in the home.
- Improve the lighting in a home.
- Removing small or loose rugs.
- Minimize height differential between rooms; use ramps when necessary.
- Make sure floor is free from small objects.
- Have vision checked.

- Have a physician evaluate medicines for side-effects such as dizziness.
- Use handrails when needed, especially in toilet and shower areas.
- **Exercise** regularly to promote wellness, increase strength, and improve balance.

Description

A hip fracture usually refers to a disruption of either the proximal femoral shaft or femoral neck. If a femoral fracture were to occur, it usually happens in the area of the zone of weakness. Hip fractures in young athletes are not common and usually occur secondary to large forces due to trauma. The older individual who has hip osteoarthritis or osteoporosis is at risk for hip fracture.

Two common fractures in the elderly are intertrochanteric and femoral neck. Intertrochanteric fractures usually occur in the elderly. These fractures occur between the greater and lesser trochanters of the proximal femur, thus the term intertrochanteric (inter: between) and trochanteric, referring to trochanters. When there is a fracture between the trochanters, the most common procedure is an open reduction with internal fixation or more commonly known as ORIF. The goal of the ORIF is to provide a strong and stable fixture for the proximal femur. Femoral neck fractures usually occur in the zone of weakness described previously in the area between the femoral head and the trochanters and are also common in the elderly. Usually the age of an individual determines the mode of treatment. For example, in a displaced fracture in a younger individual, the mode of treatment may be an open reduction with internal fixation. In an elderly individual, a displaced fracture usually results in either a partial or total hip replacement. In non-displaced fractures of the femoral neck, internal fixation with pins and/or screws is the treatment of choice.

Preparation

Hip fracture can lead to impaired function and disability. Therefore, rehabilitation is important to minimize impairment and restore function. Rehabilitation should include early ambulation (walking), stabilizing the individual medically, breathing exercises to minimize risk of pulmonary embolisms, frequent changes in position to minimize formation of pressure ulcers, and regular walking.

Aftercare

Specific **physical therapy** treatments include range of motion, resistive exercises, flexibility, transfer training, balance exercises, bed mobility, and walking.

Depending on the weight-bearing status set by the physician, a patient with ORIF or arthroplasty can either ambulate with toe-touch weight-bearing (TTWB) or weight-bearing as tolerated (WBAT). Usually, the patient will ambulate with a standard walker or rolling walker. By the first week after surgery the patient should be able to do active range of motion of the hip and perform isometric exercises of the knee and hip. Usually, the hip patient is trained on proper transfer techniques and toileting during the initial weeks of rehabilitation. The patient can ambulate with an assistive device and with assistance from a therapist. Strengthening exercises continue into the twelfth week that includes isometric and isotonic exercises to both the hip and knee. Again, weight-bearing continues from WBAT to full weight-bearing depending on the procedure and whether the fracture is stable.

Complications

Complications after hip fracture can be related to the fracture, effects of bed rest, and the internal hardware. In a femoral neck fracture a serious complication is avascular necrosis. In either type of fracture (femoral or intertrochanteric) there could be poor reduction or possible re-fracturing. Extended bed rest could lead to muscle wasting, development of pressure ulcers, lung problems such as **pneumonia**, and other medical anomalies. Complications of hip arthroplasty may include **infection**, dislocation, and loosening of the prosthesis. Usually, a standard protocol for individuals with total hip replacement are no hip internal rotation, adduction past midline, and no hip flexion beyond ninety degrees (no leaning trunk over hips while sitting). Passive range of motion should be avoided if there was a reduced fracture. Hip fractures occurring in older adults often results in deteriorating health due to compounding complications. There is a statistically high rate of mortality due to complications directly resulting from hip fractures in patients over the age of seventy.

Results

After hip fracture most individuals are full weight-bearing and independent in activities of daily living, i.e. walking, by four to six months post-surgery. Full passive and active range of motion exercise can be done; progressive resistive exercises should be continued to strengthen the hip and surrounding musculature.

Health care team roles

Unfortunately, individuals in their mid-80s and older who have a hip fracture are at a much higher risk of not

regaining prior level of function. Furthermore, almost 20% of individuals with hip fracture will require nursing **home care**. Thus, the cost of hip fracture for the individual, family, and society is quite high. Considering the aging of the United States population, it would seem reasonable to assume that the incidence of hip fracture and complications associated with this condition will increase over time. Thus, the importance of prevention and education in our society.

HIV preventative measures

Definition

Human **immunodeficiency** virus (HIV) is a systemic viral **infection** that weakens the body's ability to fight infection and can cause acquired immune deficiency syndrome (**AIDS**, the last stage of HIV disease). HIV preventative measures are a set of procedures that lower the risk of health care professionals being exposed to the virus.

Description

HIV is the most dangerous sexually transmitted disease (STD), affecting people of all ages. In 1999, HIV was considered the fifth cause of death among American men and women between 25 and 44 years of age. It is

believed that 40,000 Americans are infected every year. There have already been 700,000 cases reported in the United States. Globally, over 36 million people have been infected with the AIDS virus.

Most HIV-positive people are men. According to a 2001 survey by the United States Centers for Disease Control and Prevention (CDC) (www.cdc.gov), of 3,000 gay and bisexual men in six major U.S. cities (interviewed in public places, such as gay clubs and bars), 4.4% of gay and bisexual men, ages 23 to 29, are infected with HIV every year. Another study in 2001, also conducted by the CDC, reported that HIV infections among gay men of all races in their 20s were common in large American cities. Thirty percent of blacks, 15% of Hispanics, 7% of whites, and 3% of Asians were affected with HIV. In the general population, one in seven blacks becomes HIV-positive each year.

The incidence of the HIV and AIDS is rapidly increasing in women and children, too. Like many other **viruses**, HIV remains in the body for life. As of 2001, there is no vaccine against HIV.

Causes and symptoms

HIV infection can present no clinical symptoms, cause a spectrum of conditions, or appear as full-blown AIDS. A unique virus, HIV continually reproduces after it enters the body, eventually overwhelming the **immune system** and weakening the body's ability to fight lethal infections and cancers.

Most people infected with HIV are not ill. Some are without symptoms for more than 10 years. A "carrier" can host the virus and pass it on to other people without knowing it. Once the virus is established in the body, the chances of getting AIDS increase.

Some of the frequently reported symptoms of HIV/AIDS infections are:

- constant or rapid unexplained weight loss of more than 10 pounds in two months; lack of appetite
- unexplained long-lasting **diarrhea** or bloody stools
- constant fatigue that is not associated with physical activity or mental depression
- persistent fevers, night sweats, dry cough, or difficulty breathing for more than two weeks
- lightheadedness, dizziness, headaches, mental disorders
- a thick, whitish coating of yeast on the tongue or mouth that cannot be scraped off (This is called "thrush.")
- severe or recurring vaginal yeast infections and chronic pelvic inflammatory disease (PID)

- purplish growths or blotches on or under the skin, inside the mouth, or on the nose, eyelids, or rectum
- swollen glands or enlarged lymph nodes in the neck, armpits, or groin for more than a month

Many HIV/AIDS symptoms are similar to those of **tuberculosis, influenza, pneumonia**, minor yeast infections, and other STDs. Basically healthy people tend to ignore their symptoms until they are ill enough to seek medical care.

HIV is found in bodily fluids. It is most prevalent in **blood**, semen, vaginal secretions, and breast milk. HIV infection cannot be transmitted through casual contact. Rather, HIV is transmitted by sexual contact with an infected person, exposure to contaminated blood (e.g., by sharing needles or accidental exposure to contaminated needles) and maternal-fetal transfer.

Activities that spread HIV/AIDS to others are:

- anal and vaginal intercourse (It is less commonly transmitted through oral sex.)
- sharing contaminated needles for injecting illicit drugs
- transfusion of contaminated blood products
- **childbirth** and breast feeding
- accidental pricks with contaminated needles while providing health care to infected patients

Diagnosis

Blood tests are used to detect the presence of HIV antibodies in the blood. Antibodies are developed two weeks to three months after infection. Other bodily secretions may also provide evidence of HIV infection. Even before the antibody test is positive, a person can pass the virus to others.

AIDS is the final stage of the HIV infection. The diagnosis is supported by the presence of a variety of conditions and opportunistic infections (i.e., conditions caused by a microorganism that does not ordinarily cause disease, but which becomes pathogenic under certain circumstances) related to HIV. During the disease process, the AIDS virus attacks certain white blood cells (T-lymphocytes). AIDS destroys the body's immune (defense) system and allows otherwise controllable infections to invade the body and cause additional diseases. These opportunistic diseases gain strength in the body and may eventually cause death.

The AIDS virus may also attack the nervous system and cause **brain** damage. It may take years for symptoms of brain damage to occur, manifesting as **memory** loss, loss of coordination, partial **paralysis**, or mental disorder.

These symptoms may occur alone or in combination with any of the other symptoms associated with the disease.

HIV/AIDS can only be diagnosed by physicians or qualified health professionals. While AIDS patients are treated by physicians using established protocols for care, patients are often referred to medical specialists, known as epidemiologists, for consultation and monitoring the course of their disease. These specialists study the factors that influence the frequency and distribution of infectious diseases among populations of human beings. The physician specializing in epidemiology concentrates on research and management of infectious diseases.

Medical specialists utilize the support of pathologists in the diagnosis, management, and treatment of patients with the AIDS virus. The scientific study of bodily changes produced by AIDS, pathology is concerned with conducting research. This research is accomplished using comparative analyses of disease processes. Other research may include the practice of experimental pathology, whereby pathologic processes are artificially induced in the laboratory setting. Both methods, however, provide pathologists with the opportunity to learn about the fatal impact of AIDS.

Treatment

As of mid-2001, there is no known cure for, or vaccine against, HIV/AIDS. However, using new drug combination therapy can allow infected persons to remain symptom-free for longer periods, provided the disease is detected early. When HIV is detected early in **pregnancy**, its treatment with **antiretroviral drugs** might reduce the risk of transmitting the virus to the child. However, the an HIV-positive, pregnant woman's doctor will frequently advise delivery by cesarean section (cs) to eliminate the chance of transmitting the virus during childbirth.

Success with new, highly active antiretroviral therapy (i.e., HAART, also known as a drug "cocktail") and the decline in the number AIDS cases newly reported, as well as the number of deaths, are good news. A number of HIV-infected people who are still alive due to HAART, and that number is growing.

Drug therapies include TMP-SMX (trimethoprim-sulfamethoxazole [tri-METH-o-prim-sul-fa-meth-OX-uh-zole]). Brand names for these drugs are Bactrim, Septra, and Cotrim. The long-term effectiveness of HAART is unknown; HIV may develop resistance to these drugs. Further, this combination drug therapy is very expensive, and a vast number of HIV-infected persons do not have health insurance or the financial means to purchase medication.

Patients also have difficulty maintaining a complicated drug treatment schedule that involves taking a large numbers of pills. Many of these drugs have unpleasant or intolerable side effects, interact with other medications, and cause serious medical problems. Patients might even forget to take all of their medications, or skip doses.

Patients who feel healthy have been known to take "drug holidays," by not taking their medications for days or weeks. Treatment regimes are less effective in the overall population when there is an increased possibility of developing a drug-resistant strain of HIV. If drug resistance is developed by the evolving virus and is coupled with a relaxation in treatment regimens, resistant strains may be transmitted to others, and thus spread widely. Prevention remains the best and most cost-effective approach to controlling the HIV/AIDS epidemic and saving lives.

Prognosis

HIV infections and many AIDS-related conditions, such as pneumonias, cancers, and a variety of infections that take advantage of weakened immune systems, can be managed to some extent with different treatments. Improved treatment options are continually being developed by scientists and pharmaceutical companies. However, no one has ever recovered from full-blown AIDS. As of 2001, the disease is still considered fatal.

Health care team roles

Assessment

Nurses and allied health professionals are likely to be the first medical contact for HIV-infected patients. Information obtained about the patient's signs and symptoms, lifestyle, and social behavior must be documented by the medical staff.

Surveillance

There has been recognition by researchers that behavior that places an individual at risk for other STDs increases the risk of HIV infection. Sexually-transmitted disease (STD) surveillance can provide important indicators of sites to which HIV infection may spread, as well as point to targets to which efforts to promote safe sexual behavior should be aimed.

Monitoring

Patient care activities, patient progress, and response to symptomatic or preventive therapies need to be documented by nurses. Medical record information is vital to

KEY TERMS

Acquired immune deficiency syndrome (AIDS)—The final stage of a series of health problems caused by the human immunodeficiency virus (HIV).

Epidemiological studies—Medical research that deals with the incidence, distribution, and control of disease in a population; the sum of factors controlling the presence or absence of a disease, or pathogens.

Highly active antiretroviral therapy (HAART)—Also known as drug “cocktail,” this is a combination of powerful drugs prescribed to arrest HIV infection and delay the onset of AIDS. It is not a cure for HIV/AIDS.

Human immunodeficiency virus (HIV)—The virus that causes AIDS. HIV weakens the body’s ability to fight infections.

Opportunistic infection (OI)—Condition caused by a microorganism that does not ordinarily cause disease, but which becomes pathogenic under certain circumstances.

Sexually transmitted disease (STD)—Also called venereal disease; any disease transmitted through sexual contact.

continued research in the field. All information must be kept confidential and maintained in compliance with state and federal laws.

Education

Education about HIV prevention has been proven cost-effective when compared with the rising cost of lifetime medical management of people with AIDS. Different types of preventive messages, skills, and support are needed to help reduce sexual and drug-related risks.

Drug injectors should be educated about their high-risk behavior. Drug counseling may help them stop using drugs or sharing needles. These individuals need to be taught how to protect themselves from sexual transmission if their partners have ever been IV drug users and may have shared needles.

Substance abuse is a major problem. The combination of substance abuse and sexual HIV transmission must be given serious attention. Substance abuse prevention and intervention are sorely lacking for users of mor-

phine, cocaine, **marijuana**, and alcohol. These substances not only alter users’ behavior, but weaken their immune systems. This weakening may make them more susceptible to infection with HIV. Counseling and treatment should be available to those who abuse drugs and alcohol. They, too, are in need of assistance in helping them stop using drugs and to help them prevent HIV infection.

Comprehensive health education programs need to be directed toward generation-specific behavior and epidemiology. Programs for children and young adults should involve parents and educators. The most effective programs begin educating young people at an early age and are designed to promote healthy behaviors—such as exercising, eating healthy food, avoiding drug use, excessive alcohol consumption, smoking, and premature sexual activity.

Occupational HIV transmission

Although it is not a primary means of transmitting the spread of HIV, there are documented cases of HIV seroconversion among health workers. Responsibility for preventing occupational exposure to HIV and other bloodborne pathogens is that of the nurse. Precautions include the routine use of gloves for one-time use, goggles, and disposable protective clothing. These function as preventive barriers when there is the possibility of coming in contact with infectious materials. Good hand-washing practices are essential. It is necessary that sharp instruments and contaminated materials are handled and disposed of in a proper manner.

Prevention

Sustained, comprehensive efforts of the 1980s have had a significant impact on slowing the spread of HIV/AIDS in the United States. Although it is difficult to determine exactly how many thousands of infections were prevented as a result of deliberate effort, the mid-1980s witnessed an epidemic growing at an annual rate greater than 80%. As of mid-2001, this rate has stabilized. Nationally, 30 of every 100,000 men and nine of every 100,000 women have AIDS. Despite the occurrence of 40,000 new cases per year, fewer people are dying from AIDS and AIDS-related complications. This is indicative of tremendous progress. In general, previous preventive efforts resulted in many behavioral changes, thereby helping to slow the epidemic overall.

The decline in the number of deaths from AIDS and the effectiveness of antiretroviral therapies increase the number of HIV infected people in the general population. These successes may contribute to a person’s false sense of security when he or she believes and behaves as if pre-

venting the spread of HIV is no longer important. Complacency about the need for prevention adds a complex dimension to disease management for health care professionals and the at-risk population. The complicated nature of HIV/AIDS strongly supports valuable opportunities for prevention and intervention.

Primary HIV prevention means keeping people from becoming infected with HIV in the first place. Intervention must focus on preventing the spread of HIV by infected individuals as well as on acquisition by uninfected populations. Infected individuals need to develop skills to reduce the risk of infecting others. It is essential that there be easy access to voluntary blood testing; this will enable early detection of HIV infection.

Comprehensive school-based HIV and sex education programs are suspected to delay initiation of sexual activity in teenagers, reduce the frequency of intercourse for those who are sexually active, decrease the number of sexual partners they have, and increase the use of condoms and other contraceptives.

Stringent screening of donor blood supply for HIV antibodies, and heat-treating blood products used to treat **hemophilia** have nearly eliminated HIV transmission through transfusions.

Secondary HIV prevention is keeping HIV-infected people safe and healthy by helping them avoid opportunistic infections and stopping the infection from progressing to AIDS.

Scientists are exploring the possibility that combination drug therapies may reduce the infectious nature of the disease. With the lines between prevention and treatment beginning to merge, ongoing services for people who are HIV positive must balance medical advances with the behavioral and social support needed to preserve their quality of life and prevent the spread of infection.

A focus on behavioral change is paramount. Vaccines are not able to prevent disease if people are not vaccinated. No vaccine for lifelong immunity has yet been developed. Further, medical advances are unsuccessful unless their implementation parallels that of effective prevention strategies. People must be receptive to both in order for HIV rates to be reduced.

Pregnant women who may not know they are infected with HIV cannot reduce the risk of transmitting the disease to their unborn children unless that they get **pre-natal care**, routine HIV counseling, and submit to voluntary testing. Infected patients must have access to anti-retroviral drugs. Programs that identify and treat HIV-infected pregnant women have shown dramatic success in reducing HIV transmission to their babies. A woman who is HIV-positive and pregnant may be

advised by her doctor to deliver by cesarean section (cs) to eliminate the chance of transmitting the virus during childbirth.

Efforts to reduce the risk for HIV infection of injection drug users through public attitudes and policies have been very effective. State health departments have reported significant reductions in the sharing of drug injection equipment after implementing programs to increase access to sterile injection equipment.

Infected individuals need assistance developing skills to use the new medical treatments. Highly active antiretroviral therapy (HAART) involves complex treatment regimens and requires compliance-related skills. Patients need to learn how to deal with the side effects of medications and **drug interactions**. They must learn how to decrease the risk of developing drug resistance by taking their medications as recommended and also learn how to work with complicated medication schedules. HIV-positive individuals also depend on the support of family and friends to continue their drug regimens and to encourage prevention of transmission to others.

Hives

Definition

Hives is an allergic skin reaction causing localized redness, swelling, and itching.

Description

Hives is a reaction of the body's **immune system** that causes areas on the surface of the skin to swell, itch, and become reddened (wheals). These lesions are elevated, can be blanched with pressure applied from a finger, and are oval in shape. When the reaction is limited to small areas of the skin, it is called urticaria. Involvement of larger areas, such as whole sections of a limb, is called angioedema.

Causes and symptoms

Causes

Hives is an allergic reaction. The body's immune system is normally responsible for protection from foreign invaders. When it becomes sensitized to normally harmless substances, the resulting reaction is called an allergy. An attack of hives is set off when such a substance, called an allergen, is ingested, inhaled, or otherwise contacted. It interacts with immune cells called mast cells, which reside in the skin, airways, and **digestive system**. When mast cells encounter an allergen, they release histamine and other chemicals, both locally and into the bloodstream. These chemicals cause **blood vessels** to become more porous, allowing fluid to accumulate in tissue and leading to the swollen and reddish appearance of hives. Some of the chemicals released sensitize pain-nerve endings, causing the affected area to become itchy (pruritic) and sensitive.

A wide variety of substances may cause hives in sensitive people, including food, drugs, insect or stings, and common household items. Common culprits include:

- nuts, especially peanuts, walnuts, and Brazil nuts
- fish, mollusks, and shellfish
- eggs
- wheat
- milk
- strawberries
- food additives and preservatives
- penicillin or other antibiotics
- flu vaccines
- tetanus toxoid vaccine

Hives on the back of a young woman's legs. The accompanying inflammation develops as an allergic reaction which ranges in size from small spots to patches measuring several inches across. (Photograph by John Radcliffe, Custom Medical Stock Photo. Reproduced by permission.)

- gamma globulin
- bee, wasp, and hornet stings
- bites of mosquitoes, fleas, and scabies.
- dander from house pets
- new fragrances, laundry soaps, hand lotions, or articles of clothing
- certain plants, molds, chemicals, or dust particles

Symptoms

Urticaria is characterized by redness, swelling, and itching of small areas of the skin. These patches usually grow and recede in less than a day, but may recur in other locations, and complete resolution can take four to six weeks. Angioedema is characterized by more diffuse swelling. Swelling of the airways may cause wheezing and respiratory distress. In severe cases, airway obstruction may occur.

Diagnosis

Hives are easily diagnosed by visual inspection. The cause is usually more difficult to diagnose and requires a thorough medical history in order to determine the allergen.

Treatment

Mild cases of hives are treated with **antihistamines**, such as diphenhydramine (Benadryl). The major side effect of diphenhydramine is drowsiness. Newer antihistamines, such as loratadine (Claritin), are non sedating and are used more frequently with chronic hives management. More severe cases may require oral **corticosteroids**, such as prednisone. Prednisone helps block the release of mast cells and decreases the leakiness of **blood vessel walls**. Gradual tapering doses of prednisone are the most common way to take this medication. Topical corticosteroids are not effective. Airway swelling may require an emergency injection of epinephrine (adrenaline). Epinephrine constricts the blood vessels of the skin and immediately combats the histamine release.

An alternative practitioner will try to determine what allergic substance is causing the reaction and help the patient eliminate or minimize its effects. To deal with the symptoms of hives, an oatmeal bath may help to relieve itching. Chickweed (*Stellaria media*), applied as a poultice (crushed or chopped herbs applied directly to the skin) or added to bath water, may also help relieve itching. Several homeopathic remedies, including *Urtica urens* and *Apis* (*Apis mellifica*), may help relieve the itch, redness, or swelling associated with hives.

Prognosis

Most cases of hives clear up within one to seven days without treatment, providing the cause (allergen) is found and avoided. Some bouts of hives can persist up to six weeks and can be frustrating for the sufferer.

Health care team roles

The health care professional (R.N., L.P.N.) completing the history of a person presenting with hives should focus on specific information to determine the patient's allergen. Important information to include:

- Broad aspects about urticaria (when it started, how long and how often do episodes happen, where on the body do they usually appear, at what point do symptoms start to abate, and if there is a link with seasonal changes).
- Work and leisure activities (questions specific to possible exposure).
- Recent management of hives (previously prescribed medication, OTC medication or herbal supplements).
- Dietary review (a thorough review of the person's diet can help identify potential food substances that are common allergens).

KEY TERMS

Allergen—A substance capable of producing an immediate type of hypersensitivity or allergy.

Pruritic—Itchy.

Wheal—A smooth, slightly elevated area on the body surface, which is redder or paler than the surrounding skin.

Patient education

Patient education should focus on teaching the significance of avoiding allergens and the identification of the early signs of a hives outbreak. The patient should be made aware of the fact that diphenhydramine (Benadryl) causes sedation and should *not* be taken when driving or operating heavy machinery. If urticaria becomes a chronic problem, the patient should be made aware of the many new drugs that can help manage the condition.

Prevention

Preventing hives is only possible by avoiding the allergens causing them. Analysis of new items in the diet, new drugs taken, or new products at home may reveal the likely source of the allergen. Chronic hives can also be aggravated by **stress**, **caffeine**, alcohol, or tobacco; avoiding these may reduce the frequency of reactions. For people with chronic hives, referral to a doctor who specializes in **allergies**, skin disorders, immune disorders, or rheumatology may be helpful.

Home care

Definition

Home care is a form of health care service provided wherever a patient lives. Patients can receive home care services whether they live in their own homes with family members or in an assisted living facility. The purpose of home care is to promote, maintain, or restore a patient's health and reduce the effects of diseases or disabilities.

Description

The goal of home care is the provision of whatever a patient needs in order to remain living in his or her home, regardless of age or disability. The services provided may range from such homemaking services as cooking or cleaning to skilled medical care for patients on **ventilators** or dialysis machines or those receiving infusion therapies. Some patients require home-health aides or personal care attendants to help them with activities of daily living (ADL).

Medical, dental, and nursing care may all be delivered in the patient's home, which allows him or her to feel more comfortable and less anxious. Therapists from speech-language pathology, **physical therapy**, and **respiratory therapy** departments often make regular home visits, depending on the patient's specific needs. General nursing care is provided by both registered and licensed practical nurses; however, there are also nurses who are clinical specialists in psychiatry, obstetrics, and cardiology who provide care in these areas when prescribed. Home-health aides provide what is called custodial care in domestic settings; their duties are similar to those of nurses' aides in the hospital. Professionals who deliver care to patients in their homes are employed either by independent for-profit home-care agencies or by hospital agencies or departments. Personal care attendants can also be hired privately by patients; however, not only is it more difficult to evaluate an employee's specific background and credentials when he or she is not associated with a certified agency or hospital, but medical insurance may not cover the expense of an employee who does not come from an approved source.

Viewpoints

Often, patients are more comfortable in their own homes, rather than a hospital settings. Depending on the patient's living status and relationships with others in the home, however, the home is not always the best place for caregiving. Nevertheless, home care continues to grow in popularity. Hospital stays have been shortened considerably, starting in the 1980s with the advent of the diagnosis-related group (DRG) reimbursement system as part of a continuing effort to reduce healthcare costs. But as a result, many patients come home "quicker and sicker," and in need of some form of care or help that family or friends may not be able to offer. Community-based healthcare services are expanding, giving patients more options for assistance at home.

History

It is helpful to have some basic information about the evolution of home care in order to understand the public's demand for quality health care, cost containment, and the benefits of advances in both medical and communication technologies. The first home care was delivered by members of Roman Catholic religious orders in Europe in the late seventeenth century. This form of care giving was later performed by registered nurses who "visited" people in their homes. Visiting Nurse Associations (VNAs) were formed toward the close of the nineteenth century. Today there are many home-care agencies and VNAs that continue to deliver a wide range of home-care services to meet the specific needs of patients throughout the United States and Canada.

Social factors have historically influenced home-care delivery and continue to do so today. Before the 1960s, home care was a community-based delivery system that provided care to patients whether they could pay for the services or not. Agencies relied on charitable contributions from private citizens or charitable organizations, as well as some limited government funding. But as the life expectancy of the United States population began to rise, advances in medical science saved patients who might have died in years past. As a result, more and more elderly or disabled people required medical care in their homes as well as in institutions. Consequently, the federal government put **Medicare** and **Medicaid** into place (1965) to help fund and regulate health-care delivery for this population.

Funding and regulation

Government involvement resulted in regulations that changed the focus of home care from a nursing-care delivery service to care delivery under the direction of a

physician. Home-care delivery is paid for either by the government through Medicare and/or Medicaid; by private insurance or health maintenance organizations (HMOs); by patients themselves; or provided without cost by certain non-profit community, charitable disease advocacy organizations (e.g., ACS), or faith-based organizations.

Home-care delivery services provided by Medicare-certified agencies are tightly regulated. For example, a patient must be home-bound in order to receive Medicare-reimbursed home-care services. The home-bound requirement—one of many—means that the patient who receives home-care services from a Medicare-certified agency must be physically unable to leave his or her home (other than for infrequent trips to the doctor or hospital), thereby restricting the number of persons eligible for home-care services. Private insurance companies and HMOs also have certain criteria for the number of visits that will be covered for specific conditions and services. Restrictions on the payment source, the physician's orders, and the patient's specific needs determine the length and scope of services.

Assessment and implementation

Since home-care nursing services are provided on a part-time basis, patients, family members, or other caregivers are encouraged and taught to do as much of the care as possible. This approach goes beyond payment boundaries; it extends to the amount of responsibility the patient and his or her family or caregivers are willing or able to assume in order to reach that expected outcome. Nurses who have received special training as case managers visit the patient's home and draw up a plan of care based on assessing the patient, listing the diagnoses, planning the care delivery, implementing specific interventions, and evaluating outcomes or the efficacy of the implementation phase. Planning the care delivery includes assessing the care resources within the circle of the patient's family and friends.

At the time of the initial assessment, the visiting nurse, who is working under a physician's orders, enlists professionals in other disciplines who might be involved in achieving expected outcomes, whether those outcomes include helping the patient return to a certain level of health and independence or maintaining the existing level of health and mobility. The nurse provides instruction to the patient and caregiver(s) regarding the patient's particular disease(s) or condition(s) in order to help the patient achieve an agreed-upon level of independence. Home-care nurses are committed to helping patients make good decisions about their care by providing them with reliable information about their conditions. Since

home care relies heavily on a holistic approach, care delivery includes teaching coping mechanisms and promoting a positive attitude to help motivate patients to help themselves to the extent that they are able. Unless the patient is paying for home-care services out-of-pocket and has unlimited resources or a specific private long-term care insurance policy, home-care services are scheduled to end at some point. Therefore, the goal of most home-care delivery is to move both the patient and the caregivers toward becoming as independent as possible during that time.

Professional implications

Home-care delivery is influenced by a number of variables. Political, social, and economic factors place significant constraints on care delivery. Differences among nurses, including their level of education, years of work experience, type of work experience, and level of cultural competence (cross-cultural sensitivity) all influence care delivery to some extent.

The following list identifies some of the professional issues confronting home-care nurses at the turn of the twenty-first century. They include:

KEY TERMS

Activities of daily living (ADLs)—The activities performed during the course of a normal day, for example, eating, bathing, dressing, toileting, etc.

Home health aide—An employee of a home-care agency who provides the same services to a patient in their home as nurses aides perform in hospitals and nursing homes. Home-care agencies differ according to state regulations and agency policy regarding the scope of duties provided by home health aides.

Licensed practical nurse (LPN)—A person who is licensed to provide basic nursing care under the supervision of a physician or a registered nurse.

Medicaid—The United States' federally-funded program for state-operated programs that provide medical assistance to permanently disabled patients and to low-income people.

Medicare—The federally-funded national health insurance program in the United States for all people over the age of 65.

Personal care attendant—An employee hired either through a healthcare facility, home-care agency, or private agency to assist a patient in performing ADLs.

Psychiatric nursing—The nursing specialty concerned with the prevention and treatment of mental disorders and their consequences.

Registered nurse—A graduate nurse who has passed a state nursing board examination and been registered and licensed to practice nursing.

Respiratory therapy—The department of any healthcare facility or agency that provides treatment to patients to maintain or improve their breathing function.

Speech-language pathology—Formerly known as speech therapy, speech-language pathology includes the study and treatment of human communication—its development and disorders.

- legal issues
- ethical concerns
- safety issues
- nursing skills and professional education

Legal issues

The legal considerations connected with delivering care in a patient's private residence are similar to those of care delivered in healthcare facilities, but have additional aspects. For example, what would a home care nurse do if she or he had heard the patient repeatedly express the desire not to be resuscitated in case of a **heart** attack or other catastrophic event, yet during a home visit, the nurse finds the patient unresponsive and cannot find the orders not to resuscitate in the patient's chart anywhere? What happens if the patient falls during home-care delivery? While processes, protocols, and standards of practice cannot be written to address every situation that may arise in a domestic setting, timely communication and strong policy are essential to keep both patients and home care staff free of legal liability.

Ethical concerns

Ethical implications are closely tied to legal implications in home care—as in the case of missing DNR (do not resuscitate) orders. For example, what measures are appropriate if a home-care nurse finds a severe diabetic and recovered alcoholic washing down a candy bar with a glass of bourbon? The patient is in his or her own residence and has the legal right to do as he or she chooses. Or what about the family member who has a bad fall while the nurse is in the home providing care? Should the nurse care for that family member as well? What is the nurse's responsibility to the patient when he or she notices that a family member is taking money from an unsuspecting patient? Complex ethical issues are not always addressed in policy statements. Ongoing communication between the home-care agency and the nurse in the field is essential to address problematic situations.

Safety issues

Safety issues in home care require attention and vigilance. The home-care nurse does not have security officers readily available if a family member becomes violent either toward the health-care worker or the patient. Sometimes home-care staff are required to visit patients in high-crime areas or after dark. All agencies should have some type of supervisory personnel available 24 hours a day, seven days a week, so that field staff can reach them with any concerns. Also, clear policy statements that cover issues of personal safety must be documented and communicated regularly and effectively.

With advances in technology and the increased effort to control cost, home care is beginning to involve telecare in the delivery services. Telecare uses communications technology to transmit medical information between the patient and the health care provider.

Providing care to patients without being in their immediate presence is a relatively new form of home nursing, and is not without its problems. While some uncertainty exists regarding legal responsibilities and the potential for liability, much has been done to make telecare an effective way to hold costs down for some patients. Home-care nurses who are required to make telecare visits should know what regulations exist in that state before providing care. The chief danger lies in diagnosing and prescribing over the phone without seeing the patient.

Implications for nursing education

While there is no specific degree program required for delivery of home-care services, providing nursing care in a patient's home differs significantly from hospital care. Home-care nurses provide care for patients of every age, economic class, and level of disability. Some nurses provide specialized hospice, mental health, or pediatric care. Home-care nurses, on the average, spend more time teaching patients and caregivers than in an institutional setting, since the emphasis in home care is to foster independence and to improvise with the tools at hand. And while all nurses are patient advocates, home-care nurses must respect social and cultural values as part of the impact that the family and the home environment have on the patient's overall health. Home-care nurses are case managers, since they apply the entire nursing process to each of their patients. They must implement their own quality improvement during care delivery. Home care nursing often involves more than biomedically-based care, depending on the patient's religious or spiritual background. Nurses who visit patients in their homes often spend more time with them and encounter situations and opportunities where each communicate on a higher level of understanding and sensitivity. Finally, home care delivery demands that employees exercise a high level of flexibility, creativity, and the ability to work without constant supervision.

Homeopathy

Definition

Homeopathy, or homeopathic medicine, is a holistic system of treatment that originated in the late eighteenth century. The name homeopathy is derived from two Greek words that mean "like disease." The system is based on the idea that substances that produce symptoms of sickness in healthy people will have a curative effect when given in very dilute quantities to sick people who exhibit those same symptoms. Homeopathic remedies are believed to stimulate the body's own healing processes. Homeopaths use the term "allopathy," or "different than disease," to describe the use of drugs used in conventional medicine to oppose or counteract the symptom being treated.

Origins

Homeopathy was founded by German physician Samuel Hahnemann (1755-1843), who was much disturbed by the medical system of his time, believing that its cures were crude and some of its strong drugs and

treatments did more harm than good to patients. Hahnemann performed experiments on himself using Peruvian bark, which contains quinine, a **malaria** remedy. He concluded that in a healthy person, quinine creates the same symptoms as malaria, including fevers and chills, which is the reason why it is effective as a remedy. He then began to analyze the remedies available in nature by what he called provings. Provings of homeopathic remedies are still compiled by dosing healthy adults with various substances and documenting the results, in terms of the dose needed to produce the symptoms and the length of the dose's effectiveness. The provings are collected in large homeopathic references called *materia medica* or materials of medicine.

Hahnemann formulated these principles of homeopathy:

- Law of Similars (like cures like).
- Law of the Infinitesimal Dose. (The more diluted a remedy is, the more potent it is.)
- Illness is specific to the individual.

Hahnemann's Law of Similars was based on thinking that dated back to Hippocrates in the fourth century B.C. It is the same thinking that provided the basis for vaccinations created by Edward Jenner and Louis Pasteur. These vaccines provoke a reaction in the individual that protects against the actual disease. Allergy treatments work the same way. By exposing a person to minute quantities of the allergen, the person's tolerance levels are elevated.

The Law of the Infinitesimal Dose has always caused controversy among those outside the field of homeopathy. Hahnemann contended that as he diluted his remedies with water and alcohol and succussed, or shook, them, the remedies actually worked more effectively. In fact, diluted homeopathic remedies may have no chemical trace of the original substance. Practitioners believe that the electromagnetic energy of the original substance is retained in the dilution, but toxic side effects of the remedy are not. It is this electrochemical "message" that stimulates the body to heal itself.

Homeopathic practitioners believe that illness is specific to an individual. In other words, two people with severe headaches may not receive the same remedies. The practitioner will ask the patient questions about lifestyle, dietary habits, and personality traits, as well as specific questions about the nature of the headache and when it occurs. This information gathering is called profiling or case-taking.

In the early 1900s, homeopathy was popular in America, with over 15 percent of all doctors being homeopathic. There were 22 major homeopathic medical

schools, including Boston University and the University of Michigan. However, with the formation of the American Medical Association, which restricted and closed down alternative practices, homeopathy declined for half a century. When the 1960s invigorated back-to-nature trends and distrust of artificial drugs and treatments, homeopathy began to grow again dramatically through the next decades. In 1993, *The New England Journal of Medicine* reported that 2.5 million Americans used homeopathic remedies and 800,000 patients visited homeopaths in 1990, and it has continued to grow. Homeopathy is much more popular in Europe than in the United States. French pharmacies are required to make homeopathic remedies available along with conventional medications. Homeopathic hospitals and clinics are part of the national health system in Britain. It is also practiced in India and Israel, among other countries.

Benefits

Homeopathic physicians seek to cure their patients on the physical, mental and emotional levels, and each treatment is tailored to a patient's individual needs. Homeopathy is generally a safe treatment, as it uses medicines in extremely diluted quantities, and there are usually minimal side effects. Its non-toxicity makes it a good choice for the treatment of children. Another benefit of homeopathy is the cost of treatments; homeopathic remedies are inexpensive, often a fraction of the cost of conventional drugs.

Homeopathic treatment has been shown effective in treating many conditions. Colds and flu may be effectively treated with aconite and bryonia. **Influenza** sufferers in a double-blind study found that they were twice as likely to recover in 48 hours when they took homeopathic remedies. Studies have been published in British medical journals confirming the efficacy of homeopathic treatment for rheumatoid arthritis. Homeopathic remedies are effective in treating infections, circulatory problems, respiratory problems, **heart** disease, depression and nervous disorders, migraine headaches, **allergies**, arthritis, and diabetes. Homeopathy is a good treatment to explore for acute and chronic illnesses, particularly if these are found in the early stages and where there is not severe damage. Homeopathy can be used to assist the healing process after surgery or **chemotherapy**.

Description

A visit to a homeopath can be a different experience than a visit to a regular physician. Surveys have shown that homeopathic doctors spend much more time during initial consultations than conventional doctors spend. This is because a homeopath does a complete case-taking

to get a complete picture of a person's general health and lifestyle, as well as particular symptoms, on the physical, mental, and emotional levels. Some symptoms can be so subtle that the patient is not always completely aware of them, and the doctor must spend time getting to know the patient.

The initial visit often includes a long questionnaire about a patient's medical and family history, and then a long interview with the doctor, who prompts the patient with many questions. Sometimes a homeopathic doctor will use lab tests to establish a patient's general level of health. The initial interview usually lasts between one and two hours.

The purpose of homeopathy is the restoration of the body to homeostasis, or healthy balance, which is its natural state. The symptoms of a disease are regarded as the body's own defensive attempt to correct its imbalance, rather than as enemies to be defeated. Because a homeopath regards symptoms as positive evidence of the body's inner intelligence, he or she will prescribe a remedy designed to stimulate this internal curative process, rather than suppress the symptoms.

In homeopathy, the curative process extends beyond the relief of immediate symptoms of illness. Healing may come in many stages, as the practitioner treats layers of symptoms that are remnants of traumas or chronic disease in the patient's past. This is part of Hering's Laws of Cure, named for Constantine Hering, the father of homeopathy in America. Hering believed that healing starts from the deepest parts of the body to the extremities, and from the upper parts of the body to the lower parts. Hering's Laws also state that homeopaths should treat disease symptoms in reverse chronological order, from the most recent to the oldest, restoring health in stages. Sometimes, the patient may feel worse before feeling better. This is called a healing crisis.

When prescribing a remedy, homeopaths will match a patient's symptoms with the proper remedy in a repertory or *materia medica* that has been compiled throughout the history of homeopathy. Classical homeopaths prescribe only one remedy at a time. However, it is becoming more common, especially in Europe, to use combination formulas of several remedies for the treatment of some combinations of symptoms.

The cost of homeopathic care can vary. The cost of visits will be comparable to conventional medicine, with initial visits ranging from \$50 to \$300. Non-M.D. homeopaths can charge from \$50 to \$250. Follow-up visits are less, at about \$35 to \$100. Homeopathic medicine is significantly cheaper than pharmaceuticals, and most remedies cost between \$2 and \$10. Some doctors provide remedies without charge. Homeopaths rarely use lab

tests, which reduces the cost of treatment further. In general, homeopathy is much more economical than conventional medicine. In 1991, the French government did a study on the cost of homeopathic medicine, and found that it costs half as much to treat patients, considering all costs involved.

When homeopaths are licensed professionals, most insurance companies will pay for their fees. Consumers should consult their insurance policies to determine individual regulations. Insurance usually will not cover homeopathic medicine, because it is sold over-the-counter.

Precautions

Although homeopathic remedies sometimes use substances that are toxic, they are diluted and prescribed in non-toxic doses. Remedies should be prescribed by a homeopathic practitioner. Those preparing to take homeopathic remedies should also avoid taking *antidotes*, substances which homeopathic doctors believe cancel the effects of their remedies. These substances include alcohol, coffee, prescription drugs, peppermint (in toothpaste and mouthwash), camphor (in salves and lotions), and very spicy foods. Homeopathic medicine should also be handled with care, and should not be touched with the hands or fingers, which can contaminate it.

Side effects

A homeopathic *aggravation* sometimes occurs during initial treatment with homeopathic remedies. This means that symptoms can temporarily worsen during the process of healing. Although this is usually mild, the aggravation can sometimes be severe. Homeopaths see aggravation as a positive sign that the remedy is a good match for the patient's symptoms. The healing crisis, which happens when the patient is undergoing treatment for layers of symptoms, may also cause the patient to feel worse before feeling better. Some patients can experience emotional disturbances like weeping or depression, if suppressed emotional problems led to the illness in the first place.

Research and general acceptance

Since the early 1900s, when the American Medical Association and pharmacists waged a battle against it, homeopathy has been neglected and sometimes ridiculed by mainstream medicine. Aside from politics, part of the reason for this is that there are some aspects of homeopathy which have not been completely explained scientifically. For instance, homeopaths have found that the more they dilute and succuss a remedy, the greater effect it seems to have on the body. Some homeopathic reme-

KEY TERMS

Aggravation—Temporary increase in symptoms due to homeopathic remedy.

Antidote—Substance which cancels the effect of homeopathic remedies.

Homeopath—A homeopathic physician.

Proving—Case study of the effect of a homeopathic medicine.

Repertory—Reference manual of homeopathic remedies.

Vital force—Innate wisdom and energy of the body.

dies are so diluted that not even a single molecule of the active agent remains in a solution, yet it still works; studies have demonstrated this paradox, yet can't explain it. Also, homeopathy puts an emphasis on analyzing symptoms and then applying remedies to these symptoms, rather than working by classifying diseases. Thus, some people with the same disease may require different homeopathic medicines and treatments. Furthermore, conventional medicine strives to find out how medicines work in the body before they use them; homeopathy is less concerned with the intricate biochemistry involved than with whether a remedy ultimately works and heals holistically. For all these reasons, conventional medicine claims that homeopathy is not scientific, but homeopaths are quick to reply that homeopathy has been scientifically developed and studied for centuries, with much documentation and success.

There continue to be many studies that affirm the effectiveness of homeopathic treatments. Among the most celebrated, the *British Medical Journal* in 1991 published a large analysis of homeopathic treatments that were given over the course of 25 years. This project involved over 100 studies of patients with problems ranging from vascular diseases, respiratory problems, infections, **stomach** problems, allergies, recovery from surgeries, arthritis, trauma, psychological problems, diabetes, and others. The study found improvement with homeopathic treatment in most categories of problems, and concluded that the evidence was "sufficient for establishing homeopathy as a regular treatment for certain indications."

Training and certification

The Council on Homeopathic Education is the only organization that accredits training programs in classical

homeopathy. To date, it has accredited five institutions: Bastyr University of Natural Health Sciences in Seattle, Ontario College of Naturopathic Medicine in Toronto, Hahnemann Medical Clinic in Albany, California, the National College of Naturopathic Medicine in Portland, and the International Foundation for Homeopathy, also in Seattle. Other well-known training programs include the Pacific Academy of Homeopathic Medicine in Berkeley, California, and the New England School of Homeopathy in Amherst, Massachusetts.

There are several organizations that certify homeopathic practitioners:

- The National Center for Homeopathy is the largest homeopathic organization, with over 7,000 members. It also runs the Council on Homeopathic Education, and provides a listing of all its members and their credentials. Address: 801 N. Fairfax St., #306, Alexandria, VA 22314, phone (703) 548-7790.
- The American Institute of Homeopathy is the oldest national medical body. It provides a list of D.Ht.s (Diplomate in Homeopathy) certified by the American Board of Homeotherapeutics. Address: 1585 Glencoe, Denver, CO 80220, phone (303) 898-5477.
- The Council for Homeopathic Certification was created in 1992 to establish a certification exam and a code of ethics. It confers upon qualified practitioners a C.C.H. (Certification in Classical Homeopathy). Address: P.O. Box 157, Corte Madera, CA 94976.
- The Homeopathic Academy of Naturopathic Physicians offers a certification based on a competency exam, the "Diplomate in the Homeopathic Academy of Naturopathic Physicians" (D.H.A.N.P.).
- The North American Society of Homeopaths certifies non-physician homeopaths. Address: 10700 Old County Rd. 15, #350, Minneapolis, MN 55441, phone (612) 593-9458.

Hospices

Definition

The term *hospice* refers to an approach to end-of-life care as well as to a type of facility for supportive care of terminally ill patients. Hospice programs provide palliative (care that relieves discomfort but does not improve the patient's condition or cure the disease), patient-centered care, and other services. The goal of hospice care, whether delivered in the patient's home or in a health-care facility, is the provision of humane and compassionate medical, emotional, and spiritual care to the dying.

Description

History

The hospice movement began in the United Kingdom during the middle of the nineteenth century. In Dublin, the Roman Catholic Sisters of Charity undertook to provide a clean, supportive environment for care for the terminally ill. Their approach spread throughout England and as far as Asia, Australia, and Africa; but until the early 1970s, it had not been accepted on any wide scale in the United States.

Two physicians, Drs. Cicely Saunders and Elisabeth Kübler-Ross, are credited with introducing the hospice concept in the United States. Dame Saunders had originally trained as a nurse in England and afterward attended medical school. She founded St. Christopher's Hospice just outside of London in 1962. St. Christopher's pioneered an interdisciplinary team approach to the care of the dying. This approach made great strides in **pain management** and symptom control. Dr. Saunders also developed the basic tenets of hospice philosophy. These include:

- acceptance of death as the natural conclusion of life
- delivery of care by a highly trained, interdisciplinary team of health professionals who communicate among themselves regularly
- an emphasis on effective **pain** management and comprehensive **home care** services
- counseling for the patient and bereavement counseling for the family after the patient's death
- ongoing research and education as essential features of hospice programs

During this same period, Dr. Kübler-Ross, a psychiatrist working in Illinois, published results from her ground-breaking studies of dying patients. Her books about the psychological stages of response to catastrophe and her lectures to health professionals helped to pave the way for the development and acceptance of hospice programs in the United States. The merit of the five stages of acceptance that Dr. Kübler-Ross outlines is that they are not limited to use in counseling the dying. Many patients who become disabled—especially those whose disability and physical impairment are sudden occurrences—go through the same stages of “grieving” for the loss of their previous physical health or quality of life. Paraplegics, quadriplegics, amputees, and patients with brain-stem injuries all progress through these same stages of “acceptance”—and they are not dying.

The first hospice programs in North America opened during the 1970s. In New Haven, Connecticut, the Yale University School of Medicine started a hospice home care program in 1974, adding inpatient facilities in 1979. In 1976, another hospice/home-care program, the Hospice of Marin, began in northern California. After a slow start, interest in and enthusiasm for the hospice concept grew. Health professionals as well as the public at large embraced the idea of death with dignity. The notion of quality care at the end of life combined with grief counseling and bereavement care (counseling and support for families and friends of dying persons) gained widespread acceptance. The hospice movement also benefited from government efforts to contain health-care costs when reimbursement for inpatient hospital services was sharply reduced. Home-based hospice care is a cost-effective alternative to end-of-life care in a hospital or skilled nursing facility.

Present models of hospice care

According to the Hospice Foundation of America, there are presently about 3,100 hospice programs operating in the United States, including Puerto Rico and Guam. During 1998, hospice programs in the United States cared for nearly 540,000 people.

KEY TERMS

Hospice—An approach for providing compassionate, palliative care to terminally ill patients and counseling or assistance for their families. The term may also refer to a hospital unit or freestanding facility devoted to the care of terminally ill patients.

Palliative—A type of care that is intended to relieve pain and suffering, but not to cure.

Patient-controlled analgesia (PCA)—An approach to pain management that allows the patient to control the timing of intravenous doses of analgesic drugs.

Today, there are several successful hospice models. As of 2001, about 80% of hospice care is delivered in patients' homes, although the hospice programs that direct the care may be based in medical facilities. Home health agency programs care for patients at home, while hospital-based programs may devote a special wing, unit, or floor to hospice patients. Freestanding independent for-profit hospices devoted exclusively to care of the terminally ill also exist. Most hospice programs offer a combination of services, both inpatient and home-care programs, allowing patients and families to use both as needed.

One limitation of present hospice models is that most require physicians to estimate that the patient is not likely to live longer than six months. This requirement is related to criteria for **Medicare** eligibility. Unfortunately, it means that terminal patients with uncertain prognoses are often excluded from hospice care, as well as homeless and isolated patients.

Viewpoints

Although the hospice movement has gained widespread acceptance, it is often easier for health professionals to accept hospice theory as opposed to practice. For example, most American health professionals are trained to fight disease with the goal of cure. The hospice concept, on the other hand, requires that physicians, nurses, and other caregivers accept **death and dying** as the natural, inevitable conclusion to life, rather than viewing death as a battle lost. Some health professionals continue to view death as a personal defeat, however, and they remain uncomfortable with hospice care.

Along with acceptance of death as a natural part of the life cycle, health professionals who refer patients to

or work in hospice programs must become especially well informed about pain management and symptom control. This knowledge is necessary because about 80% of hospice patients are dying of end-stage **cancer**. In traditional medical settings, pain medication is often administered when the patient requests it. Hospice care approaches pain control quite differently. By administering pain medication regularly, before it is needed, hospice caregivers hope to prevent pain from recurring. Since addiction and other long-term consequences of narcotic **analgesics** are not a concern for the terminally ill, hospice caregivers focus on relieving pain as completely and effectively as possible. Hospice patients often have **patient-controlled analgesia (PCA)** pumps that allow them to control their pain medication.

Symptom relief often requires more than simply using narcotic analgesia. Hospices consider the patient and family as the unit of care; "family" is broadly defined as embracing all persons who are close to the patient as well as blood relatives. Seeking to relieve physical, psychological, emotional, and spiritual discomfort, hospice teams rely on members of the clergy, pastoral counselors, social workers, psychiatrists, massage therapists, and trained volunteers to comfort patients and family members, in addition to the solace offered by nurses and physicians.

In addition to mainstream medicine, many hospices offer patients and families the opportunity to use complementary and alternative approaches to control symptoms and improve well being. Acupuncture, bodywork, **massage therapy**, aromatherapy, Reiki (energy healing), Native American ceremonies, herbal treatments, and other non-Western practices may be used to calm and soothe patients and their families.

The goal of freestanding hospices and even hospital-based programs is the creation and maintenance of warm, comfortable, home-like environments. Rather than the direct overhead lights found in hospitals, these hospices use floor and table lamps along with natural light to convey a sense of brightness and uplift. Some hospices offer music or pet therapy and fill patient rooms with original artwork and fresh flowers.

Since the patient and his or her family members are considered the unit of care, hospice programs continue to support families and loved ones after the patient's death. Grief and bereavement counseling as well as support groups offer opportunities to express and resolve emotional concerns and share them with others.

Professional implications

The hospice approach emphasizes caring instead of curing, and some health professionals find this practice inconsistent with their previous education, experiences, beliefs, and traditions. Moreover, the involvement of complementary and alternative medicine practitioners may be unsettling for health professionals unaccustomed to interacting with these practitioners.

The hospice approach also requires health professionals to collaborate; they must work together as a team to identify and meet the needs of patients and family members. A hospice team is different from the traditional health-care team because the physician is not necessarily the team leader. In hospice programs, patients and families receive more of their care from nurse specialists with advanced coursework and education, nursing assistants, social workers, pastoral counselors, and volunteers than they do from physicians. Hospice team members support, encourage, and rely on one another as they work together toward the shared goal of assisting patients and families through life's final passage.

Health professionals and volunteers who work in hospice programs have special needs related to professional and emotional support. Since they work so closely with patients and families, they often experience grief and depression when patients die. Sympathy and empathy, the qualities that enable them to perform effectively in their hospice roles, may also hinder their abilities to maintain the emotional distance needed to successfully perform their work, or may lead to premature burnout.

Professional associations, support groups, and counselors provide forums in which hospice workers may share their challenges, frustrations, and losses. Many hospice programs teach workers and volunteers a variety of ways to reduce work-related **stress** and prevent burnout. In addition to teaching various **relaxation** techniques and the healing power of laughter, these programs help health professionals concentrate on the unique satisfactions of their work, their shared values, and their important contributions to the lives of patients and families.

Hospital administration

Definition

Hospital administration is a phrase used to describe those professionals who choose to be a part of upper management in organized hospitals.

Description

In addition to traditional hospitals and medical centers, hospital administrators provide leadership for psychiatric and mental health facilities, alcohol and/or drug rehabilitation centers, and long term care and nursing-home-type agencies. Job qualifications for a career in hospital administration include a college degree and often a master's degree in either business, public administration, or in organizational administration/management. Occasionally a physician, **registered nurse**, pharmacist, social worker, or an individual in another health-related profession employed within the hospital setting will choose the upward mobility route of the hospital administrator. Job titles for individuals in these roles include Administrator, Director, Executive Director, Chief Operating Officer, and Chief Executive Officer. Hospital administrators tend to be at the top of the organizational pay scale and are often considered to be the top-level leaders within the facility, answering to the Board of Directors or the Board of Trustees. The salary

range varies with the region but tends to be higher than that of most other hospital employees, except for physicians who maintain private practices.

There are multiple skills needed for effective hospital administration. Knowledge of basic leadership skills and organizational management is required along with an understanding of organizational culture, i.e., the unwritten rules that determine how an organization operates as a separate system. The hospital administrator provides leadership and strategic directions within the organization to insure continuity and targeted growth over time. People-skills is a phrase used to describe someone who interacts positively with others at all levels. Administrators use people-skills along with an effective communication style to deal with issues in human resources, negotiation, and conflict resolution. Ability to interact positively with the Board of Directors/Trustees, the varied specialty physician groups, allied health care providers, paid staff in general, and the public is essential. Intermixed with the above skills, an administrator uses marketing expertise to ensure that the organization is meeting its market share in providing care. Administrators often interact with patients and families to determine if the organization is meeting patient/family expectations. Also, the administrator must be concerned with maintaining a positive image for the organization and must be able to maintain effective public relations within the community.

Practical business skills are a strong asset for the hospital administrator. Being able to deal with concepts such as overhead, costs, charges, fund asset replacement, capital availability, joint ventures, and how group purchasing arrangements benefit the organization are often a requirement for effective administrators. Financial management skills are critical. The use of financial systems, computer applications, consolidation of services, and network development are needed to achieve positive outcomes and insure quality of care and optimal performance of all employees. Job expectations for hospital administrators demand current knowledge of reimbursement policy within the state as well as an in depth understanding of the way the hospital is reimbursed for services under **Medicare**, **Medicaid**, managed care organizations, and other insurance carriers such as Blue Cross and Blue Shield. The ability to articulate the role the institution plays in the delivery of charity care and more importantly implementing corrective measures as needed for the percentage of charity care provided is crucial to overall organizational outcomes. Hospital administrators spend a significant amount of time addressing legal issues including contracts, partnerships, joint ventures, joint operating agreements, group purchasing, and management contracts.

A working knowledge of health care policy such as the balanced budget act and new regulations dealing with medical record confidentiality are beneficial to the hospital administrator. Administrators should possess a comprehensive view of regulatory requirements mandated by the city, regional, and/or state health departments. A cursory understanding that each specialty group within the hospital setting has its own national board with an accompanying set of requirements that divisions or departments within hospitals are required to meet is also an expectation. A specific example is the National Voluntary Laboratory Accreditation Program that visits hospitals to evaluate the standards in clinical laboratories. And finally inherent in this concept of policy is the hospital administrator's ability to understand what needs to be done for the facility to meet the requirements of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). All hospital administrators should have a working knowledge of coding requirements of **medical records**, national patient classification systems in common use, and the use of diagnostic related groups (DRGs), which is a classification system used to identify specific medical diagnoses. These varied systems are used to report all sorts of data to the regulatory agencies and must be understood to use the data provided by state or federal agencies when communicating with the hospital about things like patient mix or staffing ratios.

Perhaps one unique aspect of role expectations for hospital administrators is learning to identify and keep current with health care issues of regional and national interest. Access to information about changes in reimbursement and managed care regulations, as well as new laws effecting the hospital, is needed. Awareness that many large hospitals are difficult to manage is important. Knowing that the Baby Boomers will shortly be demanding care in hospitals and that this will increase the demand for senior services and put pressure on already scarce resources is beneficial to the administrator. And finally, understanding the impact a nursing shortage has on the hospital is vital to survival.

Effective strategies for success within the role are multifaceted. Management-by-walking-around is a phrase that describes the principle that effective leadership and management is best achieved by directly observing and seeing for oneself the services provided and the overall milieu of the organization. Future outlook includes consideration and understanding of the pros and cons of developing an Internet site for the hospital that provides health information for patients and interested visitors to the web address is an emerging reality. Being able to change with time, evaluating the evolution of the hospital organization, and avoiding the overflow of new

initiatives is crucial to personal survival. Most importantly, successful administrators demonstrate a code of ethics within the organization and demand the same of employees. And finally a basic understanding of mechanisms used to deliver patient care is very helpful. Knowing that practice guidelines, national standards for outcomes, **patient education**, and risk management are all intertwined remains an asset for the effective hospital administrator.

Readers interested in the field of hospital administration are encouraged to explore the web site of the American Hospital Association or related sites listed below to increase personal knowledge about issues that are current and highly significant for hospitals.

Human anatomy

Definition

Human anatomy is the study of the structure of the human body and the relationship between its parts.

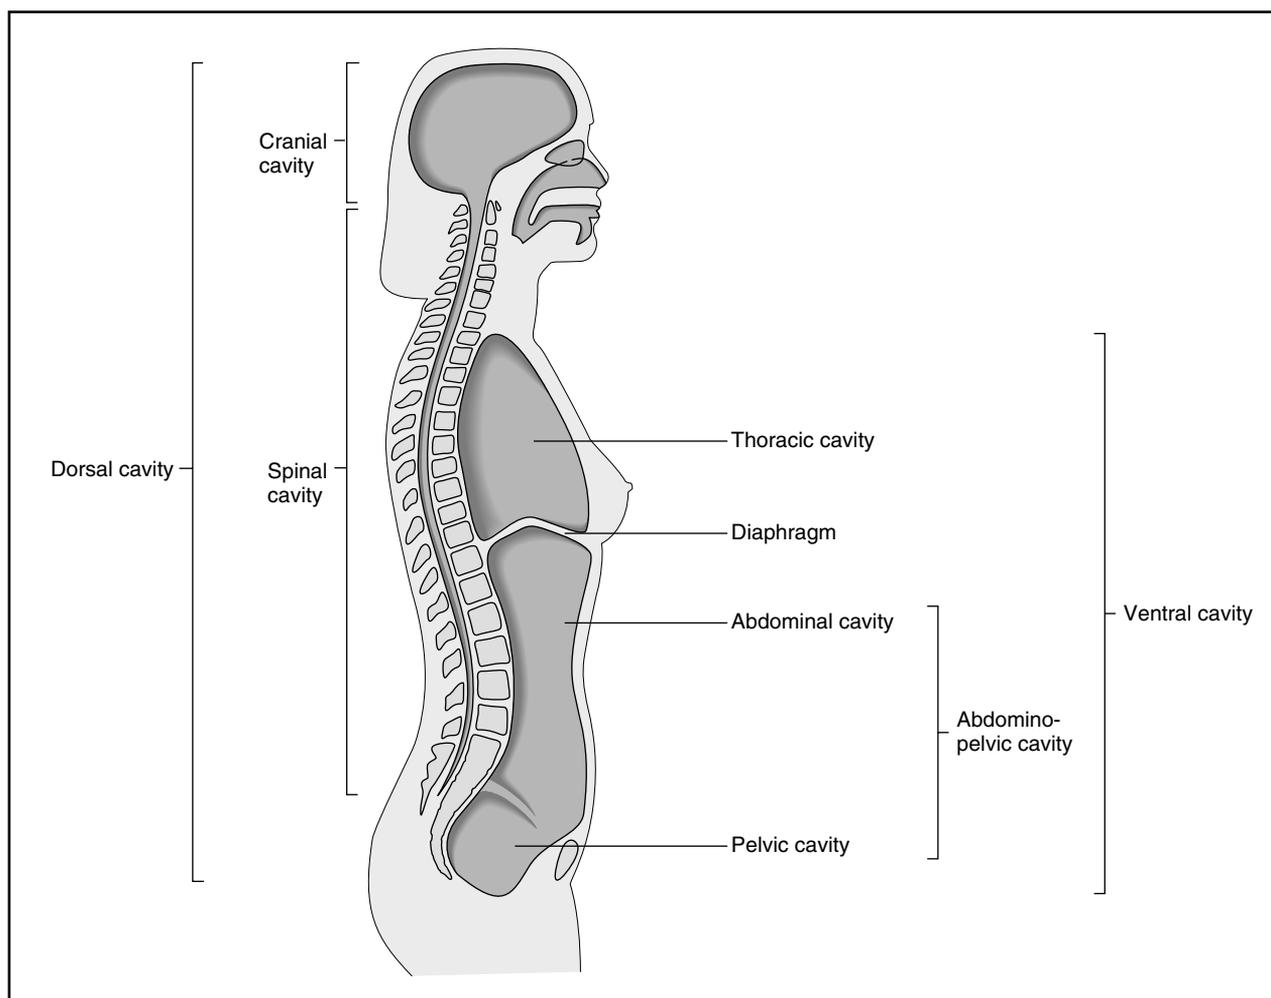

Description

Anatomic position

Discussions on the subject of human anatomy assume that the person is standing erect, feet slightly apart, arms by the side with palms facing forward, thumbs pointing away from the body. This is referred to as the anatomic position and acts as a common reference point for anatomists (an expert or student of anatomy). If the body is lying face up, it is referred to as supine, if it is lying face down, the body is in a prone position.

Various structures can be described in relation to any number of imaginary flat surfaces or planes that bisect the body. The median sagittal plane is a vertical plane that passes through the center of the body, dividing it into right and left sides. The coronal plane, on the other hand, is a vertical plane that is perpendicular to the sagittal plane and divides the body into front and back halves. A paramedian plane passes vertically through the body at any point parallel to the median sagittal plane, while a horizontal or transverse plane is perpendicular to both the sagittal and coronal planes. A plane on an angle to the transverse plane is called an oblique plane.

A number of terms can be used to describe the location of body structures in relation to the above planes. One structure that is closer to the sagittal plane than another is said to be medial, while one that is farther from the sagittal plane is lateral (e.g. the **heart** is medial to the left lung). Structures found on the same side of the median sagittal plane are referred to as ipsilateral, while those on opposite sides of the body are called contralateral. A structure is anterior or ventral if it is before or in front of

The major body cavities. (Delmar Publishers, Inc. Reproduced by permission.)

another structure, and posterior or dorsal if it found after or behind (e.g. the trachea or windpipe is anterior to the esophagus). Superior or cranial structures are found closer to the top or crown of the head than inferior or caudal structures (e.g. the heart is superior to the **stomach**). It is important to remember that the terms left and right are used from the perspective of the person being viewed, not the observer; for instance, the right lung would be on the left hand side of a body as viewed by an observer.

The head, neck, and trunk (the main axis) make up the axial portion of the body while the appendages or limbs compose the appendicular portion. To describe the limbs, the term proximal refers to a structure that is closer to the limb origin; a distal structure is farther from the limb origin (e.g. the wrist is distal to the elbow). The hand has a palmar surface (the anterior side) and a dorsal surface (the posterior side). The upper surface of the foot is called the dorsal surface, while the bottom side is called the plantar surface. Superficial structures are locat-

ed nearer to the surface of the body; those found farther from the surface are referred to as deep structures (e.g. the skin is superficial to the **skeletal muscles**). Internal structures are found inside of an organ or cavity, in contrast to external surfaces which are found outside (e.g. alveoli are internal to the **lungs**).

Terms of movement

A joint is a site where two or more bones come together. Some joints allow no movement between bones (e.g. the bones of the **skull**); others allow only slight movement (e.g. the joints between bones of the **vertebral column**). Still other joints allow free movement (e.g. the hip joint). There are subsequently numerous terms to describe the various movements that joints can make.

Flexion is the bending of a joint, typically in the anterior direction; an example is the bending of the arm at the elbow. In contrast, the term extension describes the

straightening of a joint; an example is the straightening of the leg at the knee. Abduction is the movement of a joint away from the midline along the coronal plane, while adduction is the movement toward the midline along the same plane; the arm, for example, abducts at the shoulder if it moves away from the torso in the same plane. Rotation occurs when a body part moves around its axis; medial rotation results in the anterior surface facing medially and lateral rotation results in the anterior surface facing laterally. The term pronation describes movement of the hand so that it faces posteriorly; supination causes the hand to face anteriorly. Circumduction is a movement that combines flexion, extension, abduction, and adduction; circling the arm around the shoulder joint is an example.

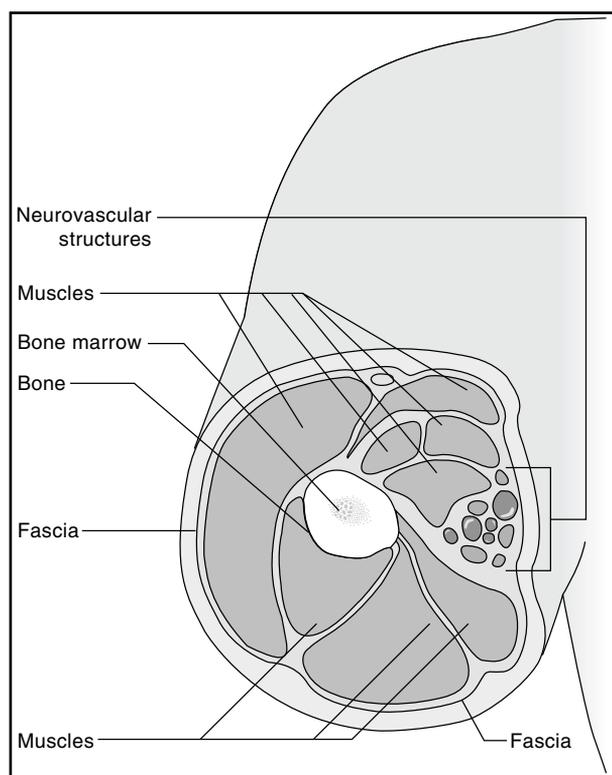

The term protraction describes a motion forward and retraction a motion backward; these describe the movement of the mandible (jaw) at the temporomandibular joints. Inversion occurs when the sole of the foot is turned to face the median (this would happen if you tried to stand on the outer side of your foot); eversion is movement that causes the sole of the foot to face laterally.

Cavities of the body

Within the axial portion of the body lie two major cavities: the dorsal and ventral body cavities. The dorsal body cavity lies posterior to the ventral body cavity and protects the organs of the **central nervous system**. It is composed of the cranial cavity (enclosing the **brain**) and the vertebral cavity (containing the **spinal cord**).

The ventral body cavity is the larger of the two and encloses the viscera or visceral organs (internal organs). It also has two major subdivisions: the thoracic cavity and the abdominopelvic cavity. The thoracic cavity is surrounded anteriorly by the ribs and chest muscles. It encloses two pleural cavities, each encasing a lung, and the mediastinum. The pericardial cavity is located inside of the mediastinum and encloses the heart. The mediastinum also surrounds the esophagus, trachea, and other thoracic organs. The abdominopelvic cavity is separated from the thoracic cavity by the diaphragm, a thin muscle below the lungs and heart that is important for breathing. The abdominopelvic cavity contains the abdominal cavity (enclosing the stomach, **liver**, spleen, intestines, and other digestive organs) and the pelvic cavity (containing the bladder, reproductive organs, and rectum).

There are also smaller body cavities that exist throughout the axial portion of the body. The oral cavity (mouth) contains the teeth and tongue. The digestive cavity includes the oral cavity and extends down to the anus, including all digestive organs. The nasal cavity is found posterior to the nose and is part of the **respiratory sys-**

The anatomic relationship between the skin, muscles, fascia, and bone. (Delmar Publishers, Inc. Reproduced by permission.)

tem. The middle ear cavity is medial to the external ear and contains three small bones (the malleus, the incus, and the stapes) that are essential to normal **hearing**. The orbital cavities are found in the skull and contain the eyes, as well as skeletal muscles and nerves. The freely movable joints of bones are found in synovial cavities, where synovial fluid is secreted that helps lubricate joints and reduce friction between bones.

VENTRAL BODY CAVITY MEMBRANES. The ventral body cavity is lined with a thin membrane called the parietal serosa; internal organs are covered with a similar membrane called the visceral serosa. These membranes secrete a small amount of fluid called serous fluid that separates and lubricates them. Different parietal and visceral membranes have different names for the cavities and organs that they protect. The parietal pericardium lines the cavity that contains the heart and the visceral pericardium covers the surface of the heart. Likewise, the parietal pleura lines the thoracic cavity and the visceral pleura covers the surface of the lungs.

Regions and quadrants

The abdominopelvic region is often further divided into regions or quadrants for reference in study or clinical

cal examination. The abdomen may be partitioned into nine regions, with two transverse planes and two parasagittal planes positioned in a grid. The central grid surrounds the umbilicus (navel) and is subsequently called the umbilical region; the left and right lumbar regions are found lateral to the umbilical region. The epigastric region is located superior to the umbilical region and includes the area of the stomach; the left and right hypochondriac regions are found to each side. Inferior to the umbilical region is the hypogastric or pubic region in which the urinary bladder is found; to each side are the left and right iliac or inguinal regions.

The quadrant system is often used by health care workers during examinations to localize **pain**, tumors, or abdominal structures. The median sagittal plane marks the vertical division while a transverse plane across the umbilicus marks the horizontal division. The subsequent four divisions are named the left upper quadrant (LUQ), right upper quadrant (RUQ), left lower quadrant (LLQ), and right lower quadrant (RLQ).

Different regional terms exist that help to specifically identify different regions or parts of the body. The following are some of the more common regional terms: nasal (nose), oral (mouth), otic (ear), cervical (neck), sternal (sternum or breastbone), axillary (armpit), thoracic (chest), mammary (breast), brachial (arm), abdominal (abdomen), olecranal (elbow), carpal (wrist), digital (fingers and toes), manus (hand), pubic (genitals), patellar (kneecap), crural (leg), femoral (thigh), tarsal (ankle), pedal (foot), vertebral (spinal column), dorsal (back), and gluteal (buttock). If an individual broke a bone in or near the elbow, for example, he or she would experience pain in the olecranal region.

Organization of the body

The complex structures of the human body are organized into numerous hierarchies. The chemical level is the most basic level and is the foundation on which life is based. Many different chemicals are essential to sustain life; these include carbon (C), oxygen (O), nitrogen (N), potassium (K), sodium (Na), and **calcium** (Ca). Atoms (single particles of an element) combine to form molecules that in turn combine to form various structures that are the building blocks of cells. The cell is the basic functional unit of life; on the cellular level, however, it is evident that it is an extremely complex structure. Different types of cells found in the human body include muscle cells, nerve cells, **blood** cells, and epithelial cells.

Similar cells may unite to perform a specific function; these groups of cells are called tissues. These are organized on the tissue level into four major groups: epithelial tissue that covers the internal and external sur-

faces of the body, nervous tissue that transmits electrical signals, muscle tissue that is specialized for contraction, and connective tissue that provides a structural matrix for other tissues. At the organ level, different tissues (at least two types) combine to form an organ, a structure that is capable of performing specialized tasks. Examples of organs are the stomach, lungs, **kidneys**, and liver.

A system consists of groups of organs that have a common function. This next level of organization includes systems such as the respiratory system, reproductive system, and **endocrine system**. The organs of the respiratory system, for example, work together to accomplish the intake of oxygen and the output of carbon dioxide. The organ systems together make up the organism, the individual human being. The organismic level is the highest level in the structural hierarchy; it represents the unification of all body structures and their complex interaction.

ORGAN SYSTEMS. Numerous organ systems are found in the human body. Each corresponds to a group of specialized organs that perform related activities. The following list represents the major organ systems of the human body and their key functions:

- **Integumentary system:** This includes the skin, nails, hair, and sweat and sebaceous glands. The integumentary system provides an external protective covering for the body; helps to regulate body temperature; protects internal organs from injury; excretes sebum, a oily substance with antimicrobial activity; synthesizes **vitamin D**; and has sensory receptors that are sensitive to pain, pressure, temperature, and touch.
- **Skeletal system:** Bones, cartilage, and ligaments make up the skeletal system. It provides a point of attachment for muscles and a framework that supports them. Blood cells are produced in bone marrow (the spongy material found in the center of most large bones); bones also store essential **minerals** such as calcium.
- **Muscular system:** Muscles are the organs of the muscular system. They provide the force necessary for body movement, support organs or body parts, help to maintain posture, provide the main source of body heat, and help in breathing.
- **Nervous system:** This includes the brain, spinal cord, nerves, and sense organs. Nervous impulses are the means by which organs and tissues communicate with the brain; nerve tissues carry impulses from various structures to the brain and vice versa. The nervous system can quickly respond to changes in the internal or external environment.
- **Endocrine system:** The hormone-secreting glands (**pituitary gland**, pineal gland, **thyroid gland**, thymus,

KEY TERMS

Abduction—Movement away from the midline along the coronal plane.

Adduction—Movement toward the midline along the coronal plane.

Anatomic position—Standing erect with feet slightly apart, arms at the side with palms facing forward, thumbs pointing away from the body.

Anterior—Situating before or in front of.

Circumduction—Movement that combines flexion, extension, abduction, and adduction.

Deep—Situating farther from the surface of the body.

Distal—Situating farther from the origin of a limb.

Eversion—Movement that turns the sole of the foot laterally.

Extension—Movement that straightens a joint.

Flexion—Movement that bends a joint.

Inferior—Situating farther from the crown of the head.

Inversion—Movement that turns the sole of the foot medially.

Lateral—Situating farther from the midline.

Medial—Situating closer to the midline.

Organ—A structure composed of different tissues that is capable of performing specialized tasks.

Plane—An imaginary line or surface that passes through the body.

Posterior—Situating after or behind.

Pronation—Movement that turns the hand so that it faces posteriorly.

Prone—The body lying face down.

Proximal—Situating closer to the origin of a limb.

Superficial—Situating closer to the surface of the body.

Superior—Situating closer to the crown of the head.

Supine—The body lying face up.

Tissue—Groups of similar cells that unite to perform a specific function.

adrenal gland, **pancreas**, testis, ovary, and parathyroid gland) make up the endocrine system. They are important in the regulation of different processes such as growth, **metabolism**, reproduction, and milk production in nursing women.

- **Cardiovascular system:** This is composed of the heart, **blood vessels** (arteries and veins), and the blood. The cardiovascular system is the means by which gases, nutrients, and wastes are transported throughout the body; it is also responsible for disseminating hormones, maintaining the **acid-base balance** in blood, and preventing extensive blood loss by the formation of clots.
- **Lymphatic system:** The lymphatic vessels, thymus, spleen, lymph nodes, and red bone marrow are all components of the lymphatic system. It is important in activating the **immune response** against foreign substances, returning tissue fluid to the blood, and supporting the maturation and proliferation of white blood cells.
- **Digestive system:** This includes the oral cavity (mouth, tongue, and teeth), salivary glands, pharynx, esophagus, stomach, liver, **gallbladder**, pancreas, small and large intestines, rectum, and anus. The purpose of the digestive system is to break down food and

absorb necessary nutrients. It is also important in the process of detoxification.

- **Respiratory system:** The nasal cavity, pharynx, larynx, trachea, bronchi, and lungs together make up the respiratory system. It is responsible for the intake of oxygen and the output of carbon dioxide, the exchange of gases through the walls of alveoli (air sacs), and the vocalization of sounds.
- **Urinary system:** The kidneys, ureters, urinary bladder, and urethra are the major components of the urinary system. It is important for removing wastes from the body; maintaining a balance of water and electrolytes in the blood; and producing, storing, and transporting urine (a fluid made up of water, electrolytes, and nitrogenous wastes such as urea, uric acid, and creatinine).
- **Reproductive system:** In males, the reproductive system is made up of the testes, scrotum, penis, epididymes, vas deferens, seminal vesicles, prostate gland, and urethra. Its purpose is to produce the male sex cell (sperm) and transfer sperm to the female reproductive tract. The reproductive system in females is composed of the ovaries, uterus, fallopian tubes, vagina, vulva, and mammary glands. Its purpose is to produce the female sex cell (egg), provide an environment for

sperm to fertilize an egg, support a developing fetus, and produce milk to nourish a newborn baby.

Human growth and development

Definition

In the context of the physical development of children, growth refers to the increase in the size of a child, and development refers to the process by which the child develops his or her psychomotor skills.

Description

Growth

The period of human growth from birth to adolescence is commonly divided into the following stages:

- **Infancy:** From birth to weaning.
- **Childhood:** From weaning to the end of **brain** growth.

- **Juvenile:** From the end of childhood to adolescence.
- **Adolescence:** From the start of growth spurt at **puberty** until sexual maturity.

Growth curves are used to measure growth. The distance curve is a measure of size over time; it records height as a function of age and gets higher with age. The velocity curve measures the rate of growth at a given time for a particular body feature (such as height or weight). The height velocity curve is highest in infancy, up to two years of age, with more consistent annual growth afterwards and increases again at puberty. The height of the average infant increases by 30% by the age of five months and by 50% by the age of one year. The height of a five-year-old usually doubles relative to that at birth. The limbs and arms grow faster than the trunk, so that body proportions undergo marked variation as an infant grows into an adolescent. Different body systems grow and develop at different rates. For example, if infants grew in height as quickly as they do in weight, the average one-year-old would be approximately 5 ft (1.5 m) tall. Thus, weight increases faster than height—an average infant doubles his birth weight by the age of five months and triples it by the age of one year. At two years of age, the weight is usually four times the weight at birth.

Physical development

During the growth period, all major body systems also mature. The major changes occur in the following systems:

- **Skeletal system.** At birth, there is very little bone mass in the infant body, the bones are softer (cartilagenous) and much more flexible than in the adult. The adult skeleton consists of 206 bones joined to ligaments and tendons. It provides support for the attached muscles and the soft tissues of the body. Babies are born with 270 soft bones that eventually fuse together by the age of 20 into the 206 hard, adult bones.
- **Lymphatic system.** The lymphatic system has several functions. It acts as the body's defense mechanism by producing white **blood** cells and specialized cells (antibodies) that destroy foreign organisms that cause disease. It grows at a constant and rapid rate throughout childhood, reaching maturity just before puberty. The amount of lymphatic tissue then decreases so that an adult has approximately 50% less than a child.
- **Central nervous system (CNS).** The CNS consists of the brain, the cranial nerves, and the **spinal cord**. It develops mostly during the first years of life. Although brain cell formation is almost complete before birth, brain maturation continues after birth. The brain of the

newborn is not yet fully developed. It contains about 100 billion brain cells that have yet to be connected into functioning networks. But brain development up to age one is more rapid and extensive than was previously realized. At birth, the brain of the infant is 25% of the adult size. At the age of one year, the brain has grown to 75% of its adult size and to 80% by age three, reaching 90% by age seven. The influence of the early environment on brain development is crucial. Infants exposed to good **nutrition**, toys, and playmates have better brain function at age 12 than those raised in a less stimulating environment.

Psychomotor development

During the first year of life, a baby goes through a series of crucial stages to develop physical coordination. This development usually proceeds cephalocaudally, that is from head to toe. For example, the visual system reaches maturity earlier than do the legs. First, the infant develops control of the head, then of the trunk (sitting up), then of the body (standing), and, finally, of the legs (walking). Development also proceeds proximodistally, that is from the center of the body outward. For example, the head and trunk of the body develop before the arms and legs, and infants learn to control their neck muscles before they learn to direct their limbs. This development of physical coordination is also referred to as motor development and it occurs together with cognitive development, meaning the development of processes such as knowing, learning, thinking, and judging.

The stages of motor development in children are as follows:

- First year. The baby develops good head balance and can see objects directly in his line of **vision**. He learns how to reach for objects and how to transfer them from one hand to the other. Sitting occurs at six months of age. Between nine and 10 months, the infant is able to pull himself to standing and takes his first steps. By the age of eight to 24 months, the baby can perform a variety of tasks such as opening a small box, making marks with a pencil, and correctly inserting squares and circles in a formboard. He is able to seat himself in small chair, he can point at objects of interest, and can feed himself with a spoon.
- Second year. At 24-36 months, the child can turn the pages of a book, scribble with a pencil, build towers with blocks up to a height of about seven layers, and complete a formboard with pieces that are more complex than circles or squares. He can kick a ball, and walks and runs fairly well, with a good sense of balance. Toilet training can be started.

- Third year. The child can now draw circles, squares, and crosses. He can build 10-block towers and imitate the building of trains and bridges. He is also achieving toilet independence. Hand movements are well coordinated and he can stand on one foot.
- Four years. At that age, a child can stand heel to toe for a good 15 seconds with his eyes closed. He can perform the finger-to-nose test very well, also with eyes closed. He can jump in place on both feet.
- Five years. The child can balance on tiptoe for a 10-second period, he can hop on one foot, and can part his lips and clench his teeth.
- Six years. The child can balance on one foot for a 10-second period, he can hit a target with a ball from 5 ft (1.5 m), and jumps over a rope 8 in (20 cm) high.
- Seven years. He can now balance on tiptoes for a 10-second period, bend at the hips sideways, and walk a straight line, heel-to-toe for a distance of 6 ft (1.8 m).
- Eight years. The child can maintain a crouched position on tiptoes for a 10-second period, with arms extended and eyes closed. He is able to touch the fingertips of one hand with his thumb, starting with the little finger and repeating in reverse order.

The development of motor skills in the child goes hand in hand with the development of cognitive skills, a process called cognitive development. Cognitive development can be divided into four stages:

- Sensorimotor stage. At this stage, infants discover their environment using a combination of sensory impressions (sight, **smell**, **hearing**, **taste**, and touch) and motor activities.
- Preoperational stage. At this stage, children are not able to use information in rational and logical ways, rather they use images and symbols. They learn how to associate cause and effect and to represent something with something else. Speech development begins.
- Concrete operational stage. At this stage, children understand elementary logical principles that apply to concrete external objects. They learn to sort things into categories, reverse the direction of their thinking, and think about two concepts (such as length and width) simultaneously.
- Formal operational stage. This stage is reached at adolescence. The individual can think in the abstract and speculate about probabilities and possibilities as well as reflect on their own thinking activities.

The simultaneous development of motor skills and cognitive skills is commonly referred to as psychomotor development and it occurs with the maturation of the central nervous system (CNS).

KEY TERMS

Bilirubin—A pigment produced as the liver processes waste products. Fetal bilirubin is eliminated from the fetus by placental transfer into the mother's plasma. At birth, the infant's liver takes over the elimination of bilirubin.

Central nervous system (CNS)—In humans, the system that consists of the brain, the cranial nerves, and the spinal cord.

Cognitive skills—Skills required to perform higher cognitive processes, such as knowing, learning, thinking, and judging.

Endocrine system—The endocrine system is the collection of glands that produce hormones. Endocrine glands release hormones directly into the bloodstream, where they are transported to organs and tissues throughout the entire body.

Frontal lobes—The frontal lobes of the brain are responsible for higher cognitive processes, meaning the mental processes of knowing, learning, thinking, and judging.

Hormone—Specialized substances required for normal body functions and produced by the glands of the endocrine system. Hormones regulate metabolism, growth, and sexual development.

Human growth hormone (hGH)—Hormone produced by the pituitary gland in the brain. It is usually released during sleep in response to positive and negative signals from the hypothalamus. Also known as the master hormone of the body, hGH affects growth, development, immunity, and metabolism.

Hypothalamus—The hypothalamus is located in the brain, connected to the cerebral cortex, thalamus, and other parts of the brain stem so that it can receive impulses from them and send impulses to

them. It thus functions as a link between the nervous and endocrine systems, being controlled by the central nervous system and controlling, in turn, the pituitary gland.

Immune system—The system that defends the body against infection, disease, and foreign substances.

Motor activity—The physical activity of an individual.

Motor cortex—The area of the frontal lobes of the brain concerned with primary motor control.

Motor skills—Skills required to perform complex motor acts, meaning acts that produce physical movement.

Nervous system—The nervous system is the entire system of nerve tissue in the body. It includes the brain, the brainstem, the spinal cord, the nerves, and the ganglia.

Placenta—An organ that joins the mother to the fetus and provides endocrine secretions as well as the capacity to exchange bloodborne substances, such as nutrients and waste products.

Psychomotor skills—Skills that develop with the maturation of the central nervous system and include both motor and cognitive skills.

Puberty—The period during which the secondary sexual characteristics begin to develop and at which the individual becomes capable of sexual reproduction.

Sense—A perception by the sensory organs of the body. The major senses are sight, smell, hearing, taste, and touch.

Sensory organs—Organs that allow the body to see, smell, hear, taste, and touch.

Function

The function of postnatal growth and development is to bring the individual to the stage of healthy adulthood, physically characterized by the end of growth with full sexual maturity and fertility for the individual.

Role in human health

Successful growth and development promotes health, providing not only physical but also emotional and psychological well-being.

Common diseases and disorders

There are many possible reasons for the impairment of growth and development in a child. Growth and development depend on the interplay of several factors, such as the genetic make-up of the child, the completion of normal **fetal development**, the diet from time of birth, the normal development of the central nervous system, and the quality of the psychological and physical environment, to name but a few. Any disturbance in any of the factors required for growth and development will accordingly affect the successful outcome of the process.

Specific disorders affecting growth and development include:

- Neonatal disorders. During the nine months of gestation, life sustaining functions, such as supplying of oxygen and nutrients, the elimination of waste, and the regulation of body temperature, are all taken care of by the mother. At the moment of birth, the newborn must abruptly take over the performance of all these tasks. Neonatal disorders include all conditions resulting from the unsuccessful transition from fetus to newborn. They cover the wide range of all body systems that undergo significant change at birth. For example, the inability to change from placental to lung-based respiration may include **respiratory distress syndrome** (RDS), which can occur in **premature infants**, and several other breathing disorders. Problems with the blood circulation transition may, for example, result in inadequate oxygen intake (asphyxia) and/or in the decrease of oxygen supply to the tissues (hypoxia). Bilirubin excretion problems may also occur (**jaundice**) if the infant's **liver** can not adequately replace the mother's placenta. Immunological disorders or infections may also result due to the immaturity of the newborn's immune system.
- Feeding and gastrointestinal disorders. Infant feeding disorders include milk regurgitation, overfeeding, underfeeding, vomiting, **diarrhea**, constipation, colic, and adverse effects due to the presence of drugs, if any, in the mother's milk. There are also a number of gastrointestinal disorders that may lead to poor absorption and utilization of food by the body. Failure to absorb nutrients and energy from food then leads to growth deficiencies.
- Inadequate nutrition. Nutritional deficiencies will cause poor growth and development. A balanced diet with adequate calories and protein intake is essential for optimal growth. Children who do not eat proper food-stuffs (malnutrition) develop growth disorders accompanied by intellectual underachievement.
- Attention deficit disorder (ADD). ADD is characterized by the inability to concentrate, hyperactivity, irritability, and impulsivity. As of 2001, 3–10% of the nation's school-age children were diagnosed with the disorder.
- Human growth hormone (hGH) deficiencies. hGH, also known as the master hormone of the body, is responsible for regulating growth, development, immunity, and **metabolism**. It affects the growth of tissues, bones, cartilage, muscles, skin, liver, and **kidneys**. hGH deficiency results in increased body weight and abdominal **obesity**, decreased lean body mass and decreased muscle mass, decreased strength, poor sleep, decreased

physical performance capacity, and lower cardiac performance.

- Diseases affecting the kidneys. Diseases of the kidneys may also impair growth and development as a result of buildup of waste products and undesirable substances in the body. For example, diabetic children grow slowly if their blood sugar is not maintained in the normal range.
- Disorders of the nervous system. Disorders affecting the nervous system can occur before or after birth with diagnosis usually made before one year of age. Some of the conditions that may affect growth and development include partial **paralysis** (spastic paresis), seizures (often infantile spasms), and abnormally large head (macrocephaly) or small head (microcephaly). Infants with nervous system disorders may have poor or absent speech development, epilepsy, abnormal fluid accumulation in the brain and **skull** (hydrocephalus), shrinkage or shortening of muscle tissue (spastic contractures), and mental retardation.
- Genetic or chromosomal abnormalities. There are many genetic disorders that may cause growth failure in children or affect it more or less seriously. They include hereditary defects incompatible with long-term development and survival, as well as hereditary conditions that are seriously life-threatening or that impair some aspect of growth and development.
- Severe **stress** or emotional deprivation. The child's psychological environment also affects physical development. A child requires care, affection, and stimulation for the normal growth and development of his body, brain, and nervous system. A striking example is provided by failure-to-thrive syndrome, in which children suffering from prolonged neglect or abuse simply stop growing. In these children, the psychological stress produced by their social environment causes the **endocrine system** to stop secreting growth hormones.

Human leukocyte antigen test

Definition

The human leukocyte antigen test, also known as HLA or tissue typing, identifies antigens on the white **blood** cells that determine tissue compatibility for organ transplantation (i.e., histocompatibility testing). There are six loci on chromosome 6 where the genes that produce HLA antigens are inherited: HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ, and HLA-DP.

Unlike most blood group antigens which are inherited as products of two alleles (alternative genes), many different alleles can be inherited at each of the HLA loci. These are defined by antibodies (antisera) that recognize specific HLA antigens, or by DNA probes that recognize specific oligonucleotide sequences within the HLA allele. Using specific antibodies, 26 HLA-A alleles, 59 HLA-B alleles, 10 HLA-C alleles, 26 HLA-D alleles, 22 HLA-DR alleles, nine HLA-DQ alleles, and six HLA-DP alleles can be recognized. This high degree of genetic variability (polymorphism) makes finding compatible organs more difficult than finding compatible blood for transfusion.

Purpose

HLA typing, along with ABO grouping, is used to provide evidence of tissue compatibility. The HLA antigens expressed on the surface of the lymphocytes of the recipient are matched against those from various donors. HLA typing is performed for kidney, bone marrow, **liver**, **pancreas** or **heart** transplants. The probability that a transplant will be successful increases with the number of identical HLA antigens. HLA typing is not performed

for blood transfusion or corneal transplants, or for a graft of autologous tissue such as skin or bone.

Graft rejection occurs when the immune cells (T lymphocytes) of the recipient recognize specific HLA antigens on the donor's organ as foreign. These antigens are referred to as Class II histocompatibility antigens. The T lymphocytes initiate a cellular **immune response** characterized by release of cytotoxins and other cytokines that result in graft rejection. The cytotoxic reaction of the T lymphocytes is directed against the Class I histocompatibility antigens on the surface of the organ. Alternatively, T lymphocytes present in the grafted tissue may recognize the host tissues as foreign and produce a cell mediated immune response against the recipient. This is called graft versus host disease (GVHD), and it can lead to life-threatening systemic damage in the recipient. HLA testing is performed in order to reduce the probability of both allograft rejection and GVHD.

HLA typing is also used along with blood typing and DNA tests to determine parentage (i.e., for paternity testing). The HLA antigens of the mother, child, and alleged father can be compared. When an HLA antigen of the child cannot be attributed to the mother or the alleged father, then the latter is excluded as the father of the child.

A third use of HLA testing called linkage analysis is based upon the fact that the region where the HLA loci are positioned, the major histocompatibility complex (MHC), contains many other genes located very close to the HLA loci. The incidence of crossing-over between HLA genes during gamete formation is generally less than 1%. Consequently, the HLA antigens from all six loci are inherited together and segregate with many other genes located within the same region of chromosome 6. Many of the MHC region genes are involved in immunological processes. Consequently, alleles that are known to increase the chance of developing various autoimmune diseases have remained associated with specific HLA alleles. For example, 2% of people who have the HLA-B27 allele develop an arthritic condition of the vertebrae called ankylosing spondylitis. However, approximately nine out of 10 white persons who have ankylosing spondylitis are positive for HLA-B27. Because of this association the disease and this HLA type are linked. Family members of a person with ankylosing spondylitis who are HLA-B27 positive have a much higher likelihood of developing this condition than those who are not. Some notable autoimmune diseases that have a strong association with HLA antigens include Hashimoto's thyroiditis (an autoimmune disorder involving underproduction by the **thyroid gland**) associated with HLA-DR5; Graves' disease (an autoimmune disorder associated with

overproduction by the thyroid gland) associated with HLA-B8 and Dw3; and hereditary hemochromatosis (excess **iron** stores) associated with HLA-A3, B7, and B14.

Precautions

HLA testing is performed using white blood cells harvested from peripheral blood collected by venipuncture. The blood should be collected using either heparin or ACD anticoagulant. The nurse or phlebotomist performing the venipuncture should observe **universal precautions** for the prevention of transmission of blood-borne pathogens. If possible, this test should be postponed if the patient has recently undergone a transfusion. Any white blood cells from the transfusion may interfere with the tissue typing of the patient's lymphocytes.

Description

The HLA gene products can be grouped into three classes. Class I consists of the products of the genes located on the HLA-A, HLA-B, and HLA-C loci. These HLA antigens are found on all nucleated cells. Class II molecules consist of antigens inherited as genes from the HLA-DR, HLA-DQ, and HLA-DP loci. These HLA antigens are normally found only on B lymphocytes, macrophages, monocytes, dendritic cells, endothelial cells, and activated T lymphocytes. Class III molecules consist of several **proteins** belonging to the complement system and cytokines produced by lymphocytes such as tumor necrosis factor. Class III molecules are not evaluated in histocompatibility testing.

Because the HLA loci are closely linked, the HLA antigens are inherited as a group of six antigens called a haplotype. Each person receives one haplotype from each parent. HLA antigens, like blood group antigens, are codominant, and a person expresses both the alleles when two different genes are inherited from each parent. Since crossing-over does not often occur, the probability of siblings having an identical haplotypes is one in four. Therefore, siblings provide the opportunity for the best matches. Unfortunately, they can donate bone marrow, a kidney, and a section of their liver, but cannot donate other solid organs. Approximately 85% of transplants are organs from cadavers, and because the HLA antigens are so highly polymorphic, the chance of identical haplotypes falls precipitously.

Histocompatibility testing consists of three tests, HLA antigen typing (tissue typing), screening of the recipient for anti-HLA antibodies (antibody screen), and the lymphocyte crossmatch (compatibility test). HLA

antigen typing may be performed by serological or DNA methods. In the serological method, called the microcytotoxicity assay, lymphocytes are harvested from the blood by density gradient centrifugation. A solution of Ficoll-Hypaque is layered underneath the whole blood and the tube is centrifuged. Red blood cells and granulocytes are denser than the gradient and are forced to the bottom. The mononuclear cells are less dense than the gradient and are found at the top just underneath the platelets. The mononuclear cell layer is removed and washed. T-cells are removed by one of several methods, for example by binding to magnetic beads coated with T-cell antibodies. The B-cell enriched suspension is tested against a panel of specific antibodies to HLA antigens. The cells are added to wells of a microtiter tray each containing a different antibody. After incubating, rabbit complement is added to each well. Following a second incubation, a dye, Eosin Y, is added. Next, a formalin solution is added to fix the cells and stop any further immunological destruction. If the specific antibodies in the well recognize the HLA antigen on the lymphocytes, they will bind to the cells forming antigen-antibody complexes. The antigen-antibody complexes activate the complement proteins causing partial lysis of the cells. Eosin Y stains only those cells that are dead (i.e., unable to exclude the dye). The cells coated with antibodies can be identified by examining each well with an inverted phase contrast **microscope**. Cells that are stained pink are positive. The percentage of stained cells in each well is used to determine whether the cells are positive or negative for the HLA antigen. In general, when 60% or more of the cells are stained they are considered positive for the HLA antigen defined by the antibody in the well.

The alternative approach to HLA typing is DNA testing. In this method, white blood cells (granulocytes and lymphocytes) are separated from peripheral blood by lysis of the red blood cells and centrifugation. The DNA is extracted from the white cells and added to the wells of a microtiter tray. Each well contains an oligonucleotide primer complementary to a small segment of DNA. Each primer will hybridize with the DNA belonging to only one HLA allele. Therefore, if the primer attaches to the DNA, the corresponding HLA antigen coded by that allele was present on the cells. A master mix containing DNA polymerase and oligonucleotide triphosphates is added to each well and the plate is incubated in a thermal cycler that causes the DNA sequence framed by the primers to be amplified. The amplified products are detected by electrophoresis. The presence of a DNA band in the gel indicates a positive test for the respective HLA antigen.

A laboratory will perform HLA typing by either the serological or DNA method. In either case, HLA typing

KEY TERMS

Antibody—A protein (immunoglobulin) produced by B-lymphocytes in response to stimulation by a specific antigen.

Antigen—A molecule, usually a protein, that elicits the production of a specific antibody or immune response.

Autoimmune disorders—A disorder caused by a reaction of an individual's immune system against the organs or tissues of one's own body.

Cornea—The transparent outer layer of the eye. It covers the iris and lens.

Haplotype—A set of alleles of a group of closely linked genes which are usually inherited as a unit from one parent.

Lymphocyte—A class of white blood cell that is responsible for the immune response to antigens.

Phenotype—A trait produced by a gene. For example, the specific HLA antigen(s) inherited for the HLA-A locus is the phenotype for that gene.

of HLA-A, HLA-B, HLA-DR, and HLA-DQ antigens is performed for solid organ transplants. HLA typing of HLA-C antigens is also included when tissue typing is performed for bone marrow transplants.

The antibody screen is performed in order to detect antibodies in the recipient's serum that react with HLA antigens. The most commonly used method of HLA antibody screening is the microcytotoxicity test with an antiglobulin phase. Leukocytes harvested from the blood of donors of known HLA types are added to the wells of a microtiter plate. Serum from the recipient is added to each well and incubated. The cells are washed to remove any unbound proteins, and antihuman immunoglobulin (AHG) and rabbit complement are added. If an antibody against an HLA antigen is present, it will bind to the cells. The antigen-antibody complexes will bind the antihuman immunoglobulin resulting in partial lysis by the complement. Eosin Y is added and the cells are examined under the microscope. The presence of pink-stained cells indicates the presence of anti-HLA antibodies. As for HLA typing, the percentage of cells stained in each well is used to determine whether the serum is positive or negative for HLA antibody. The antibody screen is reported as the percentage of panel reactive antibodies (PRA). For example, if 50 cells are tested and 10 wells show a positive test, then the PRA is 20%. The higher the number of different HLA antibodies the lower the probability of

finding a compatible match. ELISA test kits that use HLA antigens bound to the wells of a commercially prepared microtiter tray are also available for HLA antibody screening.

The third component of a histocompatibility study is the crossmatch test. In this test peripheral blood lymphocytes from the donor are separated into B and T lymphocyte populations. Purified T cells are prepared by mixing the lymphocyte suspension with magnetic beads coated with monoclonal antibodies to the B lymphocytes. The B-cells bind to the beads that are then pulled to the bottom of the tube by a magnet. The supernatant cell suspension can be used for the T-cell crossmatch. Purified B lymphocytes are produced in like manner except that an antibody to the T-cells is used. In the crossmatch serum from the recipient is mixed with T-cells or B-cells from the donor. The T-cell crossmatch is performed by the same microcytotoxicity method as described above for the antibody screen (i.e., an AHG reagent is used). The B-cell crossmatch is performed by the same microcytotoxicity method as described previously for HLA typing. A positive finding indicates the presence of preformed antibodies in the recipient that are reactive against the donor tissues. An incompatible T-cell crossmatch contraindicates transplantation of a tissue from the T-cell donor.

Preparation

The HLA test requires a blood sample collected in heparin or acid-citrate-dextrose (ACD). There is no need for the patient to fast before the test.

Aftercare

The patient may feel discomfort when blood is drawn from a vein. Bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure should be applied to the puncture site until the bleeding stops to reduce bruising. Warm packs can also be placed over the puncture site to relieve discomfort.

Complications

Risks for this test are minimal, but may include slight bleeding from the puncture site, fainting or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Results

HLA typing either by serological or DNA methods is reported as the phenotype for each HLA loci tested. The antibody screen test is reported as the percentage of panel

reactive antibodies (PRA). The percent PRA is the number of wells reactive with the patient's serum expressed in percent. The crossmatch is reported as compatible or incompatible.

Tissue typing results for both donors and recipients and antibody screen results for recipients are submitted to the United Network for Organ Sharing (UNOS) database. The database searches all regional donors that are ABO compatible for an HLA identical match. If none is found, the database searches the national database for ABO compatible donors and scores the match. A point system is used based upon several parameters including the number of matching HLA loci, the length of time the recipient has been waiting, the recipient's age, and the PRA score.

Health care team roles

A physician specializing in transplantation medicine orders HLA typing tests. A nurse or phlebotomist draws the blood sample. Histocompatibility tests are performed by clinical laboratory scientists/medical technologists with specialized training in cellular immunology and **DNA typing** procedures. Results are interpreted by a physician who specializes in transplantation immunology.

Hydrotherapy

Definition

Hydrotherapy, or water therapy, is the use of water (hot, cold, steam, or ice) to relieve discomfort and promote physical well-being.

Purpose

Hydrotherapy is intended to relieve **pain**, increase mobility, and promote a feeling of well-being. Various methods are used to apply heat or cold to different body parts. Water is a non-toxic substance that is also used for cleansing and irrigating selected body cavities.

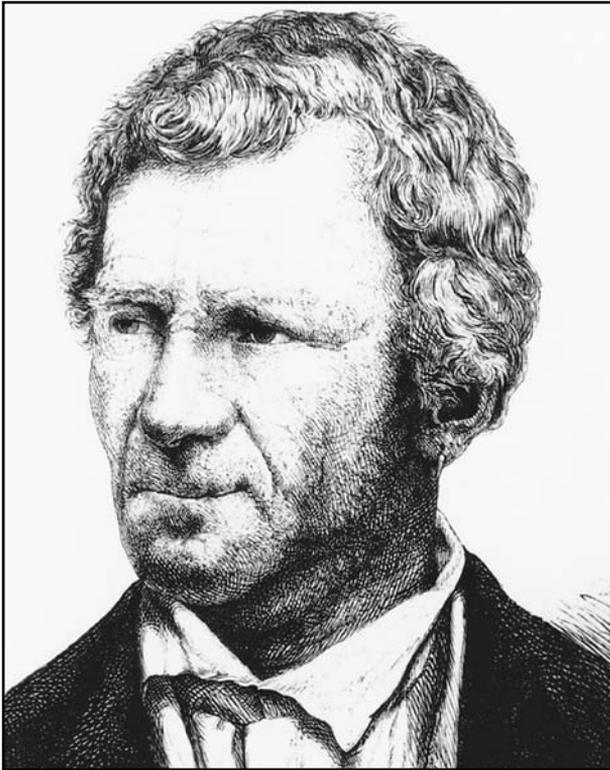

Hydrotherapy is an ancient technique. Historical and archeological evidence has shown that it has been used for several thousand years in both the east and west. Naturally occurring hot or mineral springs have long been used for therapeutic purposes. Herbs and scented oils have been added to heated water for almost as long a period of time.

Hydrotherapy treatments are used by both allopathic and complementary medicine to treat a wide variety of discomforts and disorders. Not as well accepted are invasive hydrotherapy techniques, such as colonic irrigation, **enemas**, and douching. These internal cleansing techniques can actually harm an individual by upsetting the natural balance of the digestive tract and the vagina. Most conventional medical professionals agree that vaginal douches are not necessary to promote hygiene in most women, and can actually do more harm than good.

Precautions

Water should not be hot enough to cause **burns**. Ice should not be left in contact with the skin for prolonged periods of time. Time in a sauna should be limited to avoid hypotension. Persons receiving whirlpool or Jacuzzi treatment should be monitored to avoid accidental drowning or loss of consciousness. Water in whirlpool baths or Jacuzzis should be changed after each use or regularly sanitized and tested. Long hair should be covered when a person is immersed in a whirlpool or Jacuzzi bath. Jewelry should be removed before any hydrotherapy treatment.

Individuals with **paralysis**, frostbite, or other conditions that impair the nerve endings and cause reduced sensation should only take hydrotherapy treatments under the guidance of a trained hydrotherapist, physical therapist, or other appropriate healthcare professional. Because these individuals cannot accurately sense temperature changes, they run the risk of being seriously

Vincenz Priessnitz (1799–1851), an early proponent of hydrotherapy. (Betmann/CORBIS. Reproduced by permission.)

burned. Diabetics and people with **hypertension** should also consult their healthcare professional before using hot tubs or other heat hydrotherapies.

Hot tubs, Jacuzzis, and pools can become breeding grounds for **bacteria** and other infectious organisms if they are not cleaned regularly, maintained properly, kept at the appropriate temperatures, and treated with the proper chemicals. Individuals should check with their healthcare provider to ensure that the hydrotherapy equipment they are using is sanitary. Those who are using hot tubs and other hydrotherapy equipment in their homes should follow the directions for use and maintenance provided by the equipment manufacturer.

Certain essential oils should not be used by pregnant or nursing women or by people with specific illnesses or physical conditions. Individuals suffering from any chronic or acute health condition should inform their healthcare provider before starting treatment with any essential oil.

Essential oils such as cinnamon leaf, juniper, lemon, eucalyptus blue gum, peppermint, and thyme can be extremely irritating to the skin if applied in full concentration. Oils used in hydrotherapy should always be diluted in water before they are applied to the skin.

Individuals should never apply essential oils directly to the skin unless directed to do so by a trained healthcare professional or aromatherapist.

Colonic irrigation should only be performed by a healthcare professional. Pregnant women should never douche, as the practice can introduce bacteria into the vagina and uterus. They should also avoid using hot tubs without the consent of their healthcare provider.

The benefit of vaginal douching for all women is questionable. The vagina is self-cleansing, and douches have been known to upset the balance of vaginal pH and flora, promoting vaginitis and other infections. Some studies have linked excessive vaginal douching to increased incidence of pelvic inflammatory disease (PID).

Description

Water can be used therapeutically in a number of ways. Common forms of hydrotherapy include:

- Whirlpools, Jacuzzis, and hot tubs. These soaking tubs use jet streams to massage the body. They are frequently used by physical therapists to help injured persons regain muscle strength and to soothe joint and muscle pain. Some midwives and obstetricians also approve of the use of hot tubs to soothe the pain of labor.
- Pools and Hubbard tanks. Physical therapists and rehabilitation specialists may prescribe underwater pool exercises as a low-impact method of rebuilding muscle strength in injured people. The buoyancy experienced during pool immersion also helps ease pain in conditions such as arthritis.
- Baths. Tepid baths are prescribed to reduce a **fever**. Baths are also one of the oldest forms of **relaxation** therapy. Adding Epsom salts (magnesium sulfate) or Dead Sea salts to a bath can promote relaxation and soothe rheumatism and arthritis.
- Showers. Showers are often prescribed to stimulate the circulation. Water jets from a shower head are also used to massage sore muscles.
- Moist compresses. Cold, moist compresses can reduce swelling and inflammation of an injury. They can also be used to cool a fever and treat a headache. Hot or warm compresses are useful for soothing muscle aches and treating abscesses.
- Steam treatments and saunas. Steam rooms and saunas are recommended to open the skin pores and cleanse the body of toxins. Steam inhalation is prescribed to treat respiratory infections.
- Internal hydrotherapy. Colonic irrigation is an enema that is designed to cleanse the entire bowel. Douching,

another form of internal hydrotherapy, directs a stream of water into the vagina for cleansing purposes. The water may or may not contain medications or other substances. Douches can be self-administered with kits available at most drug stores.

Preparation

Because of the expense of the equipment and the expertise required to administer effective treatment, hydrotherapy with pools, whirlpools, Hubbard tanks, and saunas is best taken in a professional healthcare facility under the supervision of a healthcare professional. However, baths, steam inhalation treatments, and compresses can be easily administered at home.

Bath preparations

Warm-to-hot bath water should be used for relaxation purposes, and a tepid bath is recommended for reducing fevers. To prepare salts for the bath, add one or two handfuls of Epsom salts or Dead Sea salts to boiling water until they are dissolved, and then add them to the tub.

A sitz bath, or hip bath, can be taken at home to treat hemorrhoids and promote healing of an episiotomy. A special apparatus is available for taking a seated sitz bath, but one can also have a sitz bath in a regular tub partially filled with warm water.

Steam inhalation

Steam inhalation treatments can be easily administered by holding one's head over a bowl of steaming water and using a large towel as a tent.

Compresses

A cold compress is prepared by soaking a cloth or cotton pad in cold water and then applying it to the area of injury or distress. When the cloth reaches room temperature, it should be resoaked and reapplied. Gentle pressure can be applied with the hand to the compress. Cold compresses are generally used to reduce swelling, minimize bruising, and to treat headaches and sprains.

Warm or hot compresses are used to treat abscesses and muscle aches. A warm compress is prepared in the same manner as a cold compress, except steaming water is used to wet the cloth instead of cold water. Warm compresses should be refreshed and reapplied after they cool to room temperature.

Aftercare

Typically, no special care is required after receiving hydrotherapy.

Complications

Most forms of hydrotherapy are well-tolerated and complications are unusual. Water that is too hot may cause burns. Contact with cold temperatures may cause transient hypothermia to the treated portion of the body. The effects of hydrotherapy typically wear off with time, so additional treatments are required if the problem persists. Repeated use of colonic hydrotherapy, however, may impair function of the **large intestine**, leading to dependence on the hydrotherapy to maintain normal bowel function.

There is a risk of allergic reaction (also known as contact dermatitis) for some people using essential oils and herbs in their bath water. These individuals may want to test for allergic sensitization to herbs by performing a skin patch test (i.e., rubbing a small amount of diluted herb on the inside of their elbow and observing the spot for redness and irritation). People who experience an allergic reaction to an essential oil should discontinue its use and contact their healthcare professional for further guidance.

The most serious possible side effect of hydrotherapy is overheating, which may occur when an individual spends too much time in a hot tub or Jacuzzi. However, this is a minimal risk when the patient is properly supervised.

Results

Relief from pain or discomfort is the usual result of hydrotherapy. Increased mobility, especially in joints, also frequently occurs. Many persons receiving hydrotherapy report having higher levels of energy.

Hydrotherapy can soothe sore or inflamed muscles and joints, rehabilitate injured limbs, lower fevers, soothe headaches, promote relaxation, treat burns and frostbite, ease labor pains, and clear up skin problems. The temperature of water used affects the therapeutic properties of the treatment. Hot water is chosen for its relaxing properties. It is also thought to stimulate the **immune system**. Tepid water can also be used for **stress** reduction and may be particularly relaxing in hot weather. Cold water is used to reduce inflammation. Alternating hot and cold water can stimulate the circulatory system and improve the immune system.

Health care team roles

A variety of doctors, such as orthopedic surgeons, sports medicine doctors, and rheumatologists may make an initial referral for some forms of hydrotherapy.

KEY TERMS

Contact dermatitis—Skin irritation as a result of contact with a foreign substance.

Episiotomy—An incision made in the perineum during labor to assist in delivery and to avoid tearing of the perineum.

Essential oil—A volatile oil extracted from the leaves, fruit, flowers, roots, or other components of a plant and used in aromatherapy, perfumes, foods and beverages.

Hubbard tank—A large water tank or tub used for underwater exercises.

Individuals also sometimes initiate visits themselves. A hydrotherapist provides the requested services.

Hydrotherapy is practiced by a number of physical therapists, medical doctors (especially those specializing in rehabilitation), nurses, and naturopathic physicians. Naturopaths are licensed in a number of states. Aromatherapists, who frequently recommend water-based treatments with herbs and essential oils, are not licensed, although there are certification programs available for practitioners.

Hypercoagulability tests

Definition

Hypercoagulability tests measure three **proteins** produced by the **liver** that when deficient increase the risk of thrombosis. These proteins are antithrombin III, protein C, and protein S.

Purpose

The **blood coagulation** process prevents people from bleeding excessively. Normally, this process occurs whenever the **blood** vessel wall incurs damage, and the resulting clot keeps the blood from escaping from the damaged vessel. The coagulation factors responsible for clot formation are mainly enzymes, and their activity is down regulated by other proteins that inactivate them. Abnormal clot formation will occur when one of these proteins is defective or diminished in concentration. The purpose of hypercoagulability tests is to determine whether a person is at increased risk for abnormal clot formation. A person with a deficiency of antithrombin III, protein C, or protein S is at increased risk for thrombus formation. This can result in occlusion of a vessel and diminished blood flow to dependent tissues.

Precautions

When functional activity is being measured for protein S or C, anticoagulant therapy with warfarin (Coumadin) will interfere with the results. Heparin therapy will interfere with functional assays for antithrombin III. Blood for these tests must be collected in sodium citrate. The nurse or phlebotomist collecting blood for this test should observe **universal precautions** for the prevention of transmission of bloodborne pathogens. Shaking the tube vigorously, collecting an insufficient sample, or using the wrong tube required for hypercoagulability tests are not acceptable and will require a second venipuncture.

Description

Hypercoagulable conditions that allow the blood to clot inappropriately pose a life-threatening risk to patients. A thrombus that forms in the absence of bleeding can obstruct the normal flow of blood to tissues beyond the clot site. If a portion of the mass breaks off and travels to another body site or organ, it is called an embolus. A thrombus or embolus can be fatal if it lodges in a vital area like the **heart** or **lungs**. When antithrombin III, protein C, or protein S is deficient or defective,

there will be an increased risk of thrombus or embolus formation.

Deficiencies of antithrombin III, protein C, and protein S may be either inherited or acquired. All three deficiencies are inherited as an autosomal dominant condition. The heterozygote (one defective gene) generally has 40-50% of the normal level of functional protein. Such persons usually have a history of thrombotic events such as deep or superficial vein thrombosis, pulmonary or cerebral embolism, ischemic heart disease or coronary thrombosis. Since the liver is the site of synthesis, a deficiency of each of these proteins can result from liver disease. Antithrombin III deficiency may also be caused by oral contraceptives, nephrotic syndrome, and disseminated intravascular coagulation. Acquired protein S deficiency is also associated with the lupus anticoagulant (an antibody to phospholipid), **pregnancy**, oral contraceptives, and **vitamin K** deficiency.

Hypercoagulability testing is performed when a patient has risk factors that increase the chance of thrombosis. These factors include:

- repeated episodes of thrombosis in the past
- family history of thrombosis
- vascular damage
- severely decreased mobility, bed rest, or paralysis
- heart disease
- severe liver disease
- severe kidney disease
- cancer
- obesity
- surgery
- pregnancy

Antithrombin III

Antithrombin III binds to factor Xa and thrombin (serine proteases involved in coagulation) and prevents them from acting on their natural substrates. Antithrombin III requires heparin for its activity. The heparin is released from the vessel wall cells and complexes the antithrombin III. This causes changes in the conformation of antithrombin III that allow it to bind to the active sites of Xa and thrombin. Two types of assays are available for measuring antithrombin III. Immunoassays such as nephelometry determine the mass of antithrombin III in the plasma based upon its reaction with specific antibody. Functional assays are usually based upon its activity against a chromogenic substrate. The plasma is incubated with excess factor Xa and heparin. The factor Xa that remains active is measured by

KEY TERMS

Immunoassay—A laboratory analysis that uses an antibody-antigen reaction. A specific antibody is used that will react with the protein of interest, for example antithrombin III. In this reaction, the antithrombin III functions as the antigen.

Nephelometry—A laboratory technique used to measure light scattering by small immune complexes suspended in the reaction solution. Light scattering is proportional to the antigen concentration with the antibody is present in excess.

its ability to split a synthetic analide substrate. This produces aniline, which is yellow in color and can be measured at 405 nm. The amount of aniline produced is inversely proportional to antithrombin III activity. Results are expressed as the percentage of a normal control plasma. It is important to note that immunoassays and functional assays may give different results. When the quantity of antithrombin III is decreased, both tests will be abnormal. However, when the protein is defective, the immunoassay result will be normal, but the functional assay will be abnormal. Some functional deficiencies are heparin dependent. When the assay is performed without heparin, the activity is equal to that of the normal control. These persons have an antithrombin III with a defective heparin binding site, and their condition is usually milder.

Protein C

Protein C is a serine protease that enzymatically inactivates both factor Va and factor VIIIa. Protein C is activated when a receptor on the blood vessel cell surface called thrombomodulin binds to and neutralizes the coagulating activity of thrombin. The activity of protein C requires phospholipids from platelets adhering to the vessel wall and also protein S. As with antithrombin III, protein C may be measured by immunoassay or by a functional assay. When immunoassay is used, only a quantitative deficiency of protein C will be detected. Two types of functional assays are used, the chromogenic substrate assay and the clot formation (activated partial thromboplastin) test. In the clot formation test, plasma is mixed with an activator of protein C, usually *Agkistrodon* snake venom. After incubation, **calcium** chloride and activated thromboplastin are added and the time required for a clot to form is measured. The time required for the clot to form is proportional to protein C activity. Results are expressed as the percentage activity of the normal

control. All forms of protein C deficiency are detected by this method. In the chromogenic substrate assay, plasma is mixed with *Agkistrodon* snake venom and incubated. A synthetic analide substrate is added. The activated protein C splits the substrate liberating aniline. The concentration of aniline is measured at 405 nm and is proportional to protein C activity. This assay detects quantitative deficiencies of protein C and some functional defects, but it does not detect defective binding of protein C by protein S.

Protein S

Protein S is a cofactor necessary for protein C activity. Approximately 60% of the circulating protein S is bound to complement and the remainder is free. Only the free protein S is physiologically active. Protein S can be measured by immunoassay or by a clot formation test. The immunoassay measures total protein S unless the protein-bound fraction has been removed prior to assay. Some persons with protein S deficiency have low levels of free protein S but normal levels of the protein-bound form. Others have a decreased concentration of both free and bound protein S. The functional assay will be abnormal in both types. The assay is performed by mixing the patient's plasma with protein S deficient plasma, activated protein C, and activated factor V. After incubation, calcium chloride is added. The time required for a clot to form is proportional to the protein S activity of the sample. The result for the patient is compared to normal plasma to determine the percentage of protein S activity.

Preparation

The reason for testing should be explained by the health care provider. If the patient is taking an anticoagulant medication, the physician may require that the medication be discontinued for a specific time period prior to hypercoagulability testing.

Aftercare

Discomfort or bruising may occur at the puncture site, or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Applying warm packs to the puncture site relieves discomfort.

Complications

Minor temporary discomfort may occur with any blood test, but there are no complications specific to hypercoagulability testing. In normal circumstances, a blood draw for these tests takes only a few minutes, and the patient experiences only minor discomfort.

Results

The results of tests for antithrombin III, protein C, and protein S depend upon the method used. Some representative normal ranges are shown below:

- Antithrombin III activity assessed by immunoassay: 20–30 mg/dL or 0.85–1.22 U/mL.
- Antithrombin III antigen assessed by chromogenic substrate assay: 80–120% of normal activity.
- Protein C activity assessed by photo-optical clot detection: 70–140% of normal activity.
- Protein C antigen assessed by immunoassay: 0.8–2.3 U/mL.
- Protein S activity assessed by photo-optical clot detection: (Male) 70–150% of normal activity; (Female) 58–130% of normal activity.
- Protein S antigen assessed by immunoassay: 0.6–1.8 U/mL.

If the level of any of these regulatory proteins is below normal, the patient has an increased risk of developing serious blood clots.

Health care team roles

A physician orders the tests and interprets the results. Usually a nurse or phlebotomist performs the venipuncture procedure. Clinical laboratory scientists/medical technologists perform the assays for antithrombin III, protein C, and protein S. Persons with family history of thrombosis and abnormal test results may be referred for **genetic testing**. A genetic counselor will explain the genetic findings and the chance of passing the abnormal gene to an offspring.

Patient education

The health care team must provide clear and accurate information for patients who require hypercoagulability testing. The medical implications of having a blood clotting abnormality are serious and the patient must understand the importance of treatment. If an abnormal gene is responsible he or she will require anticoagulant medication for life. Since these deficiencies are inherited as autosomal dominant traits an affected person has a 50% chance of passing the condition to their offspring. Additional members of the patient's family will also require testing.

Hyperopia

Definition

Hyperopia, also known as hypermetropia or farsightedness, is the condition of the eye in which incoming rays of light reach the retina before they converge into a focused image.

Description

When light goes through the lens and cornea, its velocity decreases. The greater the curvature of the lens system, the greater the change in the direction of the light. When parallel light rays from an object go through the lens system, they are bent so they converge at a point some distance behind the lens. With perfect **vision** this

Hyperopia, or farsightedness, is a condition of the eye in which incoming rays of light impinge on the retina before converging into a focused image, resulting in difficulty seeing nearby objects clearly. (Illustration by Electronic Illustrators Group.)

point of convergence is on the retina. Hyperopia is the condition in which the point of focus of parallel light rays from an object is behind the retina. This condition exists when the combined curvature of the lens and cornea is insufficient (e.g., flatter than needed for the length of the eyeball).

There is a connection between the focusing of the lens of the eye (accommodation) and convergence of the eyes (the two eyes turning in to point at a close object). The best example is during reading. The lens accommodates to bring close-up material into focus and the eyes turn in to view the print and keep it single. Because of this connection between accommodation and convergence, the eyes may appear to turn in if the lens needs to accommodate to focus, even on distant objects. This can result in a condition known as accommodative esotropia. The eyes turn in and the cause is accommodation because of hyperopia.

Causes and symptoms

Most babies are born slightly hyperopic. This tends to decrease with age. In some eyes the cornea is too flat for the distance between the cornea and the retina. If the hyperopia is not too severe the lens may accommodate and focus the image onto the retina. This results in clear distance vision, also potential headaches or eyestrain. If the lens cannot accommodate for the full amount of the hyperopia, the distance image would be blurry.

If the eyes are focusing for distance and the patient shifts his or her gaze to a near object, the eyes need to accommodate further. This may result in nearby objects appearing blurry, or the patient may experience headaches while performing work on objects that are close to the eyes.

Symptoms can range widely depending on the severity of hyperopia. There may be no noticeable symptoms, distance vision may be clear but near vision blurry, or both distance and near vision may be blurry. Headaches and eyestrain may occur, particularly when performing near tasks. An eye turned in (esotropia) may be a result of hyperopia, particularly in children.

Diagnosis

To determine hyperopia, a complete eye exam should be performed by an ophthalmologist (M.D.) or optometrist (O.D.). The exam should begin by the physician or ophthalmic assistant taking a detailed medical history from the patient. Then the physician, or in some cases a highly trained ophthalmic assistant, will begin the ocular examination by measuring the visual acuity and performing a refraction.

During the exam the physician will also determine ocular motility and alignment, nearpoint of convergence, near fusional vergence amplitudes, relative accommodation measurements, accommodative amplitude, and facility of accommodation. Additional ocular health assessment and screenings should rule out other accommodative dysfunctional disorders such as Graves' disease.

Treatment

The usual treatment for hyperopia is corrective lenses (eyeglasses or **contact lenses**). Plus-powered spherical or spherocylindrical lenses are prescribed. In some instances, physicians will choose pharmaceuticals to reduce a high accommodative convergence to accommodation.

In June 2000, the Food and Drug Administration (FDA) approved the first laser treatment for hyperopia. Laser thermal keratoplasty (LTK), performed by an

M.D., takes three seconds per eye and involves no cutting or removal of corneal eye tissue. The holium:YAG laser uses a process for shrinking collagen and applies two concentric rings of eight simultaneous spots of laser energy to the periphery of the cornea. The laser heats the corneal collagen and steepens its shape, improving refractive (focusing) power.

LTK patients must be at least 40 years old; have stable vision for at least six months; fall in the low-to-moderate range of hyperopia (+0.75 diopters to +2.50 diopters); and have no more than 0.75 diopters of **astigmatism**. A complete medical history must be taken before the procedure is performed. Patients who fall into any of the following categories should not have LTK performed are:

- pregnant or nursing women
- patients with clinically significant corneal dystrophy or scarring in the 6 mm or 7 mm central zone
- patients with a history of herpetic keratitis
- patients with an autoimmune disease, collagen vascular disease, clinically significant atopic syndrome, insulin dependent diabetes or an immune compromised status

Investigation of phakic intraocular lenses to treat hyperopia continues. As of early 2001, there were three separate FDA clinical trials in progress. The most promising is an implantable contact lens to treat hyperopia that is injected through a clear corneal incision.

In conjunction with these treatments, physicians may also want to address environmental factors to treat hyperopia, and advise patients to reduce glare and improve lighting and ergonomic conditions in their work stations.

Prognosis

Patients with low to moderate amounts of hyperopia have an excellent opportunity to receive fully corrected vision with eyeglasses, contact lenses or refractive surgery. Patients with very high hyperopia (+10.00D or more) may not achieve full correction.

Hyperopia increases the chances of chronic **glaucoma**, but vision loss from glaucoma is preventable.

Health care team roles

Nursing and allied health professionals perform an important role in the examination to determine hyperopia. They take a detailed patient history, insert eyedrops, and ready the physician's instruments. Skilled technicians also can perform the first level of refraction in the general eye exam. Depending on the technician's skill level, the physician may check these findings.

KEY TERMS

Accommodation—The ability of the eyes to focus clearly at various distances.

Cornea—The clear, dome-shaped outer covering of the front of the eye. It lies in front of the iris and pupil.

Iris—The colored ring just behind the cornea and in front of the lens that controls the amount of light sent to the retina.

Pupil—The black hole in the center of the iris. Light enters here on the way to the lens and retina.

Refraction—Method of determining the optical status of the eyes. Lenses are placed before the patient's eyes while reading from an eye chart. The result is the eyeglass prescription.

Retina—The inner, light-sensitive layer of the eye containing rods and cones; transforms the image it receives into electrical messages sent to the brain via the optic nerve.

Technology also allows technicians to perform parts of the exam previously only completed by the eye doctor, including corneal topography, retinal photography, and automated keratometry.

Ophthalmic assistants and nurses also assist in the screening of LTK patients. They prep the patients for surgery and may insert anesthetic eyedrops.

Prevention

Hyperopia is usually present at birth, and there is no known way to prevent it.

Hypertension

Definition

Hypertension is high **blood pressure**. **Blood pressure** is the force of blood pushing against the walls of arteries as it flows through them.

Description

As blood flows through arteries it pushes against the inside of the artery walls. The more pressure the blood exerts on the artery walls, the higher the blood pressure will be. The size of small arteries also affects the blood pressure. When the muscular walls of arteries are relaxed, or dilated, the pressure of the blood flowing through them is lower than when the artery walls narrow, or constrict.

Blood pressure is highest when the **heart** beats to pump blood out into the arteries. Between beats, when the heart relaxes to refill with blood, the pressure drops to its lowest point. The blood pressure peak, when the heart pumps, is called systolic pressure. The blood pressure trough, when the heart is filling, is called diastolic pressure. When blood pressure is measured, the systolic pressure is stated first and the diastolic pressure second. Blood pressure is measured in millimeters of mercury (mm Hg). For example, if a person’s systolic pressure is 120 and diastolic pressure is 80, it is written as 120/80 mm Hg. The American Heart Association considers systolic blood pressure less than 140 and diastolic blood pressure less than 90 normal for adults.

Hypertension is a significant **public health** problem. Since it has no symptoms, many people are unaware that they have hypertension. In the United States, about 50 million people age six and older have high blood pressure. Hypertension occurs more frequently in men than women and in people over the age of 65 than in younger persons. More than half of all Americans over the age of 65 have hypertension. It is also more prevalent in African-Americans than in white Americans.

Hypertension is serious because it places patients at higher risk for heart disease and other medical problems than people with normal blood pressure. Serious complications may be prevented by encouraging patients to check their blood pressure regularly, and by treating hypertension once it is diagnosed.

If left untreated, hypertension can lead to the following medical conditions:

- arteriosclerosis, also called atherosclerosis
- **myocardial infarction** (heart attack)
- cerebrovascular accident (stroke)
- left ventricular hypertrophy leading to congestive **heart failure**
- chronic renal failure (kidney damage)

Arteriosclerosis is hardening of the arteries. The walls of arteries have a layer of muscle and elastic tissue that makes them flexible and able to dilate and constrict as needed. High blood pressure can cause artery walls to thicken and harden. When artery walls thicken, the lumen (hollow center of the blood vessel) narrows. Cholesterol and fatty plaques are more likely to build up on the walls of damaged arteries, further narrowing them. Blood clots can also become trapped in narrowed arteries, blocking the flow of blood.

Arteries narrowed by arteriosclerosis may restrict blood flow to organs and other tissues. Reduced or blocked blood flow to the heart can cause myocardial infarction (a heart attack). Similarly, if an artery to the **brain** is blocked, a stroke can result.

Hypertension forces the heart muscle to work harder to pump blood through the body. The extra workload can cause the heart muscle to thicken and stretch. When the heart becomes too enlarged, it cannot pump enough blood. If hypertension continues and is not treated, the heart may fail.

The **kidneys** remove waste from the blood. Chronic hypertension thickens the arteries to the kidneys and impairs renal (kidney) function. As the condition progresses, the kidneys eventually fail and hemodialysis or kidney transplant will be needed. About 25% of people

who receive hemodialysis have kidney failure caused by hypertension.

Causes and symptoms

Blood pressure varies in response to physical and emotional stimuli. Many different actions or situations normally raise blood pressure. Physical activity can temporarily raise blood pressure. Emotionally stressful situations also can increase blood pressure. When the **stress** subsides or disappears, blood pressure usually returns to normal. These temporary increases in blood pressure are not considered hypertension. A diagnosis of hypertension is made only when a patient has multiple high blood pressure readings over a period of time.

For 90–95% of patients with hypertension, the cause is unknown. Hypertension without a known cause is called primary or essential hypertension.

When a patient has hypertension caused by another medical condition, it is considered secondary hypertension. Secondary hypertension may be caused by a variety of disorders. Many patients with kidney diseases have secondary hypertension because the kidneys regulate the balance of salt and water in the body. If the kidneys cannot rid the body of excess salt and water, blood pressure rises. Chronic pyelonephritis (kidney infections), renal artery stenosis, and glomerulonephritis are examples of kidney diseases that may cause secondary hypertension.

Cushing's syndrome and tumors of the pituitary and **adrenal glands** often increase levels of the adrenal gland hormones—cortisol, adrenaline and aldosterone—which can cause hypertension. Other conditions that may cause secondary hypertension are vasculitis, thyroid disorders, some prescription and over-the-counter medications, **alcoholism**, and **pregnancy**.

Although the cause of most hypertension is not known, some individuals have greater risk of developing hypertension. Many lifestyle-associated risk factors may be modified or eliminated to reduce the chance of developing hypertension or to reduce blood pressure in patients with hypertension.

Risk factors for hypertension include:

- Age; persons over 60 are at greater risk.
- Gender; males are more often affected.
- Race; African Americans are more often affected.
- Heredity; persons with a family history of hypertension are at greater risk.
- Salt sensitivity.
- Obesity.
- Inactive, sedentary lifestyle.

- Heavy alcohol consumption.
- Use of oral contraceptives.

Some risk factors for getting hypertension can be changed, while others cannot. Age, gender, heredity, and race are risk factors that cannot be influenced. An individual with any of these non-modifiable risk factors should avoid or eliminate other, controllable risk factors to reduce the chance of developing hypertension.

Diagnosis

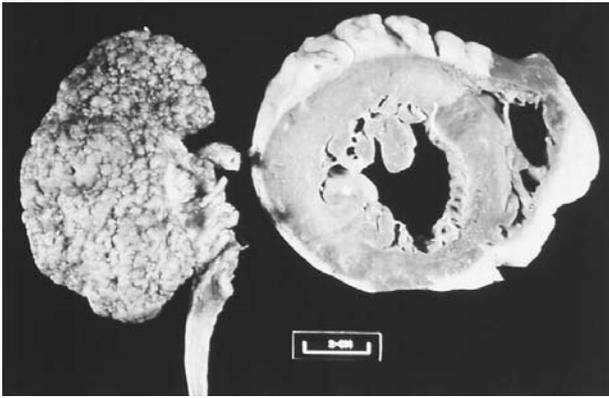

Since hypertension is asymptomatic (does not cause symptoms), it is important for patients to have regular blood pressure checks. Conventionally, blood pressure is measured with an instrument called a **sphygmomanometer**. When the cuff is inflated, an artery in the arm is squeezed to momentarily stop the flow of blood. Then, the air is let out of the cuff while a **stethoscope** placed over the artery is used to detect the sound of the blood spurting back through the artery. This first sound is the systolic pressure, the pressure when the heart beats. The last sound heard as the air is being released is the diastolic blood pressure.

Normal blood pressure is defined by a range of values. Systolic blood pressure lower than 140 mm Hg and diastolic blood pressure lower than 90 mm Hg is considered normal. A number of factors such as **pain**, stress, or **anxiety** can cause a temporary increase in blood pressure. For this reason, hypertension is not diagnosed on the basis of a single elevated blood pressure reading. If a blood pressure reading is 140/90 or higher, the physician or mid-level practitioner (physician assistant or nurse practitioner) will have the patient return for another blood pressure check or instruct the patient to check their blood pressure at home using an inexpensive, automated device. Diagnosis of hypertension usually is made based on two or more readings after the first visit.

Isolated systolic hypertension is common among older adults and is diagnosed when diastolic pressure is normal or low, but the systolic is elevated, e.g. 170/70 mm Hg. This condition usually co-exists with atherosclerosis (hardening of the arteries).

Blood pressure measurements are classified in stages, according to severity:

- Normal blood pressure: less than 130/85 mm Hg.
- High normal: 130–139/85–89 mm Hg.
- Mild hypertension: 140–159/90–99 mm Hg.
- Moderate hypertension: 160–179/100–109 mm Hg.
- Severe hypertension: 180–209/110–119.
- Very severe hypertension: 210/120 or higher.

The effects of hypertension on the heart and kidney. Hypertension has caused renal atrophy and scarring, and left ventricular hypertrophy in the sectioned heart (at right). (Photograph by Dr. E. Walker, Photo Researchers, Inc. Reproduced by permission.)

A typical **physical examination** to evaluate hypertension includes:

- medical and family history
- physical examination
- ophthalmoscopy: examination of the **blood vessels** in the eye
- **chest x ray**
- electrocardiogram (ECG)
- blood and urine tests, including electrolytes, creatinine, protein, **calcium**, random blood sugar, thyroid stimulating hormone (TSH), routine and microscopic **urinalysis** and urine for culture and sensitivity

The medical and family history help the physician or mid-level practitioner to determine if the patient has any conditions or disorders that might contribute to or cause the hypertension. A family history of hypertension may suggest a genetic predisposition for hypertension.

The physical exam may include several blood pressure readings at different times and in different postural positions. The physician or mid-level practitioner uses a stethoscope to listen to sounds made by the heart and for abdominal bruits (blood flowing through partially obstructed arteries). The pulse, **reflexes**, and height and weight are checked and recorded. Internal organs are palpated to determine if they are enlarged.

Since hypertension may cause damage to the blood vessels in the eyes, the eyes may be examined with an ophthalmoscope to detect thickening, narrowing, or hemorrhages in the blood vessels.

A chest x ray can detect an enlarged heart, other vascular abnormalities, or pulmonary (lung) disease.

An electrocardiogram (ECG) measures the electrical activity of the heart. It can detect if the heart muscle is enlarged and if there is damage to the heart muscle from blocked arteries.

Urine and blood tests may be performed to determine whether the hypertension has already caused kidney damage and to detect the presence of disorders that might cause secondary hypertension.

Treatment

There is no cure for primary hypertension, but blood pressure can almost always be lowered with appropriate treatment. The goal of treatment is to lower blood pressure to levels that will prevent heart disease and other complications of hypertension. In secondary hypertension, the underlying disease responsible for the hypertension is treated along with the hypertension itself. Successful treatment of the underlying disorder may entirely eliminate the secondary hypertension.

Treatment to lower blood pressure usually includes changes in diet, regular **exercise**, and antihypertensive medications. Patients with mild or moderate hypertension who do not have damage to the heart or kidneys may initially be treated with lifestyle changes.

Lifestyle changes that may reduce blood pressure by about 5–10 mm Hg include:

- Reducing salt intake.
- Reducing fat intake.
- Losing weight.
- Getting regular exercise.
- Quitting smoking.
- Reducing alcohol consumption.
- Managing stress.

Patients whose blood pressure remains higher than 139/89 will most likely be advised to take antihypertensive medication. Numerous drugs have been developed to treat hypertension. The choice of medication will depend on the stage of hypertension, side effects, other medical conditions the patient may have, and other medicines the patient is taking.

Patients with mild or moderate hypertension are initially treated with monotherapy, a single antihypertensive medicine. If treatment with a single medicine fails to lower blood pressure sufficiently, a different medicine may be tried or another medicine may be added to the first. Patients with more severe hypertension may initially be given a combination of drugs to control hypertension. Combining antihypertensive medicines with different mechanisms of action often controls blood pressure

with smaller doses of each drug than would be needed for monotherapy. It is not uncommon to treat a patient with hypertension with three or more different anti-hypertensive drugs.

Antihypertensive medicines include several classes of drugs:

- diuretics
- beta-adrenergic blockers
- calcium channel blockers
- angiotensin converting enzyme inhibitors (ACE inhibitors)
- angiotensin receptor antagonists
- alpha-adrenergic blockers
- alpha-beta adrenergic blockers
- vasodilators
- selective alpha-adrenergic antagonists
- centrally acting adrenergic agonists

Diuretics, such as hydrochlorothiazide, help the kidneys eliminate excess salt and water, thereby reducing intravascular volume. This results in dilatation of arteries and lower blood pressure.

Beta-adrenergic blockers, such as metoprolol or atenolol, lower blood pressure by blocking the effects of adrenaline thereby slowing the heart rate and reducing the force of the heart's contraction. They are used with caution in patients with heart failure, **asthma**, diabetes, or peripheral arterial disease.

Calcium channel blockers, such as diltiazem, nifedipine, or verapamil, block the entry of calcium into muscle cells in artery walls. Muscle cells need calcium to contract, so reducing their calcium keeps them more relaxed and the arteries dilated. This action lowers blood pressure.

ACE inhibitors, such as lisinopril or captopril, block the effects of angiotensin converting enzyme, thus reducing the production of aldosterone. They are also used for treating congestive heart failure or diabetic nephropathy. ACE inhibitors may be used together with diuretics.

Angiotensin receptor antagonists, such as losartan or candesartan, block angiotensin II receptors in many tissues, allowing blood vessels to dilate and the kidneys to eliminate excess sodium and water.

Alpha-adrenergic blockers, such as phentolamine, act on the nervous system to dilate arteries and reduce the force of the heart's contractions.

Alpha-beta adrenergic blockers, such as labetalol, combine the actions of alpha and beta blockers.

Vasodilators, such as hydralazine, act directly on arteries to relax their walls so blood can move more easily through them. They lower blood pressure rapidly and are injected in hypertensive emergencies when patients have dangerously high blood pressure.

Selective alpha-adrenergic antagonists, such as prazosin or terazosin, act on the nervous system to relax arteries and reduce the force of the heart's contractions. They usually are prescribed together with a diuretic. Selective alpha-adrenergic antagonists may cause slowed mental function and lethargy.

Centrally acting adrenergic agonists, such as clonidine or methyldopa, also act on the nervous system to relax arteries and slow the heart rate. They are usually used with other antihypertensive medicines.

Health care team roles

The diagnosis of hypertension may be made by a primary care physician, mid-level practitioner, or nurse. Often, hypertension is identified during a routine medical visit or during screening at events such as health fairs. Laboratory technologists perform needed blood work and urinalysis; radiologic technologists conduct any ordered x rays, ECG, or imaging studies. Patients returning for follow-up blood pressure checks may be seen by nurses and may receive **nutrition** education from dietitians.

Patient education

Nurses, health educators, dietitians, physicians, mid-level practitioners, and other health professionals are involved in educating the community-at-large about the risks associated with untreated hypertension. Screening programs to detect hypertension also aim to identify individuals with hypertension and encourage them to seek treatment.

Since the condition is asymptomatic, many patients mistakenly believe that they can safely stop treating their hypertension. Health professionals should not only emphasize the importance of adherence, but also should educate patients about the long-term health risks and consequences of untreated hypertension.

Prognosis

There is no known cure for hypertension. However, it can be effectively controlled with proper treatment. Therapy with a combination of lifestyle changes and antihypertensive medicines usually can maintain blood pressure at levels that will not cause damage to the heart or other organs. The key to avoiding serious complica-

KEY TERMS

Arteries—Blood vessels that carry blood to organs and other tissues of the body.

Arteriosclerosis—Hardening and thickening of artery walls.

Cushing's syndrome—A disorder in which too much of the adrenal hormone, cortisol, is produced; it may be caused by a pituitary or adrenal gland tumor.

Diastolic blood pressure—Blood pressure when the heart is resting between beats.

Hypertension—High blood pressure.

Renal artery stenosis—Disorder in which the arteries that supply blood to the kidneys constrict.

Sphygmomanometer—An instrument used to measure blood pressure.

Systolic blood pressure—Blood pressure when the heart contracts (beats).

Vasodilator—Any drug that relaxes blood vessel walls.

Ventricle—One of the two lower chambers of the heart.

tions of hypertension is to detect and treat it before damage occurs. Because antihypertensive medicines control blood pressure, but do not cure it, patients must continue taking the medications to maintain reduced blood pressure levels and avoid complications.

Prevention

Prevention of hypertension centers on avoiding or eliminating known risk factors. Even persons at risk because of age, race, or gender or those who have an inherited risk can lower their chance of developing hypertension.

The risk of developing hypertension can be reduced by making the same changes recommended for treating hypertension:

- Reducing salt intake.
- Reducing fat intake.
- Losing weight.
- Getting regular exercise.
- Quitting smoking.
- Reducing alcohol consumption.

- Managing stress.

Hyperthermia/hypothermia unit management

Definition

Hyperthermia/hypothermia unit management is the use of special electronically regulated blankets or pads to adjust body temperature until it returns to normal levels.

Purpose

The human body operates at temperatures within a fairly narrow range. A body temperature of 98.6°F (Fahrenheit), or 37°C (Celsius), is considered to be normal for human beings. In reality, normal body temperature varies not only in different individuals, but also in the same person, depending upon activities engaged in or the time of day. **Exercise**, eating, and ovulation in women can raise body temperature, while sleeping,

drinking fluids, and (for women) menses can lower it. Body temperature is typically at its lowest level at 3 A.M., and at its highest level at 6 P.M. However, all of these variations do not normally extend beyond a range of 97.8°F (36.5°C) and 99°F (37.2°C).

The purpose of hyperthermia and hypothermia units is to correct aberrant temperature and prevent the complications that can occur when this narrow range of human body temperature is not maintained. Sometimes, body temperature is purposefully lowered to aid in certain surgical procedures. The lower body temperature allows vital organs such as the **heart** to survive with decreased **blood** supply, thus increasing the available time a surgeon has to operate. But the usual reason hyperthermia or hypothermia equipment is used is because the body has exceeded the extremes in temperature.

Normally, a section of the **brain** known as the hypothalamus acts to regulate temperature in a manner similar to the workings of a thermostat. Body temperature is constantly monitored by the hypothalamus, and mechanisms to compensate for any abnormality are set in motion. Classic examples of such mechanisms are shivering and perspiring. The hypothalamus reacts to low body temperature by sending neurological impulses that cause shivering. Shivering in turn produces heat from within the body through muscle activity. When the body temperature rises, the hypothalamus causes fluid to be excreted via the skin as perspiration. As the perspiration evaporates, it lowers the body temperature.

Both excessively high and low temperatures can be medical emergencies capable of causing death without immediate, appropriate medical intervention. Among the causes of abnormally elevated or lowered temperature are:

- exposure to extreme heat or cold
- infections
- glandular disorders, especially those that involve the thyroid gland
- certain tumors
- abnormal reaction to anesthesia
- dehydration

Artificially raising a person's body temperature, or inducing hyperthermia, has not been used as a **cancer** treatment in recent years. Usually, hyperthermia is a pathological condition. Patients whose temperature rises above 105.8°F (41°C) are considered to be at serious risk of brain damage, and those with a temperature above 109.4°F (43° C) will usually not survive. Mental confusion and delirium seizures (especially in young children

and infants) are some of the serious problems associated with high fevers.

Hypothermia is medically defined as a drop in body temperature to below 95°F (35°C). Hypothermia can lead to irregular heartbeat and, eventually, cardiac arrest. The elderly and very young children are the most vulnerable to extreme drops in body temperature. The *Merck Manual* recommends that health care staff consider people with radically low body temperature as viable and treatable until the body has been warmed, and there are still no signs of life such as heartbeat and respirations. Length of exposure to cold and general health are standard predictors of survival, but the National Institute on Aging gives the following guidelines regarding the chances of recovery for hypothermia victims:

- If body temperature has not fallen below 90°F (32.2°C), the likelihood of complete recovery is good.
- When body temperature is between 80°F (26.6°C) and 90°F (32.2°C), the majority of hypothermia victims survive, but are likely to have lasting damage such as brain damage.
- People with temperatures below 80°F (26.6°C) are not likely to live.

Precautions

Hypothermia/hyperthermia units should never be placed in direct contact with the patient's skin due to the risk of **burns**.

Description

For centuries, wrapping feverish people in cold, wet sheets and immersing them in cool baths helped to lower body temperature. Hot water bottles and blankets were used to warm hypothermia victims. Today, hyperthermia blankets or pads are special medical devices that have a built-in temperature regulator, or thermostat, capable of raising or lowering body temperature. Such blankets or pads circulate solution through them at pre-set temperature levels calculated to raise or lower body temperature. There are various kinds, and manufacturer's instructions for each type must be read and understood. Some utilize dry cold to lower temperature, and are used for just one patient and then discarded. Others have a special adapter to change from heat to cold, and can be used again and again. A K-Pad is one brand of pad used in some health care facilities to raise the temperature in hypothermia victims. K-Pads are composed of tubular forms that are filled with water, which is then heated and monitored by an electronic thermostat to keep it at the correct temperature.

KEY TERMS

Axillae—The medical term for the areas under both shoulders commonly called the armpits.

Dehydration—A condition in which a living being's water level within its body has fallen to dangerously low levels.

Hyperthermia—The medical term for abnormally high body temperature.

Hypothalamus—A cherry-sized portion of the brain located behind the eyes that is responsible for the regulation of body temperature, the sympathetic nervous system, and coordination between the nervous and endocrine systems.

Hypothermia—A decrease in body temperature below 95°F (35°C).

Preparation

Often, the patient with a radical alteration in temperature may be unconscious. But if the person is aware, providing a good explanation of what is being done and why will be very important. Although some brands of hyperthermia/hypothermia blankets are cloth-covered, patients should still always have a bath blanket beneath and over them so that their skin does not come in direct contact with the hyperthermia/hypothermia equipment. This is particularly important when the unit is being used to warm the body, as direct contact can result in burns. K-Pads are filled two-thirds full of water, and superfluous air is removed before use.

Most hyperthermia/hypothermia units have dual temperature monitors for both the temperature of the unit and that of the patient. This temperature probe for the person often involves a rectal probe, as that is the most accurate measure of body temperature. Regardless, it is imperative that the person's temperature be monitored constantly, and if the unit does not measure body temperature, then the temperature must be taken with a regular **thermometer**. (In the case of hypothermia, a special thermometer that registers below 94°F [34.4°C] will be necessary.)

Aftercare

In the case of hyperthermia, the cooling unit is removed while the body temperature is still slightly above normal, as the body will continue to cool after the unit is removed. The temperature continues to be monitored, and cold packs to axillae (the armpits) and the

groins may also be used. Often, fever-reducing medications such as acetaminophen are given once the person is conscious, or may be administered by suppository.

The **vital signs** (temperature, pulse, respirations, and **blood pressure**) continue to be monitored for hypothermia patients. The warming unit is not usually removed until the body temperature rises to normal. Warm liquids may be given once the person is conscious.

Complications

The major complication involved in the use of hypothermia/hyperthermia units is either the occurrence of burns from units used for heating or the discomfort from more direct contact with cooling units. Both can be prevented by following procedures, including the placement of bath blankets between the patient and the unit and reading the manufacturer's instructions.

Results

Optimum results from the use of these units are a return to normal bodily temperature without the person sustaining any permanent damage.

Health care team roles

Emergency personnel such as emergency room technicians (EMTs) and physicians are often involved as both hypothermia and hyperthermia are often accidental happenings, occurring due to exposure to heat or cold sustained from immersion in water or being exposed to the elements.

Also, registered nurses (RNs) and licensed practical nurses (LPNs) are responsible for setting up hypothermia/hyperthermia units and caring for the patient undergoing temperature-altering treatment.

Hypopituitarism

Definition

Hypopituitarism, also known as the underactivity of the **pituitary gland** (an endocrine gland), is loss of function in the pituitary and the failure to secrete hormones that affect many of the body's functions. The pea-sized pituitary gland is located at the base of the **brain**, and is attached (by a stalk) to the hypothalamus. Patients diagnosed with hypopituitarism may be deficient in one or several hormones or have complete pituitary failure.

Description

The pituitary gland regulates many hormones that control various functions and organs within the body. Some of these regulatory substances and target glands that can be affected by hypopituitarism are those of the reproductive system, growth hormones, as well as the thyroid and pituitary glands. Hypopituitarism can affect both males and females of any age.

In hypopituitarism, interference with the production and release of some hormones affects the function of the target gland. Commonly affected hormones may include:

Reproductive hormones (i.e., gonadotropin deficiency)

Gonadotropin deficiency involves two distinct hormones affecting the reproductive system. Luteinizing hormone (LH) stimulates the testes in men and the ovaries in women. This deficiency can affect both male and female fertility, and menstruation. Follicle-stimulating hormone (FSH) has similar effects to LH.

Thyroid-stimulating hormone

Thyroid-stimulating hormone (TSH) is involved in stimulation of the **thyroid gland**. A lack of stimulation (deficiency) in the gland leads to hypothyroidism.

Adrenocorticotropic hormone

Also known as corticotropin, adrenocorticotropic hormone (ACTH) stimulates the adrenal gland to produce a hormone similar to cortisone, called cortisol. The loss of this hormone (deficiency) can lead to serious problems.

Growth hormone

Growth hormone (GH) regulates the body's growth. Patients who lose supply of this hormone before physical

maturity will suffer impaired growth. Loss of the hormone can also affect adults.

Other hormone deficiencies

Prolactin stimulates the female breast to produce milk. A hormone produced by the posterior pituitary, called anti-diuretic hormone (ADH), controls the function of the **kidneys**.

Multiple hormone deficiencies

Deficiency of a single pituitary hormone occurs less commonly than deficiency of more than one hormone. Sometimes referred to as progressive pituitary hormone deficiency, or partial hypopituitarism, there is usually a predictable order of hormone loss. Generally, growth hormone is lost first; luteinizing hormone (LH) deficiency follows. The loss of follicle-stimulating hormone (FSH), thyroid stimulating hormone (TSH), and adrenocorticotropic hormones (ACTH) follows. The progressive loss of pituitary hormone secretion is usually a slow process that can occur over a period from months to years. Hypopituitarism, however, occasionally starts suddenly, with rapid onset of symptoms.

Panhypopituitarism

This condition represents the loss of all hormones released by the anterior pituitary gland. Panhypopituitarism is also known as complete pituitary failure.

Causes and symptoms

There are several factors that can lead to the damage of the pituitary gland and the development of hypopituitarism. Causes can be congenital (from birth) or developed at a later stage in life. Interference in the interaction between the pituitary gland and the hypothalamus or other endocrine gland—such as tumors, inflammation, **infection**, lesions, or interruption of **blood** supply—can lead to an underactive pituitary gland. Interruption of the delivery of hormones may include certain tumors and aneurysms. Damage to the gland, from severe **head injury**, radiographic therapy (i.e., for cancers such as leukemia), or surgery can also lead to hypopituitarism.

Another cause of hypopituitarism can be damage to the pituitary gland cells. Destroyed cells cannot produce the pituitary hormones that would normally be secreted by the gland. Cells may be destroyed by a number of diseases and tumors.

Symptoms of hypopituitarism vary with the affected hormones and severity of hormone deficiency. Frequently, patients can have years of nonspecific symptoms that present when major illness or increased levels

of **stress** occur. Overall symptoms may include fatigue, sensitivity to cold, weakness, decreased appetite, weight loss, and abdominal **pain**. Low **blood pressure** (hypotension), headache, and visual disturbances are other associated symptoms.

Symptoms specific to individual hormone deficiencies are as follows:

Gonadotropin deficiency

Symptoms specific to this hormone deficiency include decreased interest in sex for women and **infertility** in women and men. Women may also have premature cessation of menstruation, hot flashes, vaginal dryness, and pain during intercourse. Women who are postmenopausal will not have such obvious symptoms, and may first present with headache or loss of **vision**. Men may also suffer **sexual dysfunction** as a result of gonadotropin deficiency. In acquired gonadotropin deficiency, both men and women may notice loss of body hair.

Thyroid stimulating hormone deficiency

A deficiency of TSH may produce intolerance to cold, fatigue, weight gain, constipation, and pale, waxy and dry skin. These symptoms can indicate thyroid hormone deficiency.

Adrenocorticotropic hormone deficiency

Symptoms of ACTH deficiency include fatigue, weakness, weight loss and low blood pressure. Nausea, pale skin, and loss of pubic and armpit hair in women may also indicate deficiency of ACTH.

Growth hormone deficiency

In children, growth hormone deficiency will result in short stature and growth retardation. Symptoms such as **obesity** and skin wrinkling may or may not show in adults; normal release of growth hormone normally declines with age.

Other hormone deficiencies

Prolactin deficiency is rare and is the result of partial or generalized anterior pituitary failure. When present, the symptom is absence of milk production in women. There are no known symptoms for men. Antidiuretic hormone deficiency may produce symptoms of diabetes insipidus, such as excessive thirst and frequent urination.

Multiple hormone deficiencies

Patients with multiple hormone deficiencies will show symptoms of one or more specific hormone deficiencies or some of the generalized symptoms listed above.

Diagnosis and testing

Once the diagnosis of a single hormone deficiency is made (usually through blood tests, history taking for symptoms, and **physical examination**), it is strongly recommended that tests be conducted to rule out other hormone deficiencies. Diagnostic testing varies between men and women, because of differences in hormone levels between the sexes.

Multiple and general hypopituitarism tests

Nonspecific symptoms can indicate deficiency of one or more hormones. A thorough clinical history should be conducted through questioning by medical support staff and the physician. In general, diagnosis of hypopituitarism can be accomplished with a combination of dynamic and simple blood tests, as well as imaging exams. Most of these tests can be conducted in an outpatient laboratory or radiology facility. The **magnetic resonance imaging (MRI)** exam is the preferred imaging scan to study the suspicious region of the hypothalamus and pituitary glands, and is conducted by a radiographic technician. When MRI is not available, a carefully conducted computed tomography (CT)—also known as a computed axial tomography, or CAT scan—can be performed. Examination of the images produced by a CT can reveal a tumor or other mass that may be interfering with pituitary function. Tests for specific hormone deficiencies are as follows:

Gonadotropin deficiency

The detection of low levels of gonadotropin can be accomplished through simple blood tests that measure LH and FSH simultaneously with gonadal steroid levels. The combination of results can indicate to a physician if the cause of decreased hormone levels or function is attributable to hypopituitarism or some kind of primary gonadal failure.

Thyroid-stimulating hormone (TSH) deficiency

Laboratory tests measuring thyroid function can help the doctor to determine a diagnosis of TSH deficiency. The commonly used tests are T4 and TSH measurement, conducted simultaneously to determine the reserve, or pool, of TSH.

Adrenocorticotropic hormone deficiency

An insulin tolerance test (ITT) may be administered by laboratory technicians to determine if cortisol levels rise when hypoglycemia is induced. If they do not rise, there is insufficient reserve of cortisol, indicating an ACTH deficiency. If the ITT is not safe for a particular patient, a glucagon test offers similar results. A CRH (corticotropin-releasing hormone) test may also be given. It involves injection of CRH to measure, through regularly drawn blood samples, a resulting rise in ACTH and cortisol. Other tests that stimulate ACTH may be ordered.

Growth hormone deficiency

Growth hormone deficiency is measured through the use of insulin-like growth factor tests that measure growth factors that are dependent on growth hormones. Sleep and **exercise** studies may also be used to test for growth hormone deficiency, since these activities are known to stimulate growth hormone secretion. Several drugs can also induce secretion of growth hormone, and may be given in order to measure hormone response. The standard test for growth hormone deficiency is the insulin-induced hypoglycemia test. This test, however, does carry some risk from the induced hypoglycemia. Other tests include an arginine infusion test, clonidine test, and growth-hormone-releasing hormone test.

Other hormone deficiencies

If a test calculates normal levels of prolactin, deficiency of the hormone is eliminated as a diagnosis. A thyrotropin-releasing hormone (TRH) simulation test can determine prolactin levels. A number of tests are available to detect ADH levels.

Panhypopituitarism

The insulin-induced hypoglycemia, or ITT that is used to determine specific hormone deficiencies, is an excellent test to diagnose panhypopituitarism. This test can reveal levels of growth hormone, ACTH (cortisol) and prolactin deficiency. The presence of insufficient levels of all of these hormones is a good indicator of complete pituitary failure. Imaging studies and clinical history are also important.

Treatment

Treatment differs widely, depending on the age and sex of the patient, severity of the deficiency, the number of hormones involved, and the investigation of the underlying cause of the hypopituitarism. Immediate hormone replacement is generally administered to replace the spe-

cific deficient hormone. **Patient education** regarding the medical implications of the diagnosed hormone deficiency is encouraged to help patients manage the impact of their hormone deficiency on daily life. For instance, certain illnesses, accidents, or surgical procedures may elicit adverse complications or lesser outcomes, due to hypopituitarism. Treatment options for each of the hormone deficiencies are outlined below:

Gonadotropin deficiency

Replacement of gonadal steroids is common treatment for LH and FSH deficiency. Estrogen for women and testosterone for men will be prescribed in the lowest effective dosing regimens possible, since there can be complications to this therapy. To correct women's loss of libido, small doses of androgens may be prescribed. To restore fertility in men, regular hormone injections may be required. Male and female patients whose hypopituitarism results from hypothalamic disease may be successfully treated with a hypothalamic-releasing hormone (GnRH), which can restore gonadal function and fertility.

Thyroid stimulating hormone deficiency

In patients who have hypothyroidism, the function of the **adrenal glands** will be tested and treated with steroids before thyroid hormone replacement is administered.

Adrenocorticotropic hormone deficiency

Hydrocortisone, or cortisone, may be given to compensate for this hormone deficiency. Most patients require 20 mg or less of hydrocortisone per day.

Growth hormone deficiency

It is essential to treat children suffering from growth hormone deficiency. The effectiveness of growth hormone therapy in adults, particularly elderly adults, is not as well documented. It is thought to help restore normal muscle to fat ratios. Growth hormone is an expensive and cautiously prescribed treatment.

Treatment of multiple deficiencies and panhypopituitarism

The treatment of hypopituitarism is usually very straightforward, but must normally continue for the remainder of the patient's life. Some patients may receive treatment with GnRH, the hypothalamic hormone. In most cases, treatment will be based on the specific hormone deficiency. Patients with hypopituitarism should be regularly monitored to measure treatment effectiveness and to avoid overtreatment with hormone therapy.

KEY TERMS

Adenoma—A benign (not threatening or cancerous) tumor that originates in a gland.

Androgen—A hormone that usually stimulates the sex hormones of the male.

Congenital—Present at birth.

Endocrine—Refers to the system of internal secretion of substances into the body system from glands.

Hypothyroidism—Deficient activity of the thyroid gland and resulting loss of energy.

Radiation or surgical removal are options for treatment if the disorder is caused by a tumor or lesion. Successful removal of the mass may reverse the hypopituitarism. Even after its removal, however, hormone replacement therapy may still be necessary.

Prognosis

The prognosis for most patients with hypopituitarism is positive. As long as therapy is continued, many experience normal life spans. However, hypopituitarism is usually a permanent condition, and prognosis depends on the primary cause of the disorder. It can be potentially life threatening, particularly when acute hypopituitarism occurs as a result of a large pituitary tumor. The cause is not known. It is possible that increased morbidity and death are due to overtreatment with hormones. Recovery of pituitary function without medical intervention is preferred to lifelong hormone therapy.

Health care team roles

As with all conditions and diseases, patient education is critical and provided by medical support staff (i.e., nurses, nurse practitioners, physician assistants). Because of the delicate nature of several of the hormone deficiencies (e.g., growth and reproductive hormones), patients may experience low self-esteem and depression. Staff members who are in personal contact with patients during visits record any symptoms of stress or depression/anxiety, and should alert the physician. Patients should be advised on the benefits of mental health consultations or participation in support groups.

Coordination of care between mental health care providers, specialists and, in the instance of a surgical consult, surgical and hospital staff, may be required. This necessitates follow-up calls to the various health care

providers who may become involved in the case. In some instances, patients will need to learn how to give themselves subcutaneous hormone injections, which requires teaching assistance from nursing staff or laboratory technicians. Alternatively, these patients may be required to make frequent office visits that require chart monitoring and assistance by office personnel. In this case, nursing and scheduling staff support is imperative to the avoidance of additional stress on the patient.

When the patient first presents with symptoms of hypopituitarism, explanation of testing can ease the frustration of finding the diagnosis. The importance of patient compliance with a hormone regimen should be emphasized. In the case of deficiencies of more than one hormone, a daily treatment timetable may be needed (e.g., what time of day to take each hormone supplement). Thorough knowledge of the regimen is required by support staff members, and monitoring the regimen is important. Family members may be recruited to assist the health care team in making sure that compliance is optimal. Detailed chart management, thorough history taking at each subsequent visit, and the recording of notes on the smallest changes in a patient's symptoms are vital to a positive outcome.

Prevention

There is no known means of prevention of hypopituitarism apart from the prevention of damage/injury to the pituitary/hypothalamic areas of the head.

Hysterosalpingography

Definition

Hysterosalpingography is a procedure where x rays are taken of a woman's reproductive anatomy after a contrast dye is injected into the cervix. *Hystero* means uterus and *salpingo* means tubes, so hysterosalpingography literally means to take pictures of the uterus and fallopian tubes. This procedure may also be called HSG or hystero-graphy.

Purpose

Hysterosalpingography is used to determine if the fallopian tubes are open, or if there are any apparent abnormalities or defects in the uterus. It can be used to detect tumors, scar tissue, or tears in the lining of the uterus. This procedure is often used to help in diagnosing any physical abnormalities causing **infertility** in women. The fallopian tubes are the location where an egg from the ovary joins with sperm to produce a fertilized ovum. If the fallopian tubes are blocked or deformed, the egg may not be able to descend or the sperm may be blocked from moving up to meet the egg. Up to 30% of all cases of infertility are due to damaged or blocked fallopian tubes.

Precautions

This procedure should not be done on women who suspect they might be pregnant or who may have a pelvic **infection**. The exam is usually timed within a few days after a period to minimize the chance of performing the procedure while the patient is pregnant. If a woman has a history of **heart** abnormalities, she should consult with her doctor prior to the exam. Women who have had an allergic reaction to the contrast dye used in previous x-ray procedures should inform their doctor.

Description

As with other types of pelvic examinations, the woman will lie on her back on an examination table with her legs sometimes raised in stirrups. The x-ray equipment is placed above the abdomen.

A speculum is inserted into the vagina by the radiologist. The cervix is numbed with a local anesthetic such as Xylocaine 1%, and sometimes an instrument called a tenaculum, is gently clamped onto the cervix to hold it steady. This is mostly painless, although the patient will feel some pressure from the clamp. A catheter (a thin tube) is inserted into the uterus through the cervix (the opening to the uterus). A tiny balloon in the catheter is

A hysterosalpingogram of the abdomen of a woman whose fallopian tubes are blocked. The right fallopian tube (left on image) is blocked near the uterus, the triangular shape at center. The left fallopian tube is obstructed at a point further from the uterus where dilatation has occurred.
(Photo Researchers, Inc. Reproduced by permission.)

inflated to hold it in place. A liquid water-based or oil-based dye is then injected through the catheter into the uterus. As the contrast spills into and out of the fallopian tubes, some cramping, **pain**, and spasms usually occur. The patient might also feel a burning sensation in her pelvic cavity.

As the contrast spreads through the reproductive tract, the doctor will watch for blockages or abnormalities on an x-ray monitor. Several x rays will also be taken. The procedure takes approximately 15–30 minutes. The x rays will be developed while the patient waits, but the final reading and interpretation of the x rays by a radiologist (a doctor who specializes in x rays) may not be available for a few days. Typically, the radiologist can give the patient their impression, as they watch the progress of the contrast.

Interestingly, sometimes the hysterosalpingography procedure itself can be considered a treatment. The contrast used can sometimes open up small blockages in the fallopian tubes. This happens due to the pressure created in the injection of the contrast, and it is not uncommon for the patient to become pregnant in the month or two after the exam. The need for additional test procedures or surgical treatments to deal with infertility should be discussed with the doctor.

KEY TERMS

Catheter—A thin tube, usually made of plastic, that is inserted into the body to allow the passage of fluid into or out of a site.

Fallopian tubes—The narrow ducts leading from a woman's ovaries to the uterus. After an egg is released from the ovary during ovulation, fertilization (the union of sperm and egg) normally occurs in the fallopian tubes.

Hystero-graphy—Another term for the x-ray procedure of the uterus and fallopian tubes.

Hysterosalpingogram—The term for the x ray taken during a hysterosalpingography procedure.

Speculum—A plastic or stainless steel instrument that is inserted into the opening of the vagina so the cervix (the opening of the uterus) and interior of the vagina can be examined.

Tenaculum—An instrument used to hold onto the cervix to render it immobile.

Preparation

This procedure is generally done in the x-ray department of a hospital or large clinic. **General anesthesia** is not needed. A non-aspirin based pain reliever may be taken prior to the procedure to lessen the severity of cramping.

Aftercare

No special aftercare is required after a hysterosalpingography. There may be a small amount of spotty bleeding for a few hours after the procedure, as well as some contrast that may flow out of the vaginal opening therefore a sanitary napkin may be worn after the procedure. If a blockage is seen in a tube, the patient may be given an antibiotic. A woman should notify her doctor if she experiences excessive bleeding, extensive pelvic pain, **fever**, or an unpleasant vaginal odor after the procedure. These symptoms may indicate a pelvic infection. Counseling may be necessary to interpret the results of the x rays, and to discuss any additional procedures to treat tubal blockages or uterine abnormalities found.

Complications

Cramps during the procedure are common. It is important that the radiologist inject the contrast very slowly as a blockage might cause extensive pain if the

blockage doesn't resolve from the force of the injection. The radiologist can observe this on the x-ray monitor, and adjust their technique accordingly. Rare complications associated with hysterosalpingography include pelvic infection and allergic reactions. If a patient notices a vaginal odor or unusual discharge, she should contact her own physician for treatment immediately. Although this test is relatively accurate, in some circumstances, abnormalities will not be seen on the films.

Results

A normal hysterosalpingography will show a normally shaped uterus and unblocked fallopian tubes.

Blockage of one or both of the fallopian tubes or abnormalities of the uterus may be detected. In addition, any pelvic scarring might also be observed.

Health care team roles

The technologist plays a large role in the comfort and cooperation of the patient in this exam. Being prepared with all equipment and supplies is very critical as well. It is important that the technologist be informative, gentle, and calm, as most women having this exam are stressed as a result of their infertility. The technologist can share any unusual concerns regarding the patient, with the radiologist prior to the beginning of the exam.

Training

The technologist doing the HSG is highly trained in this procedure, and must be organized and confident in his or her abilities. The technologist has often observed and assisted in numerous HSG exams, both as a student radiographer and a technologist, prior to performing them with only the physician present.

Hysteroscopy

Definition

Hysteroscopy enables a physician to look through the vagina and neck of the uterus (cervix) to inspect the cavity of the uterus with an instrument called a hysteroscope. Hysteroscopy is used as both a diagnostic and a treatment tool.

Purpose

Diagnostic hysteroscopy can be used to help determine the cause of **infertility**, dysfunctional uterine bleeding, and repeated miscarriages. It can also help locate polyps and fibroids, as well as intrauterine devices (IUDs).

The procedure is also used to investigate and treat gynecological conditions, often instead of or in addition to dilation and curettage (D&C). A D&C is a surgical procedure that expands the cervical canal (dilation) so that the lining of the uterus can be scraped (curettage). A D&C can be used to take a sample of the lining of the uterus for analysis. Hysteroscopy has advantages over a D&C because the doctor can take tissue samples of specific areas and view any fibroids, polyps, or structural abnormalities. In addition, small fibroids and polyps may be removed via the hysteroscope (in combination with other extremely small instruments that are inserted through canals in the hysteroscope), thus avoiding more invasive and complicated open surgery. This approach is also used to remove IUDs that have become embedded in the wall of the uterus.

Precautions

The procedure is not performed on women with acute pelvic inflammatory disease (PID) due to the potential for exacerbation. A hysteroscopy should be scheduled after menstrual bleeding has ended and before

ovulation to avoid a potential interruption of a new **pregnancy**.

Description

Diagnostic hysteroscopy is performed in either a doctor's office or hospital. Uterine size and potential diagnosis and complexity of treatment determine the setting. The hysteroscope itself is an extremely thin telescope-like instrument that looks like a lighted tube. The modern hysteroscope is so thin that it can fit through the cervix with only minimal or no dilation.

Before inserting the hysteroscope, the doctor administers an anesthetic. Once it has taken effect, the doctor dilates the cervix slightly, then inserts the hysteroscope through the cervix to reveal the inside of the uterus. Ordinarily, the walls of the uterus are touching each other. In order to get a better view, the uterus may be inflated with carbon dioxide gas or fluid. Hysteroscopy takes approximately 30 minutes.

Treatment involving the use of hysteroscopy is usually performed as a short-stay hospital procedure with regional or **general anesthesia**. Tiny **surgical instruments** may be inserted through the hysteroscope to remove polyps or fibroids. A small sample of tissue lining the uterus is often removed for examination, especially if the patient has any abnormal bleeding.

Preparation

If the procedure is performed under general anesthesia, the patient should have nothing to eat or drink after midnight the night before the procedure. Routine lab tests may be ordered if the procedure is performed in a hospital. Occasionally, a mild sedative is administered to help the patient relax. The patient is asked to empty her bladder. She is then placed in position (usually in a special chair that tilts back), and the vagina is cleansed. Usually a local anesthetic, like a dentist may use, is administered around the cervix. However, a regional anesthetic that blocks nerves connected to the pelvic region or a general anesthetic may be required for some patients.

Aftercare

It is normal to experience light bleeding for one to two days after surgical hysteroscopy. Mild cramping or **pain** is common after operative hysteroscopy but usually diminishes within eight hours. If carbon dioxide gas was used, the resulting discomfort usually subsides within 24 hours.

KEY TERMS

Dilation and curettage (D&C)—A surgical procedure that expands the cervical canal (dilation) so that the lining of the uterus can be scraped (curettage).

Fibroid—A benign tumor of the uterus.

Polyp—A growth that projects from the lining of the cervix or any other mucus membrane.

Septum—An extra fold of tissue down the center of the uterus. This tissue can be removed with a wire electrode and a hysteroscope.

Complications

Diagnostic hysteroscopy rarely causes complications. The primary risk is for **infection**. Prolonged bleeding may follow a surgical hysteroscopy to remove a growth.

Other complications include perforation of the uterus, bowel, or bladder caused by too forceful advancement of the hysteroscope. An infrequent but dangerous complication is increased fluid absorption from the uterus into the **blood** stream. Keeping track of the amount of fluid used during the procedure can minimize this complication. Surgery under general anesthesia poses the additional risks typically associated with this type of anesthesia.

Patients should notify their health care provider if, after the hysteroscopy, they develop any of these symptoms:

- abnormal discharge
- heavy bleeding
- fever over 101°F (38.3°C)

- severe lower abdominal pain

Results

A normal hysteroscopy reveals a healthy uterus with no fibroids or other growths. Abnormal results include uterine fibroids, polyps, or a septum (an extra fold of tissue down the center of the uterus). Sometimes, precancerous or malignant growths are discovered.

Health care team roles

The test is usually performed by a gynecologist. Nursing staff assist with providing education, positioning the patient, and specimen collection.

I Immovable joint

Definition

An immovable joint is an articulation between bones in which no movement occurs. It is also referred to as synarthrotic (meaning immovable).

Description

An immovable joint can be either one of two types of joints, fibrous or cartilaginous. In a fibrous joint, there are two types of articulations that are considered immovable, suture and gomphosis.

A suture is a type of articulation in which the bones that make up the joint are close together. An analogy to this is the interlocking fashion exhibited by placing puzzle pieces together. In a suture, the union of bones is bound by connective tissue.

A gomphosis is a type of joint in which one bone fits into another bone. The articulating edges are bound together by connective tissue. Similar to the suture, the bony surfaces in the articulation are close together. An analogy to this is a wooden dowel fitting into a hole and held together by glue, with the dowel and hole representing the bony structures and the glue representing the connective tissue.

In a cartilaginous type of joint, there is one type of articulation that is considered immovable, the synchondrosis.

The immovable joints of the skull are joined by sutures. The coronal suture is along the top of the skull, and the lambdoidal suture is seen toward the back of the skull.
(Photograph by Simon Brown. Science Source/Photo Researchers. Reproduced by permission.)

A synchondrosis is a joint in which the articulating surfaces are close together but are bound by hyaline cartilage. In a synchondrosis, the hyaline cartilage eventually converts to either bone or fibrocartilage.

Function

The function of the immovable or synarthrotic joint is to provide a stable union between bony surfaces. The suture and synchondrosis actually become more stable when ossification of the joint takes place.

KEY TERMS

Cartilaginous joint—A joint that represents the connection of two bones bound by either hyaline fibro or elastic cartilage.

Connective tissue—Tissue that has pliable fibers, which provide strength to the tissue.

Diaphysis—The center or shaft of a bone that is ossified.

Epiphysis—Considered a secondary center of ossification. This secondary center of ossification appears at the ends of long bone.

Fibrocartilage—Connective tissue made up of collagen fibers with less ground substance compared to hyaline cartilage.

Fibrous joint—Surfaces of two bones that are connected by fibrous tissue, which consists mainly of collagen fibers.

Hyaline cartilage—A mesh of collagen fibers and ground substance.

Proximal—The closest portion of a bone, structure, or other element that is close to the head of the body.

Synarthrosis—An immovable joint.

Role in human health

An example of a suture in the human body is the fibrous joints between the bones of the **skull**. Before birth the suture is fibrous tissue that forms soft spots on the skull. The common medical term is fontanelle. The fibrous joint between the bones of the skull allows the skull to be more pliable during birth as the head passes through the vagina. During infancy the pliable nature of the skull, secondary to fibrous sutures, allows for growth of the **brain**. As growth and development occurs the sutures become ossified.

An example of a gomphosis in the human body is the joining of the root of a tooth with the mandible or jaw bone. The fibrous union between the tooth and the bone secures the tooth in its position. This allows the teeth to function as grinders during chewing.

An example of synchondrosis in the human body is two distinct portions of long bone that are separated by a hyaline cartilaginous plate. This typically occurs at the ends of long bones where a cartilaginous plate separates the diaphysis from the epiphysis. This plate allows the

end of bones to grow throughout early human development. As growth and development continue, the hyaline cartilage ossifies. By adulthood the joint is gone. Another example of a synchondrosis in the human body is the articulation between the first rib and the manubrium or the upper portion of the sternum. Initially, the connection between the manubrium and first rib is hyaline cartilage. Through adulthood the hyaline cartilage is replaced by fibrocartilage. This process allows the superior portion of the thorax to be more secure and stable.

Common diseases and disorders

The most common disorder of sutures or fontanelles of the skull is the disruption of the bony components, thus compromising the integrity of the fibrous attachment. This could occur as a result of **head injury** from a blow to the head or a fall. Common disorders of the teeth that compromise the integrity of the fibrous attachment of tooth to bone are: fracture of the jaw bone, fracture of the tooth, avulsion of the tooth, loosening of the tooth secondary to decay, or a blow to the head or jaw. The most common disorder associated with a synchondrosis is a disruption of the epiphyseal hyaline cartilage plate. This is particularly evident in the proximal femur, specifically related to the hip. This disorder occurs mainly in young children as a result of a fall or other trauma. This disruption to the plate can lead to fracture, disruption of **blood** supply, and, if not treated appropriately, deformity of the hip. The medical term for this disorder is slipped capital femoral epiphysis.

Immune response

Definition

The action taken by the body to defend itself from pathogens or abnormalities is called the immune response. With the aid of the **immune system**, the body monitors constant exposure to harmful elements in the external and internal environment and provides a means of defense. Pathogens that are able to cause immune responses included **bacteria**, **viruses**, and parasites. The immune system must be able to determine what is a normal part of the body or “self,” as opposed to that which is foreign or “non-self.” The development of cancers, for example, represents a part of “self” that has been abnormally changed such that it is recognized as foreign to the immune system.

Description

The immune response can be roughly divided into two broad categories, innate (natural) immunity and adaptive (acquired) immunity. Innate immunity is the first line of defense against invasion by pathogens. This response is not directed against any one particular pathogen but is capable of destroying many different invaders. If the pathogen is able to conquer this initial protection, an adaptive immune response will follow. In this response, lymphocytes arise that can specifically kill the invader and prevent re-infection. These lymphocytes recognize specific antigens on pathogens (substances that are foreign to the host cell and cause the production of antibodies to fight the disease).

Innate (natural) immunity

Innate immunity refers to those parts of the immune system that are normally present and do not given an elevated response upon a second exposure to a pathogen (without immunological **memory**). This immunity is non-specific and is not directed against one type of pathogen. It is more generalized to allow the recognition of common elements that may be shared among pathogenic microorganisms.

Anatomical or physical barriers provide innate protection. The skin provides a protective barrier and contains substances that are antimicrobial (against bacterial growth) such as lactic acid, ammonia, and uric acid. The bacteria (microflora) that normally inhabit the skin do not cause disease under normal conditions. These organisms also contribute to innate immunity. The competition of the microflora with pathogens for resources and nutrients limits the growth of pathogens. If the skin is broken due to **wounds** or **burns**, pathogenic bacteria may enter

to cause disease. In the urinary and biliary tracts, the increased flow of secretions provides protection against the establishment of harmful organisms.

Physiologic barriers are also a part of the innate immune system. **Stomach** acid can kill and inhibit the growth of many microorganisms and degrade potentially harmful **proteins**. A rise in body temperature can create an environment that is no longer suitable for the growth of some bacteria. Saliva, nasal secretions, tears, and mucus also contain substances that block viruses and help in the destruction of harmful bacteria.

Some cells of the immune system are able to attack and engulf pathogens, molecules, or particles by a process known as phagocytosis. The Russian immunologist Eli Metchnikoff observed that some pathogenic microorganisms were destroyed by phagocytic cells he called macrophages. These phagocytic cells originate in the bone marrow, are called monocytes in the bloodstream, and become macrophages in the tissue. These phagocytic macrophages in the tissue are able to ingest and destroy some pathogens even though they have not previously encountered them. These cells are capable of migration and are found in many sites throughout the body, including the lymph nodes, spleen, **liver**, **lungs**, as well as the peritoneal lining that surrounds the organs and the lungs. Macrophages in the bone are called osteoclasts, in the **central nervous system** they are called microglia, and in the connective tissue they are known as histiocytes. The neutrophils (polymorphonuclear leukocytes or PMNs) are another type of phagocytic cell that is critically important for innate immunity. These cells are found in great numbers and are one of the most important types of white **blood** cells found in the bloodstream. They are quickly recruited to the site of **infection** to engulf pathogens. Both neutrophils and macrophages contain enzymes that break down the engulfed material.

Natural killer (NK) cells are a type of lymphocyte in the blood that can detect and destroy cells infected by certain viruses. Viruses attack host cells and use them to facilitate viral replication and production of more viruses. Infected host cells must be rapidly destroyed to prevent this replication and spread of disease. It has been observed that natural killer cells play an especially important role in the early defense against herpes viruses. They also are involved in the killing of some tumors. Natural killer cells may kill by activating a process called apoptosis, the programmed cell death that is present in all cells and is responsible for their self-destruction.

The plasma contains a group of proteins called complements that act in a coordinated manner to attack pathogens. When some pathogens bind with a complement protein called C3b, a series of reactions in the alter-

native complement pathway occur. The surface of the pathogen is changed so that phagocytic cells can ingest them, a process called opsinization.

If the pathogen is able to effectively cross the barriers of innate immunity, an early induced, non-adaptive response will occur. This response serves to stop pathogens or slow them down until the body can initiate an adaptive immune response. Additional phagocytic cells and molecules are summoned to the site of infection by cytokines, a group of proteins that affect the actions of other cells. Some cytokines can cause an increase in the number of neutrophils in the circulation and **fever**, an elevation in body temperature. As most pathogenic bacteria have optimal growth at lower temperatures, this temperature rise helps to inhibit their growth. The fever also enhances the adaptive immune responses that follow. Local effects from injury or infection give rise to inflammation as white blood cells, fluid, and plasma proteins gather at the site. This is evident clinically at the site by redness, **pain**, heat, and swelling. The **blood vessels** in the site of injury or infection increase in diameter and allow more blood to flow into the area at a slower rate. Immune cells arrive quickly to the site and move into the tissue from the bloodstream. Small proteins called chemokines assist in this process and enhance the migration and activation of cells. Other special proteins called interferons are produced by virally infected cells and may stop the virus from multiplying within other cells, preventing the spread of infection.

Adaptive (acquired) immunity

In adaptive immunity, the immune response is specific for a particular antigen, causes lymphocytes that recognize the antigen to multiply (clonal expansion), and imparts the quality of immunological memory of prior encounters with the antigen. Specificity is an essential component of adaptive immunity as many organisms have evolved to evade the innate immune system. A system of defense is needed to specifically eliminate these elusive invaders, of which there are countless numbers. Two parts of adaptive immunity meet this challenge: cellular-mediated immunity and humoral (antibody-mediated immunity).

CELL-MEDIATED IMMUNITY. Once a pathogen has evaded the innate immune system, the cellular immune response mechanisms are initiated. In the lymphoid tissues, naive lymphocytes that have not been exposed to the pathogen encounter pathogen antigens for the first time. Dendritic cells, macrophages, and B cells take up the antigens that have been trapped in the lymphoid tissue and present them to naive T cells. These T cells become activated, recognizing specific antigens from the

pathogen and become effector cells; helper T cells (TH1 or TH2) and cytotoxic T cells. The TH1 cells produce interferons and cytokines that assist in the activation of macrophages that have ingested pathogens. They also help B cells make antibodies that are used to opsinize pathogens and secrete cytokines that draw phagocytic cells to the site of infection. The TH2 cells produce B cell growth factors that activate the B cells, causing them to multiply and produce antibodies that give rise to a humoral (antibody) response. A delicate balance exists between the TH1 and TH2 cells and is directed by cytokines. Cytotoxic T cells are involved in the killing of pathogens that live inside host cells (cytosolic pathogens) such as viruses and some bacteria. These pathogens hide within cells, and cannot be reached with antibodies. Cytotoxic T cells cause infected cells to undergo programmed cell death or apoptosis and also secrete cytokines that assist in the immune response.

HUMORAL (ANTIBODY-MEDIATED) IMMUNITY. The humoral immune response uses antibodies produced by B cells to destroy pathogens. Pathogens travel in the extracellular fluid (outside of the cell) during the spread of infection. Antibodies specific for foreign pathogen antigens combine with them and neutralize the pathogen, preventing the spread of infection. Toxins secreted by bacteria, such as those from diphtheria and tetanus, are harmful to the body may also be neutralized by antibodies. Bacterial surfaces may be coated with antibody such that phagocytic cells can recognize them and ingest them (opsinization). When antibodies bind with pathogen antigens, the complement system of plasma proteins is activated. This results in opsinization and draws phagocytes to the site of infection.

The B cells are activated upon exposure to antigen, such as that which occurs in the lymphoid tissue. B cell surfaces contain immunoglobulin proteins (antibody) that bind with antigens from pathogens. With the aid of antigen-specific helper T cells, the B cells begin to multiply and produce cells that make antibody (plasma cells). This antibody is directed against the same specific antigen that was recognized by the helper T cell. Memory B cells are also produced and are involved in the protection of the body upon a second exposure to the pathogen at another time. Some pathogens can also cause the B cells to become activated without the help of T cells.

Role in human health

Pathogens have evolved over time such that they can avoid detection by the immune system. Bacteria may change their antigens to escape recognition by immune cells. Such mechanisms occur in the case of bacteria that cause **pneumonia**, **food poisoning**, and gonorrhea. The

influenza virus may undergo a similar process, hence the reason that new flu vaccines are continually under development. The protozoans that cause **malaria** and sleeping sickness also use such methods to escape detection. Epstein-Barr and herpes simplex viruses enter a period of latency within the cells in which the virus does not multiply. The disease is “hidden” from immune surveillance, yet persists in the system to become active at a later time.

In opportunistic infections, a microorganism that is normally present as part of the microflora is no longer controlled by the host and seizes an opportunity to establish infection. This occurs in HIV infection due to suppressed immunity in the body. Opportunistic infections may arise following medical or surgical treatments. Such is the case with urinary tract infections when *Esherichia coli* that are normally found on the gut enter the urinary tract during catheterization or yeast infections following the administration of **antibiotics**.

Immune responses are particularly important during the process of organ transplantation where the recipient may perceive donor antigens as “non-self.” Careful matching of donor and recipient tissues and the use of immunosuppressive agents that diminish the immune response minimize rejection. Graft-vs-host disease occurs during bone marrow transplants when the T cells of the donor recognize antigens in the recipient as “foreign.”

Directions in immunotherapy

Humans have tried to understand the immune response and prevent the spread of disease throughout history. In ancient China and Asia Minor, attempts were made to inoculate against the smallpox virus by a process called variolization. In 1774 a farmer, Benjamin Jesty, used the cowpox virus to protect his children from smallpox. Edward Jenner began studies using cowpox virus in 1796 and demonstrated that immunization with cowpox protected a child from developing a smallpox infection. He published his results, calling this process **vaccination**. Efforts to refine this process ultimately lead to the declaration by the World Health Organization 1979 that the disease had been eradicated. Research directions for 2000 and beyond include vaccine development for HIV, tumors, schistosomiasis (a parasitic disease), and malaria.

Advances in cytokine therapy are another promising area of research and development. This approach involves boosting the body’s own immune modulators to initiate an increased response. The use of cytokines has been explored in bone marrow transplantation, sepsis trials, and treatment of leprosy.

KEY TERMS

Adaptive immunity—The immune response is specific for a particular antigen, causes lymphocytes that recognize the antigen to multiply (clonal expansion), and imparts the quality of immunological memory of prior encounters with the antigen.

Apoptosis—The programmed cell death that is present in all cells and is responsible for their self-destruction.

Innate immunity—Parts of the immune system that are normally present, non-specific, and do not given an elevated response upon a second exposure.

Phagocytosis—The process whereby a cell engulfs particles or materials.

Immune system

Definition

The immune system is composed of cells, organs, tissues, and molecules that protect the body from disease. The term “immunity” comes from the Latin word *immunitas*.

Description

Physical barriers

Anatomic barriers provide protection against invading bacterial and viral pathogens. The skin is composed primarily of keratin, which cannot be digested by most microorganisms. The skin is usually dry with a high salt concentration due to sweat. These conditions are not favorable for bacterial growth. Sweat and sebaceous skin secretions also contain substances that kill **bacteria**. Some types of bacteria inhabit the skin surface and do not cause disease under normal conditions (microflora). These bacteria may produce substances that kill other more pathogenic bacteria. The microflora may also consume nutrients required by pathogens. This gives rise to a competitive relationship that limits the growth of the pathogens. If the skin is broken, due to injuries or **burns**, harmful bacteria may enter and give rise to **infection**. The cilia of the **lungs** protect this organ from inhaled pathogens, transporting secretions to the throat so that they can be swallowed and destroyed by **stomach** acid. Secretions in the nose, saliva, and components of tears also contain substances that protect against bacteria and **viruses**.

Cells of the immune system

Lymphocytes. There are two major types of lymphocytes, the T-cells and B-cells, which comprise 20–50% of the white **blood** cells in normal adult human circulation. T-cells mature and differentiate in the thymus gland and assist in cellular immune responses. These cells are responsible for the recognition of antigens (materials that give rise to an **immune response**, such as components of pathogenic bacteria). There are three major types of T-cells that are classified according to their function: cytotoxic T cells (T_c) that kill abnormal cells, helper T cells (T_h) that enhance an immune response, and suppressor T-cells (T_s) that diminish the immune response. The B-cells mature in the bone marrow and recognize antigens with the help of T-cells. Upon activation, these cells give rise to plasma cells, which produce antibodies (immunoglobulins). Antibodies bind with toxic pathogen **proteins** or antigens and interact with other cells to remove the invader

from the system. Plasma cells are found in the lymph nodes, spleen and bone marrow. B-cells also give rise to **memory** cells that remain alive for long periods of time and assist in a more effective immune response upon the next exposure to the same antigen.

The natural killer cells (NK) are a third type of lymphocyte and comprise approximately 3% of normal blood circulation. These large cells are responsible for the killing of some tumors and virus-infected cells. Additionally, some cells can be induced to kill their targets in a non-specific manner under the appropriate conditions. These cells are called lymphokine activated killer (LAK) cells.

Granulocytes. The granulocytes or polymorphonuclear leukocytes (PMNs) are a group of cells that display a characteristic staining of granules in blood smears, hence their name. These cells have a short life span in the blood (about two or three days), and make up the majority of the white blood cells under normal conditions. They are usually found in greater numbers during an immune response to injury or infection. The neutrophils are a very important type of granulocyte and demonstrate phagocytosis (ingestion of particles by cells, such as particles of bacteria, with ultimate destruction by lysosomal enzymes). These cells are critical in the development of the immune response to pathogens and can migrate from the blood to the tissues during infection by a process known as chemotaxis (the movement of cells in response to and external chemical stimulation). They comprise approximately 40–75% of the blood. The eosinophils are mainly involved in an immune response to parasitic infection and also play a role in the allergic response, and comprise only 1–6% of the blood. The basophils, normally present in low numbers in the circulation (less than 1% of the blood), are thought to play a role in the inflammation and damage to tissue associated with allergic reactions.

Monocytes, Macrophages, and Mast Cells. Monocytes are a type of cell that circulates in the bloodstream, comprising 2–10% of the blood. Upon migration into the tissues, these cells differentiate into macrophages that are capable of ingesting microorganisms by phagocytosis and have a critical role in the host defense to pathogens. They also produce substances called monokines that are a type of secreted protein (cytokine) that affects the actions of other cells.

Mast cells are distributed in the connective tissues, especially in the skin and mucosal surfaces of the respiratory, gastrointestinal, and urogenital tracts as well as the eye. These cells are also involved in the allergic response.

Platelets. Platelets are cell fragments in the blood that are involved in blood clotting and inflammation.

DENDRITIC CELLS. Dendritic cells are potent stimulators of immune responses. These cells play an important role in the increased immune response upon a second exposure to an antigen. Dendritic cells are distributed throughout the body, especially in the T-cell areas of lymphoid organs. In the lymphoid tissue, dendritic cells are involved in the stimulation of T-cell responses.

Central lymphoid tissues

The central lymphoid organs include the bone marrow and thymus. At these sites, the lymphocytes interact with other cells to enhance their development or increase their ability to assist in an immune response. They also acquire the ability to recognize specific antigens before they actually become exposed to them, and are antigen-independent. At this stage the lymphocytes are called naïve lymphocytes because they have not yet been exposed to antigens. The bone marrow is the site of hematopoiesis. Both B-lymphocytes and T-lymphocytes come from this site, but only the B cells undergo maturation in this area (hence the name *B-cell T-cell*).

Peripheral lymphoid tissues

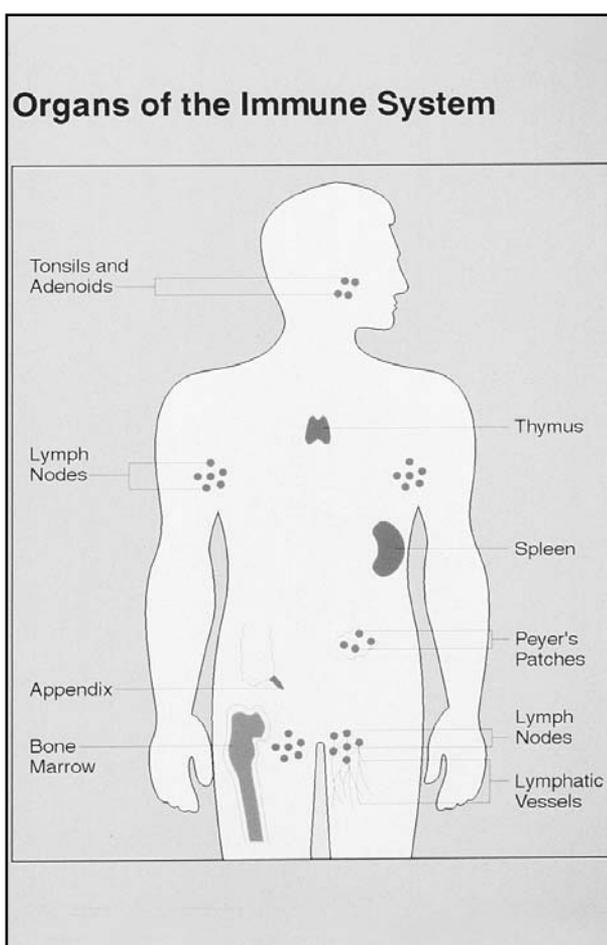

The peripheral lymphoid tissues include the lymphatic vessels, lymph nodes, various lymphoid tissues, and spleen. The events that occur in these areas require exposure to an antigen, and are called antigen-dependent events.

Lymphatic vessels

The filtration of the blood results in the production of extracellular fluid called lymph. The lymphatic vessels that carry the fluid back to the bloodstream also carries cells with antigens. These antigens come from other sites within the body where infection may be present. The fluid passes through the lymph nodes. This fluid is eventually returned to the blood via lymphatic vessels. All the lymph from the body is carried back to the **heart** by way of the thoracic duct.

Lymph nodes and lymphoid tissue

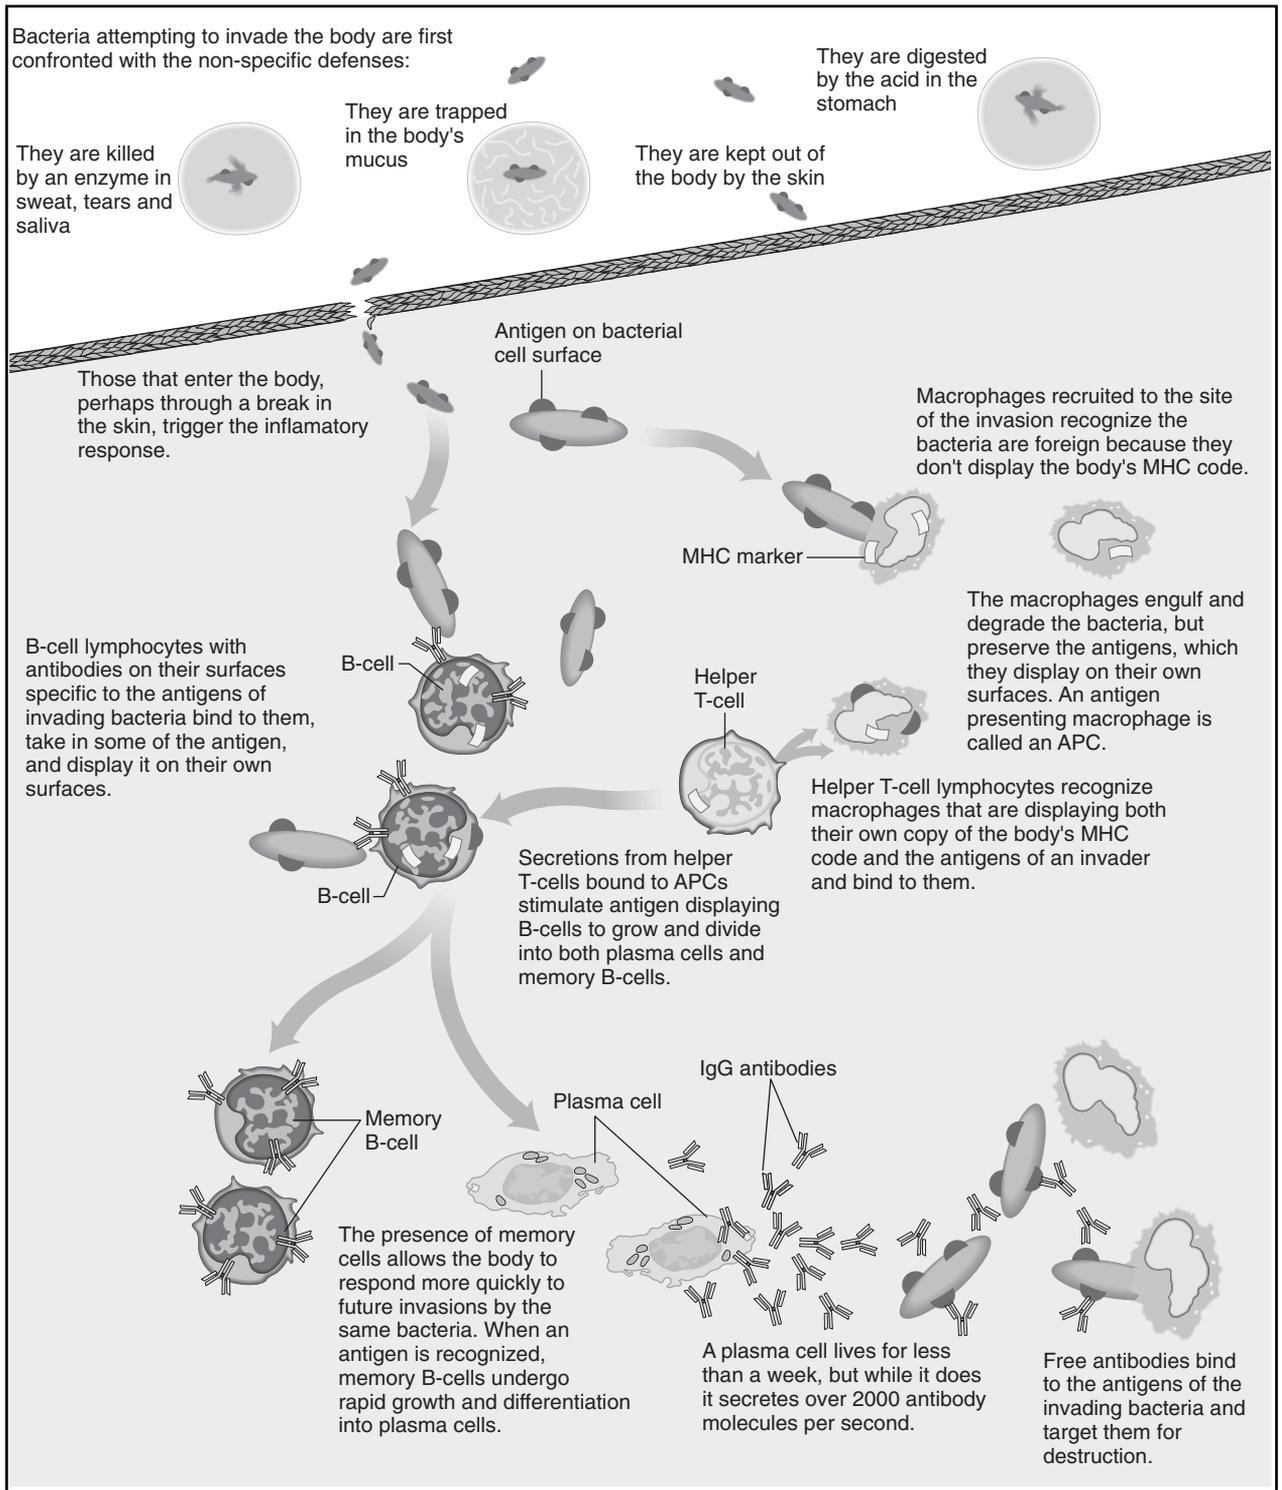

Lymph nodes are distributed along lymphatic vessel pathways and act as a filter for the lymph. The lymph nodes are distributed throughout the **lymphatic system**, and are especially prominent in the neck, axilla (underarm), and groin. These fibrous nodes contain immune cells such as lymphocytes, macrophages, and dendritic cells. Dendritic cells have long, filamentous cytoplasmic processes. These processes have the ability to bind antibodies such that the antibodies can also bind with their specific antigens. This creates a web that traps antigens. The macrophages in the lymph nodes degrade debris and

The organs of the immune system are located throughout the body. (National Institutes of Health. Reproduced by permission.)

extract material that contains antigens, such as those from pathogenic bacteria. The structure of the lymph nodes is such that both T- and B-cells are exposed to this antigenic material. The cells that recognize this material are held in the lymphoid nodes and tissues where they multiply and differentiate. These cells become effector cells that are capable of fighting disease. The node may enlarge during this process, giving rise to the clinical observation of swollen glands.

Lymphocytes can also be found in several other areas throughout the body. The gut-associated lymphoid tissue is a broad term that describes lymphoid tissue found in the Peyer's patches of the intestine, appendix, adenoids, and tonsils. Cells that protect the respiratory tract are called bronchial-associated lymphoid tissue (BALT). Other mucosal areas are protected as well, and are collectively known as mucosal-associated lymphoid tissue (MALT).

Immune system. (Illustration by Hans & Cassidy. Courtesy of Gale Group.)

Spleen

Blood is filtered in the spleen, where damaged or dead red blood cells are removed from the blood as well as antigens. This organ also serves as a site for storage of

erythrocytes and platelets. In the fetus, it is the site of erythropoiesis (formation of red blood cells). Within this organ reside B-cells, T-cells, macrophages, and dendritic cells. As in the lymph nodes, lymphocytes are trapped in

this organ. Antibodies and effector cells are produced in the spleen.

Common disorders and diseases

Hypersensitivity reactions result from an immune-mediated inflammatory response to an antigen that would normally be innocuous (causing no harm to the body). Examples include allergic reactions, such as hay **fever**, **asthma**, reactions to insect bites, and the systemic anaphylactic **shock** that occurs in response to bee stings, **allergies** to **antibiotics**, and foods.

Delayed-type hypersensitivity reactions are due to the release of lymphokines. These lymphokines are small polypeptides produced by lymphocytes that have been stimulated by an antigen, affecting other cells. This hypersensitivity reaction may occur as part of the normal immune response to infection by bacteria and viruses. This effect is responsible for the tissue damage in the lungs due to **tuberculosis**, the skin lesions that occur in leprosy and herpes, and rashes associated with chicken pox and measles. This may also occur via skin exposure to cosmetics, poison ivy, and allergy to metals in jewelry, resulting in contact dermatitis.

Autoimmune diseases occur when the immune system begins to attack the body or “self.” In Grave’s disease, antibodies are produced against the thyroid-stimulating hormone (TSH) receptor. In **multiple sclerosis** (MS), antibodies are produced against elements of the myelin sheaths in the **brain** and **spinal cord**. The effects of myasthenia gravis are traced to antibodies directed against the acetylcholine receptor. Following a heart attack, antibodies may form against heart muscle antigens resulting in autoimmune myocarditis. Rheumatoid arthritis (RA) develops from complexes of antibodies to immunoglobulin G (IgG) in the joints and connective tissue. In systemic lupus erythematosus, the body produces antibodies directed against nuclear antigens and DNA.

In acquired **immunodeficiency** syndrome (AIDS), the HIV retrovirus attacks T-cells (CD4), dendritic cells, and macrophages. The number of CD4 T-cell in the blood eventually declines and the body can no longer resist the HIV infection. With the immune system compromised, constitutional disease can develop with fever, weight loss, or **diarrhea**. Neurological disease can occur, resulting in **dementia** and effects to the peripheral nervous system. Pathogenic microorganisms may cause opportunistic infections in this compromised immune state, such as **pneumonia**, diarrhea, skin and mucous membrane infections, and **central nervous system** infections. Cancers may also arise, such as lymphomas. Death from HIV is due to one of these complications or a combination of effects.

KEY TERMS

Antibodies (immunoglobulins)—Proteins that bind to their corresponding specific antigen.

Antigen—A material that gives rise to an immune response.

Autoimmune disease—An immune response that occurs when the immune system begins to attack the body or self.

B lymphocyte—A lymphocyte that contains an immunoglobulin on the surface (the B-cell receptor). B cells mature in the bone marrow.

Effector cells—Mature lymphocytes that assist in the removal of pathogens from the system and do not require further differentiation to perform this function.

Hypersensitivity—An immune reaction that results from an immune mediated inflammatory response to an antigen that would normally be innocuous.

Macrophages—Cells that are capable of ingesting microorganisms by phagocytosis and have a critical role in the host defense to pathogens.

Pathogen—A microorganism that has the potential to cause a disease.

T cytotoxic cells (Tc)—T lymphocytes that kill abnormal cells.

T helper cells (Th)—T lymphocytes that enhance an immune response.

T lymphocyte—A lymphocyte that matures in the thymus and has receptors related to CD3 complex proteins.

T suppressor cells (Ts)—T lymphocytes that diminish the immune response.

Immunoassay tests

Definition

Immunoassays are chemical tests used to detect or quantify a specific substance, the analyte, in a **blood** or body fluid sample using an immunological reaction. Immunoassays are highly sensitive and specific assays. Their high specificity results from the use of antibodies and purified antigens as reagents. An antibody is a protein (immunoglobulin) produced by B lymphocytes in response to stimulation by an antigen. Immunoassays measure the formation of antibody-antigen complexes and detect them via an indicator reaction. This may be done by precipitation of the immune complexes and measurement of turbidity or light scattering or by labeling either the antibody or antigen with a radioactive tag, enzyme, fluorescent, or chemiluminescent molecule. High sensitivity is achieved by using an indicator system (e.g. enzyme label) that results in amplification of the measured product.

Immunoassays may be qualitative or quantitative. An example of a qualitative assay is an immunoassay test for **pregnancy**. Pregnancy tests detect the presence of human chorionic gonadotropin (hCG) in urine or serum. In a typical **pregnancy test**, two antibodies are used. The hCG molecule, a protein hormone produced by the trophoblast, is the antigen. One antibody is directed against the alpha polypeptide chain of hCG and the other against the beta polypeptide chain. The sample is added to a support medium containing immobilized antibody to the alpha subunit of hCG. If hCG is present in the sample, it will bind to the antibody. The support is washed to remove all unbound molecules, and an antibody to the beta subunit is added. This second antibody is conjugat-

ed to an enzyme. After washing away any unbound antibody-conjugate, a substrate is added that changes color when acted on by the enzyme. Therefore, the presence of color at the end of the test indicates that hCG was present in the sample. With the use of highly purified antibodies and the enzyme indicator system, pregnancy can be detected within two days after fertilization.

Quantitative immunoassays are performed by measuring the signal produced by the indicator reaction. This same test for pregnancy can be made into a quantitative assay of hCG by measuring the concentration of product formed using a spectrophotometer. A calibration curve is produced by measuring several standards of known hCG concentration, and the curve is used to calculate the concentration of hCG in the sample after measuring the amount of product formed.

Purpose

The purpose of an immunoassay is to measure (or in a qualitative assay detect) an analyte. Immunoassay is the method of choice for measuring analytes normally present at very low concentrations which cannot be determined accurately by less expensive colorimetric tests. Common uses include measurement of drugs, hormones, specific **proteins**, tumor markers, and markers of cardiac injury. Qualitative immunoassays are often used to detect antigens on infectious agents and antibodies produced against them. For example, immunoassays are used to detect antigens on *Hemophilus*, *Cryptococcus*, and *Streptococcus* organisms in the cerebrospinal fluid of **meningitis** patients. They are also used to detect antigens associated with organisms that are difficult to culture such as hepatitis B virus and *Chlamydia trichomatis*. Immunoassays for antibodies produced in viral hepatitis, HIV, and Lyme disease are commonly used to identify patients with these diseases.

Immunoassay methods

Immunoprecipitation

The reaction of antibodies with protein antigens is a two-phase reaction. The first phase results in the formation of an antibody-antigen complex and takes place within seconds. This is followed by cross linking of individual immune complexes to form a macromolecular aggregate which precipitates out of the solution or gel. This second reaction is slow and often requires overnight incubation to reach completion. The simplest immunoassay method measures the quantity of precipitate which forms after the reagent antibody (precipitin) has incubated with the sample and reacted with its respective antigen to form an insoluble aggregate. Immunoprecipitation reactions may be qualitative or quantitative. In quantita-

tive assays, the immune complexes can be measured by turbidimetry or by performing the reaction in an agarose gel. In gel assays, an excess of the specific antibody is usually poured into the gel. The sample is placed in a well cut into the gel and is allowed to diffuse into the gel. The result will be a ring of precipitated immune complexes which grows larger with time until the endpoint is reached. At the endpoint, the diameter of the ring is proportional to antigen concentration. There will be insufficient antigen beyond the ring to form a visible reaction. Inside the ring, antigen concentration is in excess resulting in small invisible antibody-antigen complexes. The ring position represents the equivalence point or optimal molar ratio of antibody to antigen for the visible reaction. An alternative and more rapid immunoprecipitation method is the Laurel rocket electrophoresis or electroimmunoassay method. In this procedure the antigen is added to wells on one side of the gel which contains a specific antibody throughout. The gel is electrophoresed, and the antigen migrates toward the anodal side of the gel (see Electrophoresis tests). This results in an immunoprecipitation reaction in the shape of a rocket (peak). The height of the peak is logarithmically proportional to antigen concentration.

Particle immunoassays

Immunoprecipitation reactions can be direct or indirect. In direct assays the union of antibody with antigen occurs without attaching the antibody or antigen to a solid phase. In passive or indirect assays, the visible phase of the reaction is enhanced by binding one of the reactants to a solid phase such as latex, red blood cells, or suspension of colloidal gold particles. Particle immunoassays add sensitivity by enhancing surface area and visibility. By linking several antibodies to the particle, the particle is able to bind many antigen molecules simultaneously. This greatly accelerates the speed of the visible reaction. Particle assays may also be performed using antigens bound to the particle. This allows rapid and sensitive detection of antibodies that are markers of diseases such as infectious mononucleosis and rheumatoid arthritis.

Immunonephelometry

The immediate union of antibody and antigen forms immune complexes that are too small to precipitate. However, these complexes will scatter incident light and can be measured using an instrument called a nephelometer. These instruments measure the rate at which the immune complexes form. Incident light from a high intensity monochromatic light source is passed through the reaction cuvet. A photomultiplier tube is placed at an angle (e.g. 70 degrees) to the incident light beam. The

amount of light striking the tube is proportional to antigen concentration. The antigen concentration can be determined within minutes of the reaction. A calibration curve based on a nonlinear model such as a cubic spline plot is used to calculate the antigen concentration from the reaction rate.

Radioimmunoassay (RIA)

RIA is a method employing radioactive isotopes to label either the antigen or antibody. Isotopes are atoms that have unstable nuclei and emit radiation in order to transform into stable atoms. Most RIA methods employ 125 iodine (^{125}I) as the radiolabel. This isotope emits gamma rays. It has a high specific activity so that a very small mass of isotope is needed, and a short half-life (60 days). These properties result in minimal disposal problems with leftover or spent reagents. Gamma rays emitted by the immune complexes are usually measured following removal of unbound (free) radiolabel. Since background radiation is very low and the counting time can be extended if needed to generate more counts, RIA is the most sensitive of all immunoassay methods.

There are two types of RIA, competitive and immunoradiometric (sandwich) assays. Competitive assays use radiolabeled antigen. The labeled antigen “competes” with non-radioactive antigen in the sample for a limited number of binding sites on the reagent antibody. Following incubation, the free radiolabeled antigens are removed by decanting or washing and the radioactivity of the antibody-bound antigens is measured. The radioactivity of the antibody-antigen complexes is inversely proportional to antigen concentration. In the immunoradiometric (IRMA) or sandwich assay, two antibodies are used and one is radiolabeled. In the test system, the sample is incubated with a specific antibody usually attached to a solid phase such as a plastic bead or the wall of a plastic test tube. After washing to remove unbound sample components, a radioactively labeled antibody is added. The second antibody may be directed against a different part of the antigen molecule, or it may be directed against the first antibody (e.g. anti-human immunoglobulin). The second antibody binds to the immune complexes making an antibody-antigen-antibody “sandwich.” After washing to remove the unbound radiolabeled antibody, the radioactivity is measured. The amount of radioactivity is directly proportional to antigen concentration.

As with immunonephelometric assays, the calibration curve for RIA is nonlinear. The reagent antibodies reacting with different parts of the antigen have different binding affinities causing the curve to be hyperbolic. Various methods are used to transform the plot so that

result can be more accurately determined. Concentration is plotted on the x-axis and radioactivity on the y-axis. In competitive assays, radioactivity is usually expressed as %B/Bo where B is the count per minute of the sample and Bo is the count per minute of the zero calibrator. This keeps the slope of the curve from changing each day as the amount of radioactivity of the reagent decreases naturally. The most common plotting method converts the concentration (x-axis) to \log_{10} and the %B/Bo to $\text{logit } B/Bo$ (the natural log of B/Bo divided by $1-B/Bo$). This produces a linear plot from which the concentration of unknown can be easily determined.

The major advantages of RIA when compared to other immunoassays are higher sensitivity, easy signal detection, and well-established, rapid assays. The major disadvantages are the health and safety risks posed by use of radiation and the time and expense associated with maintaining a licensed radiation safety and disposal program. For this reason, RIA has been largely replaced in routine clinical laboratory practice by enzyme immunoassay. It is still the gold standard to which other immunochemical methods are compared and is still performed in reference laboratories for analytes such as 11-deoxycortisol, which are not available by other methods.

Enzyme immunoassay (EIA)

Enzyme immunoassay was developed as an alternative to RIA. These methods use an enzyme to label either the antibody or antigen. As for RIA, the EIA methods may be divided into competitive or sandwich type assays. Competitive assays use enzyme labeled antigen, and sandwich assays use an enzyme labeled antibody. The steps performed in RIA and EIA are similar. However, EIA requires an additional step, the addition of substrate which follows the immunological reaction. The sensitivity of EIA approaches that for RIA because a single enzyme molecule can catalyze the conversion of many molecules of substrate to product. Therefore, the enzyme label amplifies the reaction by producing many colored, fluorescent, or chemiluminescent molecules for each antibody-antigen reaction. As with RIA, the relationship between enzyme activity and concentration is nonlinear, and curve-fitting methods such as the cubic spline plot or the four-parameter logistic curve are used to calculate concentration. Many EIA assays use monoclonal antibodies as reagents to increase the sensitivity and lot to lot reproducibility of the assay. Monoclonal antibodies are made by fusing the immunoglobulin genes from a B lymphocyte, which produces the desired antibody specificity with a malignant plasmacytoma cell line. This results in a malignant cell line called a hybridoma that secretes large quantities of the desired antibody. Since the antibodies are derived from identical cells, the antibody mol-

ecules are identical and all have the same binding affinity for the antigen.

In addition to safety, another advantage of EIA is that light (versus) radiation is measured. This obviates the need for a scintillation counter that is more expensive than a light measuring instrument. In addition, some competitive EIA methods do not require the separation of antibody-bound and free antigen. These methods are called homogenous assays. Examples of homogenous EIAs are the enzyme multiplied immunoassay technique (EMIT), fluorescence polarization immunoassay (FPIA), and cloned enzyme donor immunoassay (CEDIA).

One of the most widely used EIA methods for detection of infectious diseases is the enzyme-linked immunosorbent assay (ELISA). The ELISA method is a heterogenous sandwich immunoassay, which means that separation of bound and free enzyme label is required. The term ELISA refers to the use of a solid phase to which the antibody (or antigen) is bound in order to facilitate the separation. ELISA methods are usually performed using a microtiter plate containing 96 wells rather than in test tubes. Incubation, washing, and signal reading steps are performed as with EIA sandwich assays described above.

Fluorescent immunoassay (FIA)

FIA refers to immunoassays that utilize a fluorescent label or an enzyme label that acts on the substrate to form a fluorescent product. In fluorescence measurements short wavelength light (usually near ultraviolet light) is used to excite the molecules. Fluorescent molecules stabilize by losing part of the absorbed light energy as heat and part as longer wavelength (visible) light. Fluorescent measurements are inherently more sensitive than colorimetric (spectrophotometric) measurements. Therefore, FIA methods have greater analytical sensitivity than EIA methods which employ absorbance (optical density) measurement.

Chemiluminescent immunoassay

Chemiluminescent immunoassays utilize a chemiluminescent label. Chemiluminescent molecules produce light when they are excited by chemical energy. The energy usually comes from an oxidation-reduction reaction. These molecules can be conjugated directly to antigens, or they can be used as substrates for enzyme labels. The most commonly used chemiluminescent labels are acroдинium, luminol, and dioxetane. Acroдинium and luminol are excited by peroxidase enzyme reactions and can be used with EIAs that employ a horseradish peroxidase label. Dioxetane-phosphate can be excited by hydrolysis of the phosphate bond using the enzyme alka-

line phosphatase as the label. Consider this example of a competitive binding assay for thyroxine (T4) based on chemiluminescence. The sample is mixed with T4 labeled with alkaline phosphatase (ALP) in a plastic tube containing anti-T4 conjugated to the tube wall. T4 in the sample competes with the ALP-labeled T4 for the antibody. After the reaction, the tube is washed to remove any unbound T4 and dioxetane-phosphate is added. The enzyme hydrolyzes the phosphate ester bond exciting the dioxetane which releases flashes of light. These emissions are measured by a light detector and are inversely proportional to the T4 concentration of the sample.

Precautions

Blood samples are collected by venipuncture using standard precautions for reducing exposure to blood-borne pathogens. It is not necessary to restrict fluids or food prior to collection. Blood should be collected in tubes containing no additive. Risks of venipuncture include bruising of the skin or bleeding into the skin. Random urine samples are acceptable for drug assays; however, 24-hour urine samples are preferred for hormones and other substances which show diurnal or pulse variation.

Special safety precautions must be observed when performing radioimmunoassay (RIA) methods. RIA tests use radioactive isotopes to label antigens or antibodies. Pregnant females should not work in the area where RIA tests are being performed. Personnel handling isotope reagents must wear badges which monitor their exposure to radiation. Special sinks and waste disposal containers are required for disposal of radioactive waste. The amount of radioisotope discarded must be documented for both liquid and solid waste. Leakage or spills of radioactive reagents must be measured for radioactivity; the amount of radiation and containment and disposal processes must be documented.

Results

Immunoassays that are qualitative are reported as positive or negative. Quantitative immunoassays are reported in mass units along with reference intervals (normal ranges) for the test. Normal ranges may be age and gender dependent. Immunoassays that measure antibody concentration may be reported as an antibody titre. The titre is the reciprocal of the highest dilution of sample that gives a positive (detectable) result. Positive immunoassay test results for HIV and drugs of abuse generally require confirmatory testing.

Although immunoassays are both highly sensitive and specific, false positive and negative results may

KEY TERMS

Antibody—A protein produced by B lymphocytes in response to stimulation by an antigen.

Antigen—Any substance which induces an immune response.

Chemiluminescent immunoassay—An immunoassay in which the label is a molecule that emits light when excited by a chemical reaction.

Enzyme immunoassay—An immunoassay using an enzyme as the label. The enzymatic reaction product is measured to determine the concentration of the analyte in the sample.

Fluorescent immunoassay—An immunoassay that uses a fluorescent label or produces a fluorescent product.

Immunoassay—A method that measures antibody-antigen complexes formed by reacting purified antibody or antigen with the sample.

Nephelometry—A method for measuring the light scattering properties of a sample.

Radioimmunoassay—A method that uses a radioisotope label in an immunoassay.

occur. False negative results may be caused by improper sample storage or treatment, reagent deterioration, or improper washing technique. False positive results are sometimes seen in persons who have heterophile antibodies, especially to mouse immunoglobulins that may be used in the test. False positive results have been reported for samples containing small fibrin strands that adhere to the solid phase matrix. False positives may also be caused by substances in the blood or urine that cross react or bind to the antibody used in the test.

Preparation

Generally, no special instructions need be given to patients for immunoassay testing. Some assays require a timed specimen collection while others may have special dietary restrictions.

Aftercare

When blood testing is used for the immunoassay, the venipuncture site will require a bandage or light dressing to accomplish hemostasis.

Complications

Immunoassay is an *in vitro* procedure, and therefore not associated with complications. When blood is collected slight bleeding into the skin and subsequent bruising may occur. The patient may become lightheaded or queasy from the sight of blood.

Health care team roles

Immunoassay tests are ordered by physicians and samples may be collected by a physician, physician assistant, nurse, or phlebotomist. Simple immunoassay tests (e.g. pregnancy tests and rapid Strep tests) may be performed by medical personnel without special laboratory training. More complex testing is performed by clinical laboratory scientists CLS(NCA) or medical technologists, MT(ASCP) or by clinical laboratory technicians, CLT(NCA) or medical laboratory technicians, MLT(ASCP).

Immunodeficiency

Definition

Immunodeficiency disorders are characterized by an **immune system** that is lacking, impaired, or defective. As a result, patients with immunodeficiency disorders have increased susceptibility to **infection** and neoplasia (**cancer** development). They have more frequent infections that are generally more severe and last longer than

those experienced by persons with healthy, functioning immune systems. Patients with immunodeficiency disorders also are susceptible to infection with organisms that do not normally infect healthy people.

Description

The immune system is the body's primary defense against infections. Any defect in the immune system decreases the body's ability to combat infections. Patients with immunodeficiency disorders may suffer more frequent infections, heal more slowly, and have a higher incidence of some cancers.

The normal immune system involves a complex interaction of cells and molecules that can recognize and attack invaders such as **bacteria**, **viruses**, and **fungi**. It also plays a role in fighting cancer. The immune system has both innate and adaptive components. Innate immunity is the immune protection present at birth. Adaptive immunity develops throughout life and has two components, humoral immunity and cellular immunity.

The innate immune system consists of the skin (which serves as a barrier to prevent organisms from entering the body), white **blood** cells called phagocytes, a system of **proteins** called the complement system, and chemicals called interferon. When phagocytes encounter an invading organism, they surround and engulf it to destroy it. The complement system attacks bacteria. The elements of the complement system create a hole in the outer layer of the target cell, which leads to the death of the cell.

The adaptive component of the immune system is extremely complex and is still not entirely understood. Basically, it has the ability to recognize a foreign organism, tumor cell, or foreign chemical as an invader, and to develop a response to attempt to eliminate it.

The humoral response of adaptive immunity involves a type of cell called B lymphocytes that manufacture proteins called antibodies (also called immunoglobulins). Antibodies attach themselves to the foreign substance allowing phagocytes to begin engulfing and destroying the invading organism. The action of antibodies also activates the complement system. The humoral response is particularly useful for attacking bacteria.

The cellular response of adaptive immunity is useful for attacking viruses, some parasites, and possibly cancer cells. The main type of cell in the cellular response is the T lymphocyte. There are helper T lymphocytes and killer T lymphocytes. Helper T lymphocytes play a role in recognizing invading organisms and help killer T lympho-

A nurse holds a baby with immunodeficiency, who must be treated in a sterile environment. (Science Source/Photo Researchers. Reproduced by permission.)

cytes to multiply. As the name suggests, killer T lymphocytes destroy the target cell or organism.

Defects can occur in any component of the immune system. They can also occur in several components simultaneously, and are then referred to as combined immunodeficiency. Defects can be congenital or acquired.

Congenital immunodeficiency disorders

Congenital immunodeficiency is present at the time of birth and is the result of genetic defects. Though more than 70 different types of congenital immunodeficiency disorders have been identified, they are rare. They may be caused by defects in either B lymphocytes or T lymphocytes, or both, and can also occur in the innate immune system.

B LYMPHOCYTE DEFICIENCY. If there is an abnormality in either the development or function of B lymphocytes, then the ability to make antibodies is impaired. Impaired antibody production results in increased susceptibility to recurrent infections. Bruton's agammaglobulinemia, also known as X-linked agammaglobulinemia, is one of the most common congenital immunodeficiency

disorders. The defect results in a decrease or absence of B lymphocytes and therefore a decreased ability to produce antibodies. Patients with this disorder are particularly susceptible to infections of the throat, skin, middle ear, and **lungs**. It is seen only in males because it is caused by a genetic defect on the X chromosome. Since males have only one X chromosome, they always have the disorder if the defective gene is present. Females may have the defective gene; however, since they have two X chromosomes, only one will have the defective gene and the other will have a normal gene to counter the defective gene. Women may pass the defective gene to their male offspring.

Another type of B lymphocyte deficiency involves a group of disorders called selective immunoglobulin deficiency syndromes. There are five different types of immunoglobulins—IgA, IgG, IgM, IgD, and IgE. The most common type of immunoglobulin deficiency is selective IgA deficiency. Some patients with selective IgA deficiency experience no symptoms while others have occasional lung infections and **diarrhea**. In another immunoglobulin disorder, IgG and IgA antibodies are deficient and there is increased IgM. Patients with this disorder tend to develop severe bacterial infections.

Common variable immunodeficiency is another type of B lymphocyte deficiency. In this disorder production of one or more of the immunoglobulin types is decreased and the antibody response to infections is impaired. This disorder generally develops between the ages of 10 and 20 years. Symptoms vary among affected patients, however, most suffer frequent infections and some also experience anemia and rheumatoid arthritis. Many patients with common variable immunodeficiency develop cancer.

T LYMPHOCYTE DEFICIENCIES. Severe defects in the ability of T lymphocytes to mature results in impaired immune responses to infection with viruses, fungi, and certain types of bacteria. These infections are often severe and can be fatal. DiGeorge syndrome is a T lymphocyte deficiency that begins during **fetal development**, although it is not inherited. Children with DiGeorge syndrome either have no thymus or have an underdeveloped thymus. Since the thymus directs the production of T lymphocytes, people with this immunodeficiency have very low numbers of T lymphocytes. They are susceptible to recurrent infections and usually have physical abnormalities as well, which may include low-set ears, a small receding jawbone, and widely spaced eyes. In some cases no treatment is required for DiGeorge syndrome because T lymphocyte production spontaneously improves. Either an underdeveloped thymus begins to produce more T lymphocytes or organ sites other than the thymus compensate by producing more T lymphocytes.

COMBINED IMMUNODEFICIENCIES. Some types of immunodeficiency disorders affect both B lymphocytes and T lymphocytes. For example, severe combined immunodeficiency disease (SCID) is caused by defective development or function of both of these types of lymphocytes. It results in impaired humoral and cellular immune responses. SCID is usually recognized during the first year of life. It tends to cause thrush (a fungal infection of the mouth), diarrhea, failure to thrive, and other serious infections. Treatment requires bone marrow transplant and, if left untreated, children with SCID generally die from infections before the age of two years.

DISORDERS OF INNATE IMMUNITY. Disorders of innate immunity affect phagocytes or the complement system. These disorders also result in recurrent infections.

Acquired immunodeficiency disorders

Acquired immunodeficiency is more common than congenital immunodeficiency. It is the result of an infectious process or other disease. For example, the human immunodeficiency virus (HIV) is the virus that causes acquired immunodeficiency syndrome (**AIDS**). It is not,

however, the most common cause of acquired immunodeficiency.

Acquired immunodeficiency often occurs as a complication of other conditions and diseases. For example, the most common causes of acquired immunodeficiency are malnutrition, some types of cancer, and infections such as chickenpox, cytomegalovirus, German measles, measles, **tuberculosis**, infectious mononucleosis (Epstein-Barr virus), chronic hepatitis, lupus, and bacterial and fungal infections.

Sometimes, acquired immunodeficiency is a side effect or consequence of drugs used to treat another condition. For example, organ transplant patients are given drugs to suppress the immune system so the body will not reject the transplanted organ. Some **chemotherapy** drugs, given to combat cancer, have the side effect of killing immune system cells. The risk of infection increases significantly while these drugs are being taken and usually returns to normal one the patient is off the drugs.

Causes and symptoms

Congenital immunodeficiency is caused by genetic defects, which generally occur while the fetus is developing in the womb. These defects affect the development and/or function of one or more components of the immune system. Acquired immunodeficiency is the result of a disease process and occurs later in life. The causes can be disease, infection, or side effects of drugs given to treat other conditions.

Patients with an immunodeficiency disorder tend to become infected by organisms that do not usually cause disease in healthy people and they suffer repeated infections that resolve slowly and cause symptoms that persist for long periods of time. Patients with chronic infections tend to be pale and thin and may have skin rashes. Their lymph nodes tend to be larger than normal and their **liver** and spleen may also be enlarged. Broken **blood vessels**, especially near the surface of the skin, may be apparent and they may develop alopecia (hair loss) and/or conjunctivitis (inflammation of the lining of the eye).

Diagnosis

One of the first signs that a patient may have an immunodeficiency disorder is failure to improve rapidly when given **antibiotics** to treat an infection. Another strong indicator is if a person becomes ill from organisms that do not normally cause diseases. When this occurs in very young children, it may indicate a genetic defect responsible for the immunodeficiency disorder. Among older children or young adults, their medical history

helps determine if childhood diseases may have caused an immunodeficiency disorder. Other possibilities to consider are recently acquired infections such as HIV, hepatitis, or tuberculosis.

Laboratory tests are used to determine the exact nature of an immunodeficiency. Most tests are performed on blood samples. A blood cell count will determine if the number of phagocytic cells or lymphocytes is below normal. Lower-than-normal counts of either of these cell types indicate the presence of immunodeficiency. The blood cells are also examined for their appearance. Some patients may have normal cell counts but their blood cells may be structurally defective. If the lymphocyte cell count is low, further testing is performed to determine whether any particular type of lymphocyte is lower than normal. A lymphocyte proliferation test determines if the lymphocytes can respond to stimuli. The failure to respond to stimulants correlates with immunodeficiency. Antibody levels may be measured by a process known as electrophoresis, while complement levels can be determined by immunodiagnostic tests.

Treatment

There is no cure for congenital or most acquired immunodeficiency disorders. Therapy is aimed at controlling infections and, for some disorders, replacing defective or absent cellular components. Patients with Bruton's agammaglobulinemia must be given periodic injections of gamma globulin throughout their lives to compensate for their decreased ability to produce antibodies. The gamma globulin preparation contains antibodies against common invading bacteria. Untreated, the disease is usually fatal.

Common variable immunodeficiency also is treated with periodic injections of gamma globulin throughout life. Additionally, antibiotics are given when necessary to treat infections.

Patients with selective IgA deficiency usually do not require any treatment for the deficiency. Instead, antibiotics are given for infections.

In some cases, no treatment is required for DiGeorge syndrome because T lymphocyte production increases spontaneously. However, in some severe cases, bone marrow transplant or thymus transplant may be performed.

For patients with SCID, bone marrow transplantation is essential. In this procedure, healthy bone marrow is removed from a compatible donor (one with a similar tissue type, usually a brother or sister). The bone marrow of the patient receiving the transplant is destroyed and replaced with the bone marrow from the donor.

Treatment of the HIV infection that causes AIDS consists of drugs called antiretrovirals. Several of these drugs, used in various combinations, can prolong the period of time before the disease becomes symptomatic. However, these drugs do not produce a cure. Other treatments for patients with AIDS are aimed at the particular infections that arise as a result of the impaired immune system. In most cases immunodeficiency caused by malnutrition is reversible. The health of the immune system is directly linked to the nutritional status of the patient. Among the essential nutrients required by the immune system are proteins, **vitamins**, **iron**, and **zinc**. Among cancer patients, periodic relief from chemotherapy drugs can restore the function of the immune system.

In general, patients with immunodeficiency disorders should be counseled to maintain a healthy diet. This is because malnutrition can aggravate immunodeficiencies. Patients should also be advised to avoid exposures to sick people because they can easily acquire new infections. For the same reason, patients should be instructed to practice good personal hygiene, especially dental care. Patients with immunodeficiency disorders should also avoid eating undercooked food because it might contain bacteria that could cause infection. Also, they should be given antibiotics at the first indication of an infection.

Prognosis

Prognosis for individuals with immunodeficiency disorders depends upon the type of disorder. Patients with Bruton's agammaglobulinemia who are given injections of gamma globulin generally live into their 30s or 40s and death is usually from chronic pulmonary infections. Patients with selective IgA deficiency generally live normal lives. They may experience allergic reactions to a blood transfusion, however, and should therefore wear a Medic Alert bracelet or have some other way to alert healthcare professionals about their disorder.

SCID is a serious immunodeficiency disorder. Without successful bone marrow transplant, a child with this disorder usually will not live beyond two years of age.

Although people with HIV/AIDS are living longer than in the past because of **antiretroviral drugs**, AIDS remains a fatal disease. AIDS patients usually die of opportunistic infections—viral and bacterial infections that occur because the impaired immune system is unable to fight them.

Health care team roles

Diagnosis and effective management of immunodeficiency disorders involves cooperation and collaboration between the patient and an interdisciplinary team of

KEY TERMS

Agammaglobulinemia—The lack of gamma globulins in the blood. Antibodies are the main gamma globulins of interest, so this term means a lack of antibodies.

Humoral immune response—Immune system response to antigens found in body fluids. This response is mediated by antibodies, which are secreted by B lymphocytes circulating in the blood.

Lymphocytes—White blood cells that fight infection and disease.

health care professionals. The patient's primary care physician or pediatrician, immunologist, nurses, laboratory technologists, respiratory therapists, pharmacists, pharmacy assistants, and health educators are involved in helping patients and families gain an understanding of how to prevent infections and effectively manage them when they occur or recur.

Patient education

Nurses and health educators help patients learn how to prevent infection. They teach patients how to identify early symptoms of infection that require prompt medical attention. Pharmacists and pharmacy assistants may offer additional instruction about antibiotic therapy and the importance of adhering to prescribed treatment.

Prevention

There is no way to prevent a congenital immunodeficiency disorder. Physicians and health care providers should recognize symptoms as early warning signs and implement appropriate treatment as soon as possible. People with congenital immunodeficiency disorders may want to consider **genetic counseling** before having children to determine if there is a chance they will pass the defect on to their children.

Some infections associated with acquired immunodeficiency can be prevented or treated before they cause problems. For example, there are effective treatments for tuberculosis and most bacterial and fungal infections. HIV infection can be prevented by practicing "safe sex," and by not using illegal intravenous drugs. These are the primary routes of transmitting the virus.

Malnutrition can be prevented by obtaining adequate **nutrition**. Although it does exist in the United States,

malnutrition is considered a problem of greater magnitude in developing countries.

Impacted stool removal see **Fecal impaction removal**

Impacted tooth

Definition

An impacted tooth is a dental disorder in which a tooth fails to fully emerge through the gums.

Description

Teeth emerge through the gums during infancy and also when primary (baby) teeth are replaced by the permanent teeth. If a tooth fails to emerge or emerges only partially, it is considered impacted. The teeth most commonly impacted are the wisdom teeth (or third molars). These teeth are the last to develop, but don't begin breaking through the bone and gum tissue until the later teen years. By this time, the upper and lower jaws have stopped growing and may be too small to accommodate these four additional teeth. As the wisdom teeth continue to grow, one or more may become impacted. If there is not enough room in the mouth to accommodate these teeth, they will remain trapped in the jawbone.

Impacted teeth can take many positions in the bone as they attempt to find a pathway that will allow them to erupt. According to the American Board of Oral and Maxillary Surgeons nine out of every ten people have an impacted tooth. Impacted tooth surgery is the leading surgical problem faced by general dentists and oral surgeons.

Causes and symptoms

An impacted tooth may be caused by overcrowding of the teeth often because the jaw is too small. Teeth may also become twisted, tilted, or displaced as they try to emerge. Less common symptoms of an impacted tooth may be:

- **pain** and tenderness of the gums
- visible gap where a tooth has not emerged
- redness and swelling of the gums around the impacted tooth area
- swollen lymph nodes of the neck
- difficulty opening the mouth
- prolonged headaches or jaw ache
- unpleasant **taste** when biting down on or near the impacted area
- raised gum tissue where impacted tooth lies under the gum tissue

Diagnosis

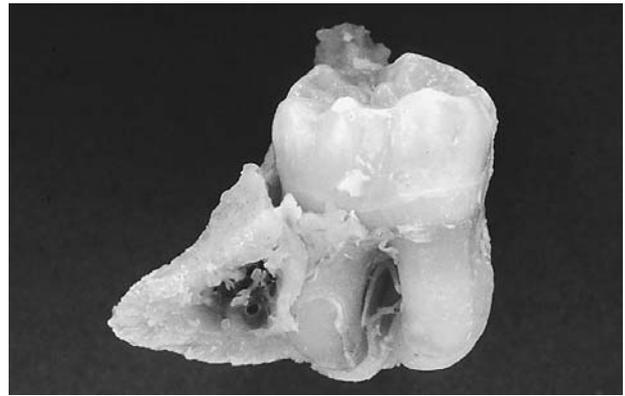

Upon visual examination, the dentist may find signs of **infection** or swelling in the area where the tooth is absent or only partially erupted. **Dental x rays** are essential in diagnosing an impacted tooth. The dentist may also see signs of enlargement of the tissue over the area where a tooth has not emerged, or has emerged only partially. The impacted tooth may also be pressing on an adjacent tooth causing pain.

Treatment

The goal of treatment is to relieve irritation of the mouth and remove pain caused by the impacted tooth. If the impacted tooth is not causing infection or inflammation, or is not affecting the alignment of the other teeth, no treatment may be necessary. Warm, salt-water rinses may be advised to aid in soothing the swollen gums.

A dentist may perform an extraction with forceps and local anesthetic agent if the tooth is exposed and appears to be easily removable. Extracting an impacted tooth typically requires making an incision through gum tissue to expose the tooth and may require removing portions of bone to free the tooth. The tooth may have to be removed in pieces to minimize destruction to the surrounding bone and tissue. The extraction site may require one or more stitches to aid healing.

Another type of treatment called ligation is performed on impacted teeth in conjunction with orthodontics. A small portion of the crown of an impacted tooth is exposed through the gum tissue and a small orthodontic

This impacted wisdom tooth, attached to part of the jaw bone, was broken during extraction. (Photograph by James Stevenson, Photo Researchers, Inc. Reproduced by permission.)

bracket is attached to the exposed area so that the tooth can be brought into alignment with the rest of the teeth while the patient is being orthodontically treated. An oral and maxillofacial surgeon commonly performs this type of treatment.

Antibiotics may be required after the extraction or ligation if the area is infected or there is a risk of infection. Over the counter pain medications, such as Tylenol, Advil, or Motrin may be taken to lessen the pain of the treated area. This pain will gradually decrease over two to three days.

Prognosis

The prognosis is very good for the removal or ligation of an impacted tooth. Potential complications include postoperative infection, temporary numbness from nerve irritation, jaw fracture, and jaw joint pain. A painful condition, which may develop after an extraction, is known as a dry socket, when a **blood** clot does not completely fill the empty tooth socket, or is disturbed by an oral vacuum, by drinking through a straw, or by smoking. The bone beneath the socket is painfully exposed to air. The general dentist will pack the socket with medication to allow healing to take place. One complication of the ligation process is that the bracket and chain may come off and will need to be replaced by the oral and maxillofacial surgeon.

Health care team roles

Extraction of a symptomatic impacted tooth is often treated in a general dental office. If the tooth is deeply impacted or more difficult to remove than expected the general dentist may refer the patient to an oral and maxillofacial surgeon.

KEY TERMS

Dry socket—A painful condition following tooth extraction in which a blood clot does not properly fill the empty socket, leaving the bone underneath exposed to air and food.

Eruption—The process of a tooth breaking through the hard and soft oral tissue to grow into place in the mouth.

Extraction—The surgical removal of a tooth from its socket in the bone.

Ligated—Where a small chain and wire are glued to the impacted tooth by an oral and maxillofacial surgeon. The wire is tightened during monthly visits with an orthodontist. This brings the tooth out of the bone and gum tissue and into alignment with the other teeth.

Oral and maxillofacial surgeon—A dentist specializing in oral and maxillofacial surgical procedures of the mouth.

Wisdom teeth—Also called third molars, the last teeth to erupt in the upper and lower jawbone.

Prevention

There is no way to prevent an impacted tooth. Heredity plays a role in the growth and development of the jaw, making it hard to prevent an impacted tooth from happening. Complications with an impacted tooth can be prevented by **patient education**, good **oral hygiene**, and proper care of the extraction area.

Impedance plethysmography see **Impedance plethysmography**

Impedance plethysmography

Definition

Impedance plethysmography, also called impedance test or **blood flow** or impedance **phlebography**, is a non-invasive test that uses electrical monitoring in the form of resistance (impedance) changes to measure blood flow in veins of the leg. Information from this test helps doctors detect deep vein thrombosis (blood clots or thrombophlebitis).

Purpose

Impedance plethysmography may be done in order to:

- detect blood clots lodged in the deep veins of the leg
- screen patients who are likely to have blood clots in the leg
- detect the source of blood clots in the **lungs** (pulmonary emboli)

Accurate diagnosis of deep vein thrombosis (DVT) is critical because blood clots in the legs can lead to more serious problems. If a clot breaks loose from a leg vein, it may travel to the lungs and lodge in a blood vessel in the lungs. Blood clots are more likely to occur in people who have recently had leg injuries, surgery, **cancer**, or a long period of bed rest.

Precautions

Because this test is not invasive, it can be done on all patients and is easy to perform. However, the accuracy of the results is affected if the patient does not breathe normally or keep the leg muscles relaxed. Compression of the veins because of pelvic tumors or decreased blood

flow, due to **shock** or any condition that reduces the amount of blood the **heart** pumps, may also change the test results. Both false-positives (e.g. when thrombi are non-occlusive) and false-negatives have been reported using this technique, which justifies repeated testing over a period of seven to ten days for patients with initial negative results. Success rates for this test have been estimated at anywhere from 65–66% to 92–98%.

Description

Using conductive jelly, the examiner strategically places two to four electrodes on the patient's calf (the four-electrode configuration yields a more uniform and precise current density and consequent measurement result). These electrodes are connected to an instrument called a plethysmograph, which records the changes in electrical resistance that occur during the test and produces a graph of the results.

The patient must lie down and raise one leg at a 30° angle so that the calf is above the level of the heart. The examiner then wraps a pressure cuff around the patient's thigh and inflates it to a pressure of 45–60 cm of water for 45 seconds. The plethysmograph records the electrical impedance changes that correspond to changes in the volume of blood in the vein at the time the pressure is exerted and again three seconds after the cuff is deflated. This procedure is repeated several times in both legs.

This test takes 30–45 minutes, costs an estimated \$50–\$100 (as of 2001), and results can be available within a few minutes.

Impedance plethysmography works by measuring the resistance to the transmission of electrical energy (impedance). This resistance is dependent upon the volume of blood flowing through the veins. By graphing the impedance, the doctor or technician can tell whether a clot is obstructing blood flow.

Preparation

Patients undergoing this test do not need to alter their diet, change their normal activities, or stop taking any medications. They will wear a surgical gown during the test and should be asked to urinate before the test starts. If keeping the legs elevated causes discomfort, mild **pain** medication can be given.

Aftercare

The patient may resume normal or postoperative activities after the test.

KEY TERMS

False negative—A test result that wrongly indicates a disease or condition is not present, when, in fact, it is.

False positive—A test result that wrongly indicates the a disease or condition is present, when, in fact, it is not.

Impedance—Denoted by Z, it is an expression of the opposition that an electronic component, circuit, or system presents to an alternating current (or direct current, in which case impedance equals resistance). Included in impedance are resistance, capacitance, and inductance. Impedance thus has both a real (resistance) and imaginary (phase) part.

Thrombophlebitis—Inflammation of a vein, associated with the formation of a blood clot.

Complications

Impedance plethysmography is painless and safe. It presents no risk to the patient.

Results

Normally, inflating the pressure cuff will cause a sharp rise in the pressure in the veins of the calf because blood flow is blocked. When the cuff is released, the pressure decreases rapidly as the blood flows away.

If a clot is present, the pressure in the calf veins will already be high. It does not become sharply higher when the pressure cuff is tightened. When the pressure cuff is deflated, the clot blocks the flow of blood out of the calf vein. The decrease in pressure is not as rapid as when no clot is present and the shape of the resulting graph is different, all of which is indicative of obstruction of major deep veins.

Health care team roles

Doctors, nurses, or well-trained technicians may perform all or part of the procedure, which includes application of electrodes and placement of cuffs as well as handling of the electronic equipment and analysis of results.

Training

Training for the procedure includes instruction on placement of electrodes and cuffs, facility with the electronic equipment, correct patient positioning during the

procedure, and capability for accurate interpretation of resulting impedance graphs.

Implantable cardioverter-defibrillator

Definition

The implantable cardioverter-defibrillator (ICD) is a surgically implanted electronic device that directs an electric charge directly into the **heart** to treat life-threatening heartbeat irregularities.

Purpose

The implantable cardioverter-defibrillator is used to detect and stop serious arrhythmias and restore a normal heartbeat. The exact indications for the implantation of the device are controversial, but patients suffering from ventricular fibrillation (unproductive heartbeat), ventricular tachycardia (abnormally fast heartbeat), long QT syndrome (an inherited heart disease), or others at risk for sudden cardiac death are potential candidates for this device. A study by the National Institute for Heart, Lung, and Blood of the National Institutes of Health indicated a significant increase in survival for patients suffering from ventricular arrhythmias when ICD implant is compared to medication. Several follow-up studies indicate that this may be due to the marked increase in survival for the sickest patients, generally defined as those having a heart weakened to less than 50% of normal, as measured by the ability of the left side of the heart to pump blood. Overall,

studies have documented a very low mortality rate of 1–2% annually for persons implanted with the device, compared to approximately 15–25% for patients on drug therapy.

Description

Similar in structure to a pacemaker, an ICD has three main components: a generator, leads, and an electrode. The generator is encased in a small rectangular container, usually about 2 in (5 cm) wide and around 3 oz (85 g) in weight. Even smaller generators have been developed, measuring 1 in (2.54 cm) in diameter and weighing about half an ounce (14.17 g). The generator is powered by lithium batteries and is responsible for generating the electric shock. The generator is controlled by a computer chip that can be programmed to follow specific steps according to the input gathered from the heart. The programming is initially set and can be changed using a device (called a wand programmer) that communicates by radio waves through the chest of the patient after implantation.

One or two leads, or wires, are attached to the generator. These wires are generally made of platinum with an insulating coating of either silicone or polyurethane. The leads carry the electric shock from the generator. At the tip of each lead is a tiny device called an electrode that delivers the necessary electrical shock to the heart. Thus, the electric shock is created by the generator, carried by the leads and delivered by the electrodes to the heart. The decision of where to put the leads depends on the needs of the patient, but they can be located in the left ventricle, the left atrium, or both.

According to the American College of Cardiology, more than 100,000 persons worldwide currently have an ICD. The battery-powered device rescues the patient from a life-threatening arrhythmia by performing a number of functions in order to reestablish normal heart rhythm, which varies with the particular problem of the patient. Specifically, if encountered with ventricular tachycardia, many devices will begin treatment with a pacing regimen. If the tachycardia isn't too fast, the ICD can deliver several pacing signals in a row. When those signals stop, the heart may go back to a normal rhythm. If the pacing treatment is not successful, many devices will move onto cardioversion. With cardioversion, a mild shock is sent to the heart to stop the fast heartbeat. If the problem detected is ventricular fibrillation, a stronger shock called a defibrillation is sent. This stronger shock can stop the fast rhythm and help the heartbeat go back to normal. Finally, many ICDs can also detect heartbeats that are too slow. It can act like a pacemaker and bring the heart rate up to normal.

ICDs that defibrillate both the ventricles and the atria have also been developed. Such devices not only provide dual-chamber pacing but also can distinguish ventricular from atrial fibrillation. Patients that experience both atrial and ventricle fibrillation or atrial fibrillation alone that would not be controlled with a single chamber device are candidates for this kind of ICD.

Operation

ICD insertion is considered minor surgery and can be performed in either an operating room or an electrophysiology laboratory. The insertion site, in the chest, will be cleaned, shaved and numbed with the injection of a medication (local anesthetic). Generally, left handed persons have ICDs implanted on the right side and visa versa, to speed return to normal activities. Two small cuts (incisions) are made, one in the chest wall and one in a vein just under the collarbone. The wires of the ICD are passed through the vein and attached to the inner surface of the heart. The other ends of the wires are connected to the main box of the ICD, which is inserted into the tissue under the collarbone and above the breast. Once the ICD is implanted, the physician will test it several times before the anesthesia wears off by causing the heart to fibrillate and making sure the ICD responds properly. The doctor then closes the incision with sutures (stitches), staples or surgical glue. The entire procedure takes about an hour.

Immediately following the procedure, a **chest x ray** will be taken to confirm the proper placement of the wires in the heart. The ICD's programming may be adjusted by passing the programming wand over the chest. After the initial operation, the physician may induce ventricular fibrillation or ventricular tachycardia one more time prior to the patient's discharge, although recent studies suggest that this final test is not generally necessary.

A short stay in the hospital is usually required following ICD insertion but this varies with the patient's age and condition. If there are no complications, complete recovery from the procedure will take about four weeks. During that time, the wires will firmly take hold where they were placed. In the meantime, the patient should avoid heavy lifting or vigorous movements of the arm on the side of the ICD, or else the wires may become dislodged.

After implantation, the implantable cardioverter-defibrillator is programmed to respond to rhythms above the patient's **exercise** heart rate. Once the device is in place, many tests will be conducted to ensure that the device is sensing and defibrillating properly. About 50%

of patients with ICDs require a combination of drug therapy and the ICD.

Safety

Environmental conditions that can affect the functioning of the ICD after installation include:

- strong electromagnetic fields, such as those used in arc-welding
- contact sports
- shooting a rifle from the shoulder nearest the installation site
- cell phones used on that side of the body
- magnetic mattress pads, such as those believed to treat arthritis
- some medical tests such as **magnetic resonance imaging (MRI)**

Environmental conditions often erroneously thought to affect ICDs include:

- microwave ovens (the waves only affect old, unshielded **pacemakers** and do not affect ICDs)
- airport security (although metal detector alarms could be set off, so patients should carry a card stating they have an ICD implanted)
- anti-theft devices in stores (although patients should avoid standing near the devices for prolonged periods)

Patients should also be instructed to memorize the manufacturer and make of their ICD. Although manufacturing defects and recalls are rare, they do occur and a patient should be prepared for that possibility.

Maintenance

In general, if the condition of the patient's heart, drug intake, and metabolic condition remain the same, the ICD requires only periodic checking every two months or so for battery strength and function. This is done by placing a special device over the ICD that allows signals to be sent over the telephone to the doctor, a process called trans-telephonic monitoring.

If changes in medications or physical condition occur, the doctor can adjust the ICD settings using a programmer, which involves placing the wand above the pacemaker and remotely changing the internal settings. One relatively common problem is the so-called "ICD storm," where the machine inappropriately interprets an arrhythmia and gives a series of shocks. Reprogramming can sometimes help alleviate that problem.

When the periodic testing indicates that the battery is getting low, an elective ICD replacement operation is

KEY TERMS

Arrhythmia—A variation of the normal rhythm of the heartbeat.

Cardioverter—A device to apply electric shock to the chest to convert an abnormal heartbeat into a normal heartbeat.

Defibrillation—An electronic process which helps re-establish a normal heart rhythm.

Ventricles—The two large lower chambers of the heart which pump blood to the lungs and the rest of the human body.

Ventricular fibrillation—An arrhythmia in which the heart beats very fast but blood is not pumped out to the body that can become fatal if not corrected.

Ventricular tachycardia—An arrhythmia in which the heart rate is more than 100 beats per minute.

scheduled. The entire signal generator is replaced because the batteries are sealed within the case. The leads can often be left in place and reattached to the new generator. Batteries usually last about four to eight years.

Health care team roles

Electrophysiologists are specially trained cardiologists or thoracic surgeons who study and treat problems with the heart conduction system. They often implant the ICD system and oversee the programming or reprogramming of the device. They are assisted in the operating room by specially trained nurses, who can help with the testing of the ICD, and the anesthesiologist, who is responsible for numbing the area of the incision and keeping the patient comfortable. ICD manufacturers often send representatives to be present for the implantation and initial programming.

The maintenance of the ICD can be overseen by the electrophysiologist or cardiologist and associated staff, which can include specially trained cardiac medical assistants as well as nurses.

Training

The training for implantation of ICDs and their use occurs during medical training (medical or nursing school) and on the job. Physicians, nurses, and other allied health professionals can also receive training about ICDs as part of their continuing education courses.

Continuing education concerning ICD tends to be in specific subject areas, such as the psychological effects of ICD firing, the interpretation of clinical trials in the area, or comparisons between appropriate and inappropriate firing rates.

Infant nutrition

Definition

Infant **nutrition** is the feeding behavior of an infant during the first year after birth.

Purpose

Due to the tremendous amount of growth during infancy, adequate nutrition after birth is essential for the development and nourishment of children. Proper nutrition can be obtained from the use of breast milk, infant formulas, and adequate diet related to age.

Precautions

When assessing the nutritional status of infants, it is important to consider the differences in the bodily functions of infants. The gastrointestinal functions of newborns are much slower than that of older infants, especially gastric emptying, which may account for the regurgitation, or spitting up, in newborns.

Passage through the **small intestine** is slower for infants, which helps ensure proper absorption and digestion of nutrients. However, the **large intestine** has a much faster transit time, which puts infants at an increased risk of **dehydration** if resorption of water and electrolytes is compromised.

The digestion of fat is also limited in infancy due to the decreased amount of pancreatic lipase, an enzyme secreted by the **pancreas** to digest fat. However, other lipases present in breast milk compensate for the lack of this enzyme and aid in fat digestion. Thus, the fat in human milk is more readily absorbed than the fat in prepared formulas.

Renal function is also limited in newborns because their **kidneys** are not fully developed until one month of age. The immature kidneys and other factors limit the newborns' ability to cope with fluid and electrolyte loads. Infants fed breast milk or properly prepared formulas normally do not have problems with renal solute load, although problems may occur with **fever**, **diarrhea**, or a reduction in the volume of fluids consumed.

Infants who sleep through the night may need to be woken up mid-way through the night to feed if they are underweight or not consuming enough. It is important to have routine check-ups with the doctor or dietitian to ensure that infants are eating adequately. Honey should also not be given to infants because it may contain spores that cause botulism.

Description

During the first six months of life, infants can receive adequate nutrition through either breast milk or fortified formula. An infant who is breastfeeding will need to nurse on demand or usually about eight to 12 times per day, while babies who are formula fed need to eat about six to eight times per day. In both breastfed and

formula-fed infants, the number of feedings decreases as they get older, but the amount of milk the baby consumes at each feeding increases.

Prior to four months of age, an infant's **digestive system** has not developed well enough to tolerate solid foods. But at about four to six months of age, solid foods can start to be introduced into the infant's diet. It is important to look for signs that an infant is developmentally ready to handle solid foods. Once infants can hold their head up, sit up with minimal support, and begin to show an interest in food, solid feedings of iron-fortified baby cereal can be started. Mixing it with breast milk or formula to get a thin consistency is recommended until the infant can control its mouth better to handle a thicker consistency.

At six to eight months of age, the introduction of fruit juices and strained fruits and vegetables can begin. Use unsweetened juices that contain large amounts of **vitamin C**, such as orange, apple, or grape, but avoid putting an infant to sleep with a bottle of juice as this can lead to tooth decay. Introduce fruits and vegetables one at a time and wait a few days in between introductions to make sure the infant has no allergic reactions. Use plain fruits and vegetables such as carrots, squash, beans, bananas, applesauce, and pears. Introducing vegetables into the diet before fruits is often recommended because the sweet **taste** of fruit may make vegetables less appealing to the infant. Finger foods may also be introduced at this time, but avoid foods that may cause choking, such as grapes, hotdogs, nuts, and seeds. Breast milk or fortified formula should still be given about three to five times a day.

At eight to 12 months of age, an infant should still be receiving breast milk or formula three to four times a day, but also should start eating strained or finely chopped meat. Introduce different meat every week and include strained and ground meats and hotdogs. If eggs are given, only the yolk should be used until one year of age in case the infant is sensitive to egg whites.

If an infant still uses a bottle at one year of age, the bottle should only contain water, or whole (**vitamin D**) milk can be used instead of breast milk or formula. Low-fat milk should not be used until at least two years of age because infants need the extra calories for adequate development. Thereafter, no less than 2% milk should be fed to a young child.

Breastfeeding versus formula feeding

During the first year of life, breast milk is the best source of nutrition for infants. Breast milk provides several health benefits for both the mother and infant beyond the benefits of adequate nutrition. Nutritionally, breast

KEY TERMS

Antibodies—A naturally occurring protein in the blood that is produced in response to the toxicity of an antigen.

Botulism—A disease of the nervous system caused by eating spoiled foods.

Colostrum—Milk secreted for a few days after parturition that is characterized by high protein and antibody content.

Electrolytes—Compounds that form ions when they dissociate in water, such as potassium and chloride.

Enzyme—A protein catalyst that facilitates a reaction in the body without itself being altered.

Essential amino acids—Amino acids that cannot be made by the body.

Galactose—Monosaccharide that is part of the disaccharide lactose.

Glucose—Monosaccharide used for energy; also known as blood sugar.

Lactose—Disaccharide known as milk sugar.

Renal solute load—Amount of solution carried by the blood to the kidneys which is to be excreted through the urine.

Resorption—Absorb again.

Spores—Reproductive body of an organism that is capable of producing new individuals.

milk provides the appropriate amounts of carbohydrate, protein, and fat for infants, along with essential **vitamins**, **minerals**, and digestive enzymes. It also provides antibodies that help increase the infant's **immune system**, decrease gastrointestinal distress, reduce the risk of allergy, and promote the development of the jaws and teeth. Colostrum is the milk secreted from the mother's breasts during the first few days after giving birth. This milk adequately provides the infant's needs during its first week of life as it is characterized by high protein and antibody content. For the mother, breastfeeding facilitates a faster recovery from labor, allows the mother to rest more often, and saves money that would have been spent on formula.

If breastfeeding is not the chosen method of feeding, iron-fortified formulas can be used to provide adequate nutrition. Infant formula has more protein and more **iron** than human milk, but it lacks antibodies. The American

Academy of Pediatrics recommends that all formula-fed infants be given iron-fortified formula. Formula feeding also allows the mother to receive help with feedings and sleep more during the night. Formulas are available for infants who may have **allergies** to milk protein or are lactose intolerant. There are also formulas available for **premature infants** and those who have **metabolism** disorders.

Preparation

Improperly prepared formulas can be a very common cause of infant illnesses. When preparing formula, it is recommended that it not be mixed with warm tap water as this can increase the amount of lead in the formula, which can be very harmful to the infant. Bottles should also not be heated in a microwave because this could cause the milk to scald or the bottle to explode. Lastly, adding sweetened beverages or cereals to bottles should also be avoided because they will only displace the more nutrient-dense formula.

Complications

Most women are capable of breastfeeding as long as they allow their infant to nurse, although there are special circumstances when formula must be used instead of breast milk. Galactosemia is a rare genetic disease in which newborns lack the enzyme needed to convert galactose to glucose. Galactose is a component of lactose, which is very abundant in breast milk. Without the enzyme to convert it to glucose, galactose accumulates in the **blood** causing tissue damage and possibly death. Therefore, it is essential that these infants receive a lactose-free soy-based formula.

Phenylketonuria is another genetic disorder in which newborns lack the enzyme needed to convert the essential amino acid phenylalanine to the amino acid tyrosine. Accumulation of phenylalanine in the blood can cause severe mental retardation. Therefore, it is necessary to start a low phenylalanine diet with a low phenylalanine formula.

Health care team roles

The dietitian plays a very important role in educating parents on the importance of adequate infant nutrition and proper feeding methods. Dietitians are also responsible for informing people of the proper preparation of formula and the advantages and disadvantages of both breastfeeding and formula feeding. While caring for an infant, it is important to have routine check-ups with the doctor to check the infant's height and weight to ensure

that the infant is at the right stage of growth and receiving adequate nutrition.

Infection

Definition

Infection is the invasion and replication of microorganisms—**viruses**, **bacteria**, protozoa, or **fungi**—in body tissues.

Description

There are thousands of infectious agents that can cause human disease. Although the body is extraordinarily adaptive in its responses to such agents, sometimes its

Salmonella bacteria often cause infection through food contamination. (Photograph by Oliver Meckes. Photo Researchers, Inc. Reproduced by permission.)

preventative measures fail, resulting in disease. A sub-clinical infection occurs when the body's defensive mechanisms are effective, resulting in no apparent clinical symptoms. When infection persists to cause disease, it is called an acute or chronic infection.

Infectious agents

There are four major classes of organisms that infect the human body:

- **Viruses:** microscopic agents that consist of genetic material coding for the virus's reproduction enclosed in a protective protein coat or lipid membrane. Viruses are obligate intracellular parasites; they cannot replicate without first infecting a cell and exploiting its reproductive capabilities.
- **Bacteria:** microscopic prokaryotic organisms (lacking a nuclear membrane, mitochondria, and other organelles). Two major classes include gram-positive bacteria (surrounded by a protective cell wall) and gram-negative bacteria (surrounded by an outer lipid membrane).
- **Fungi:** eukaryotic organisms (containing distinct organelles and a nucleus enclosed by a nuclear membrane). Fungi can be unicellular (e.g., yeast) or multicellular (e.g., mold).
- **Parasites:** eukaryotic organisms ranging from microscopic, unicellular protozoa to macroscopic arthropods and worms.

Infectious organisms are found everywhere on Earth—in extremes of hot and cold; in acidic and alkaline environments; in air, soil, and water; in our bodies, and on our skin. The human body is colonized by numerous types of bacteria (called normal flora) that reside in the **stomach**, intestines, colon, upper respiratory tract, and

KEY TERMS

B cells—White blood cells responsible for the production of antibodies.

Ciliated cells—Cells with hair-like structures that help flush out foreign particles from the human body.

Complement system—Proteins that activate inflammation response and recruit white blood cells to the site of infection.

Endogenous infection—Infection caused by the normal flora of the human body.

Eukaryote—An organism whose cells contain a true nucleus bound by a membrane.

Exogenous infection—Infection caused by microbes found external to the human body.

Normal flora—Types of bacteria and other organisms that colonize the human body without normally causing disease.

Obligate intracellular parasites—Microbes that must remain inside of a cell in order to survive and replicate.

Phagocytosis—Engulfment and digestion of foreign particles and cells by phagocytic cells such as neutrophils and macrophages.

Prokaryote—A cell that contains no true nucleus or membrane-bound organelles.

T cells—White blood cells responsible for activating and controlling immune response.

on the skin. Ordinarily, normal flora aids in food digestion, protection against disease, and various other functions. Exogenous infections occur when organisms found outside of the body cause disease, while endogenous infections are caused by the normal flora colonizing sterile tissue sites.

Transmission

There are countless ways in which an individual can become infected with an infectious organism. The mode of transmission depends largely on the type of organism, its size, its structure, its vector (who transmitted it), and other factors. Some common ways that infectious agents are transmitted (and examples of such agents) are:

- inhalation (*Mycobacterium tuberculosis*; **influenza** viruses; *Histoplasma capsulatum*, a fungus that causes pneumonia)

- ingestion (*Salmonella*, *Vibrio*, *Giardia* and *Listeria* species; *Escherichia coli*)
- penetration of skin (*Clostridium tetani*, causative agent of tetanus; *Staphylococcus aureus*; hepatitis C virus [HCV])
- sexual transmission (human **immunodeficiency** virus [HIV]; *Neisseria gonorrhoeae*; *Chlamydia trachomatis*)
- zoonoses or animal contact (flaviviruses; rabies virus; *Yersinia pestis*, causative agent of bubonic plague)
- mother-to-child (Rubella virus or German measles; herpes simplex virus [HSV]; varicella-zoster virus or chicken pox)

Role in human health

Response to infection

The human body has three basic means of defense against invading microorganisms: natural barriers, innate non-specific immunity, and antigen-specific immunity. Each protective measure acts at a different time point in infection and varies according to the type of infectious agent.

NATURAL BARRIERS. The first barriers against infection are the skin and mucous membranes (the inner lining of the mouth, nose, vagina, urethra, and upper respiratory tract). Besides providing a physical barrier against the entry of infectious agents, these tissues are inhospitable environments for invading microbes. For example, mucus (a secretion made of protein and sugar molecules) in the upper respiratory tract can trap infectious particles before they go on to colonize the lung; ciliated cells (with hair-like structures on their surface) help flush the particles out of the respiratory tract to be expelled. The gastrointestinal tract (including the stomach and intestines) and the urinary tract (including the bladder and **kidneys**) secrete fluids such as gastric juice and bile that create hostile conditions for infectious agents.

The temperature of the human body (normally 98.6°F or 37°C) is itself a mechanism of evading infection. A major elevation of body temperature (i.e., **fever**) can slow or prevent the colonization and spread of many microbes and increase the efficiency of **immune response**.

INNATE NON-SPECIFIC IMMUNE RESPONSE. When an infectious agent is able to evade natural barriers and enter the body, the first responses to its presence are non-specific protective responses. For example, the presence of certain microbial surface molecules activates the complement system (**proteins** that activate inflammation response and recruit white **blood** cells to the site of infec-

tion). The complement system attracts phagocytic cells such as neutrophils and macrophages, which engulf foreign particles and digest them. (Neutrophils circulate primarily in the blood stream, while macrophages reside in tissues.) Activation of the complement system leads to the classic symptoms of inflammation: **pain**, fever, erythema (redness), and **edema** (swelling).

ANTIGEN-SPECIFIC IMMUNE RESPONSE. If non-specific immunity fails to slow or prevent the spread of a microorganism, another line of defense may be used: antigen-specific immunity. Two classes of white blood cells have a large role in specific immune response; these are B cells (or B lymphocytes) and T cells (or T lymphocytes).

B cells are responsible for the production of antibodies, also called immunoglobulins. Antibodies bind specifically to a foreign particle (called an antigen) so that once antibodies have been produced against a particular invader, the **immune system** can react more rapidly if that invader enters the body again. Antibodies can also enhance phagocytosis, neutralize toxins, inhibit the binding of microorganisms to human cells, and activate the complement system.

There are two main types of T cells: helper T cells (CD4 type) and cytolytic and suppressor T cells (CD8 type). Helper T cells activate and control immune response by stimulating B cells to produce antibodies. Receptors on the surface of cytolytic T cells recognize cells with surface antigens; the cell is then killed. Suppressor T cells help regulate immune response.

In some cases immune response is over-stimulated, resulting in extensive tissue damage and systemic effects. An example is toxic shock syndrome (TSS), a disease that results from infection with *Staphylococcus aureus*. Upon infection the bacteria produces a toxin that over-stimulates immune response. The result is a proliferation of T cells and over-secretion of cytokines (small proteins that act as signals between cells of the immune system). The clinical manifestations of this disease are devastating: symptoms start with fever and hypotension (low **blood pressure**) and may progress to multiple organ failure and desquamation of the skin (extensive peeling or scaling).

Infection control

In the brochure “An Ounce of Prevention: Keeps the Germs Away,” (2000) the Centers for Disease Control and Prevention (CDC) identified some simple and inexpensive means of preventing the spread of infectious diseases. These include:

- Wash hands frequently.

- Clean and disinfect.
- Handle and prepare foods safely.
- Get immunized.
- Do not take unnecessary **antibiotics** (e.g., for viral infections).
- Keep pets healthy.
- Avoid contact with wild animals.

Infection control

Definition

Infection control is the protection of patients and health care workers by the prevention of **infection** in the health care setting in a cost-efficient manner.

Standard precautions for infection control

Environmental control	Follow hospital procedures for routine care, cleaning, and disinfection of all surfaces, beds, bedrails, bedside equipment, and other frequently touched surfaces.
Linen	Handle, transport, and process used linen soiled with blood, body fluids, secretions, or excretions in a manner that prevents exposures and contamination of clothing, and avoids transferring microorganisms to other patients and environments.
Occupational health and bloodborne pathogens	Prevent injuries when using needles, scalpels, and other sharp instruments or devices; when handling sharp instruments after procedures; when cleaning used instruments; and when disposing of used needles. Never recap used needles using both hands or any other technique that involves pointing the needle toward any part of the body; instead, use a one-handed "scoop" technique or a mechanical device designed for holding the needle sheath. Do not remove used needles from disposable syringes by hand, and do not bend, break, or otherwise manipulate used needles by hand. Place used disposable syringes and needles, scalpel blades, and other sharp items in puncture-resistant sharps containers located as close as practical to the area in which the items were used, and place reusable syringes and needles in a puncture-resistant container for transport to the processing area. Use resuscitation devices as an alternative to mouth-to-mouth resuscitation.
Patient-care equipment	Handle used patient-care equipment soiled with blood, body fluids, secretions, or excretions in a manner that prevents skin and mucous membrane exposures and contamination of other patients and environments. Ensure that reusable equipment is not used for the care of another patient until it has been appropriately cleaned and reprocessed and single use items are properly discarded.
Patient placement	Use a private room for a patient who contaminates the environment or who does not (or cannot be expected to) assist in maintaining appropriate hygiene or environmental control. Consult Infection Control if a private room is not available.
Wash hands (plain soap)	Wash after touching blood, body fluids, secretions, excretions, and contaminated items. Wash immediately after gloves are removed and between patient contacts. Avoid transfer of microorganisms to other patients or environments.
Wear gloves	Wear when touching blood, body fluids, secretions, excretions, and contaminated items. Put on clean gloves just before touching mucous membranes and nonintact skin. Change gloves between tasks and procedures on the same patient after contact with material that may contain high concentrations of microorganisms. Remove gloves promptly after use, before touching non-contaminated items and other surfaces, and before going to another patient, and wash hands immediately to avoid transfer of microorganisms to other patients or environments.
Wear gown	Protect skin and prevent soiling of clothing during procedures that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions. Remove a soiled gown as promptly as possible and wash hands to avoid transferring microorganisms to other patients or environments.
Wear mask and eye protection or face shield	Protect mucous membranes of the eyes, nose, and mouth during procedures and patient-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.

SOURCE: CDC, 1996.

Purpose

The purpose of infection control is to reduce the risk of health care worker exposure and infection and nosocomial (hospital-acquired) infections, which can complicate existing diseases or injuries.

Description

Organized efforts at infection control began in the United States in the 1950s, along with the increase in intensive care units to care for critically ill patients and the emergence of nosocomial **staphylococcal infections**. Many hospitals implemented programs in the 1960s and 1970s at the insistence of various organizations. In the 1980s, state and federal agencies, along with professional organizations, began to make recommendations for infection control and require adherence to regulations.

Infection control procedures are followed in hospitals, long term care facilities, rehabilitation units, outpatient facilities, and **home care**. All infection control programs should encourage actions that limit the spread of nosocomial infections. All healthcare institutions are mandated by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to "develop specific objectives and outcome measures to determine whether or not its infection control goals have been achieved" (AJIC, 1998). Infection control programs must include the means to measure the effectiveness of procedures, policies, or programs to protect patients and health care providers and to determine if these activities are cost-effective.

Health care organizations must be in compliance with regulations and accreditation requirements by various federal and state agencies and governing bodies. JCAHO, for instance, has standards that are incorporated

into many state licensing, as well as **Medicare** and **Medicaid**, regulations. The facility's administration is responsible for ensuring compliance. Ongoing education and training are an important part of an effective infection control program. Also, the monitoring of patient-care activities can identify areas of concern, and the data obtained is vital to improving the program and ensuring successes.

The Hospital Infections Program (HIP) of the National Center for Infectious Diseases, Centers for Disease Control and Prevention (CDC), is the focus for information, surveillance, investigation, prevention, and control of nosocomial infections for the U.S. Public Health Service, state and local health departments, hospitals, and professional organizations in the United States and around the world. Studies indicate that one-third of nosocomial infections can be prevented by well-organized infection control programs, yet only 6-9% are actually prevented. The Study of Efficacy of Nosocomial Infection Control (SENIC) carried out by HIP over ten years showed that, to be effective, nosocomial infection programs must include the following: 1) organized surveillance and control activities, 2) a ratio of one infection control practitioner for every 250 acute care beds, 3) a trained hospital epidemiologist, and 4) a system for reporting surgical wound infection rates back to surgeons (NNIS, 1996). The National Nosocomial Infections Surveillance (NNIS) System has been gathering information for 20 years regarding nosocomial infections. This information is being used to assist hospitals in conducting successful surveillance of these infections.

In 1987, the Centers for Disease Control (CDC) expanded previous recommendations to prevent the spread of human **immunodeficiency** virus (HIV), hepatitis B virus (HBV), and other bloodborne pathogens. Previously, certain isolation precautions were recommended only for those patients who were known or suspected to have bloodborne infectious diseases. Because of the growing number of persons infected with HIV and the high mortality rates associated with **AIDS**, Universal Blood and Body Fluids Precautions were developed. Under these new recommendations, all patients are considered potentially infectious for bloodborne infections. In 1991, the Occupational Safety and Health Administration's (OSHA) Bloodborne Pathogen Standard required the use of **universal precautions** and dictated that all staff must be trained annually on the risk of exposure to bloodborne pathogens. Preventing exposure is the best and safest way to reduce infection.

The effectiveness of infection control programs are evaluated in several ways: lower rates of infection for the patient, shorter periods of hospital stays, decreased morbidity, and reduction of on-the-job exposure of health

Methods of disinfection

Method	Use
Alcohols	Skin degerming.
Autoclaving	Sterilize instruments not harmed by heat and water pressure.
Boiling water	Kill non-spore-forming pathogenic organisms.
Chlorines	Water disinfection; food surface sanitization.
Ethylene oxide gas	Sterilization of heat-sensitive materials or those that must be kept dry.
Fiberglass filters	Air disinfection.
Formaldehyde (formalin)	Drastic disinfection.
Formaldehyde gas	Fumigation; sterilization of heat-sensitive materials.
Germicidal soaps (hexachlorophene)	Skin degerming.
Iodines, tincture	Skin degerming.
Iodines, iodophors	General disinfectant.
Ionizing	Sterilize medicines, some plastics, sutures, and biologicals.
Membrane filtration	Water purification.
Mercurials	Skin degerming.
Phenols	General disinfectant.
Quaternary ammonia compounds, tincture	Skin degerming.
Quaternary ammonia compounds, aqueous	General disinfectant.
Ultrasonic	Disinfect instruments.
Ultraviolet light	Air and surface disinfection.
Washing	Disinfect hands and surfaces.

SOURCE: Benarde, M.A., ed. *Disinfection: A Treatise*. New York: Marcel Dekker, 1970.

care workers to infection and contamination from patients. To do this, infection control policies focus on strategies for isolation, barrier precautions, case investigation, health care worker education, immunization services, and employee health programs. When healthcare institutions are successful in their infection control programs, it decreases the cost of care and has a positive impact on the institution's image within the community.

It is the responsibility of infection control to identify problems, collect and analyze data, change policies and procedures when necessary, and monitor data. The specific functions of an infection control program should be based on the needs of the individual healthcare institution. It is most important to monitor infection activity. Data is collected and disseminated based on the principles of epidemiology to implement quality-improvement activities and improve patient outcomes. Policies and procedures of the facility must be based on scientific and valid infection control prevention and be reviewed and updated frequently to reflect practice guidelines and standards.

SELECTED INFECTIOUS DISEASES AND CORRESPONDING TREATMENT

<i>Disease</i>	<i>Symptoms</i>	<i>Transmittal</i>	<i>Treatment</i>
Chicken pox	Rash, low-grade fever	Person to person	None
Common cold/ Influenza	Runny nose, sore throat, cough, fever, headache, muscle aches	Person to person	None
Hepatitis	Jaundice, flu-like symptoms	Sexual contact with an infected person, contaminated blood, food, or water	None
Legionnaire's Disease	Flu symptoms, pneumonia, diarrhea, vomiting, kidney failure, respiratory failure	Air conditioning or water systems	Antibiotics
Measles	Skin rash, runny nose and eyes, fever, cough	Person to person	None
Meningitis	Neck pain, headache, pain caused by exposure to light, fever, nausea, drowsiness	Person to person	Antibiotics for bacterial meningitis, hospital care for viral meningitis
Mumps	Swelling of salivary glands	Person to person	Anti-inflammatory drugs
Ringworm	Skin rash	Contact with infected animal or person	Antifungal drugs applied topically
Tetanus	Lockjaw, other spasms	Soil infection of wounds	Antibiotics, antitoxins, muscle relaxers

(Public Domain.)

Transmission of infection within a health care organization requires three elements: a source of infecting microorganisms, a susceptible host, and a means of transmission for the microorganism. The skin of patients and personnel can function as a reservoir for infectious agents and as a vehicle for transfer of infectious agents to susceptible persons. The microbial flora of the skin consists of resident and transient microorganisms. Resident microorganisms persist and multiply on the skin. Transient microorganisms are contaminants that can survive for only a limited period of time. Most resident microorganisms are found in superficial skin layers, but about 10-20% inhabit deep epidermal layers. Handwashing with plain soaps is effective in removing many transient microorganisms. Resident microorganisms in the deep layers may not be removed by hand-

washing with plain soaps, but usually can be killed or inhibited by antimicrobial products. *Handwashing is the single most important measure for preventing nosocomial infections.*

Hand-washing indications

Health care workers should wash their hands:

- after removing gloves
- when coming on duty
- when hands are soiled, including after sneezing, coughing, or blowing the nose
- between patient contacts
- before medication preparation
- after personal use of the toilet

- before performing invasive procedures
- before taking care of particularly susceptible patients, such as those who are severely immunocompromised and newborns
- before and after touching wounds
- before and after eating
- after touching inanimate objects that are likely to be contaminated with pathogenic microorganisms, such as urine-measuring devices and secretion collection apparatuses
- after taking care of infected patients or patients who are likely to be colonized with microorganisms of special clinical or epidemiologic significance; for example, **bacteria** that are resistant to multiple antibiotics

Preparation

Routine hand-washing is accomplished by vigorously rubbing together all surfaces of lathered hands followed by thorough rinsing under a stream of water. This should take 10-15 seconds to complete. The hands should be dried with a paper towel. Immediate recontamination of the hands by touching sink fixtures may be avoided by using a paper towel to turn off faucets.

Universal precautions recommend that all health care workers who come into contact with a patient's blood or body fluids that contain visible blood should wear an appropriate type of barrier to prevent the spread of blood-borne pathogens. Other body fluids for which barrier protection is recommended include semen, vaginal secretions, cerebrospinal fluid (CSF), synovial fluid, pleural fluid, pericardial fluid, and amniotic fluid. The type of exposure determines the specific barrier that should be used. Universal precautions are designed to augment, not replace, standard infection control procedures such as hand washing and the use of gloves when touching obviously infected materials.

Adequate routine cleaning and removal of soil should be the environmental sanitation procedure for all healthcare facilities. Microorganisms are normal contaminants of the environment. A healthcare facility's environmental services department should maintain schedules for routine cleaning in all rooms and include equipment and working surfaces. General and infectious wastes are disposed of on a regular schedule. All departments, though, are responsible for implementing infection control policies.

Complications

Health care workers must not be complacent about implementing their facility's infection control policies.

Perhaps due to long-time exposure to occupationally acquired infections, they have the tendency to minimize or ignore the ramifications. Infections oftentimes go undetected, underreported, or overlooked by health care workers.

Results

If infection control programs are successful, the result will be a reduction in the risk of infection and related adverse outcomes in the healthcare setting, achieved in a cost-efficient manner.

Health care team roles

Much of the responsibility for infection control rests on the shoulders of the clinical staff providing care at the bedside. Because nurses are close to the patient physically, they are able to prevent the spread of infection, but they can also be a means of transmitting infection. Therefore they need to foster compliance with infection control policies to ensure a high quality outcome for the patient. Infection control practices should have a positive effect on not only the clinical staff, but the patient as well.

Infectious mononucleosis test

Definition

Infectious mononucleosis (IM) tests detect the presence or absence of antibodies in the **blood** stream directed against **proteins** of the Epstein-Barr Virus (EBV), the cause of IM.

Purpose

Infectious mononucleosis tests are used to diagnose infectious mononucleosis in patients with symptoms compatible with the disease. Initial testing is based on the demonstration of heterophile antibodies produced in infectious mononucleosis. Heterophile antibodies are those that react with the cells from a different (nonhuman) species. A positive result from a rapid slide (Monospot) test for IM specific heterophile antibodies is diagnostic, and no further testing is necessary. The Monospot test will be positive in more than 90% of adults or adolescents with IM, but is more frequently negative in young children. When the Monospot test results are negative, an EBV antibody panel may be needed to differentiate EBV infections from mononucleosis-like illnesses induced by cytomegalovirus, adenovirus, or *Toxoplasma gondii*. The EBV antibody panel can differentiate persons who have never been infected with EBV, acute infections, and past infections. EBV antibody tests are not needed when the doctor believes that a person has IM and the Monospot test is positive.

Precautions

Blood for this test is collected by venipuncture. The nurse or phlebotomist performing the procedure should observe **universal precautions** for the prevention of

transmission of bloodborne pathogens. False positive Monospot results occur in a small percentage of the patient population. False negative Monospot results occur in 10% to 15% of patients, primarily in children under the age of 10. With the EBV panel false positive results may occur in patients with rheumatoid arthritis, leukemia, lymphoma, or HIV.

Description

The Epstein-Barr Virus (EBV) is one of the most common human **viruses**, and most of the world's population is infected at sometime during their lives. According to the CDC, when an EBV **infection** occurs during adolescence or young adulthood, it causes infectious mononucleosis 35–50% of the time. The virus is believed to be transmitted primarily via salivary exchange, including intimate kissing, sharing toothbrushes, cups, or eating utensils..

Symptoms of infectious mononucleosis include **fever, sore throat**, swollen lymph glands lasting for two to three weeks, and fatigue and a swollen spleen or **liver** typically lasting for approximately one month. While the infection is rarely fatal and usually resolves in one or two months, the course is more chronic in some persons, and the virus may remain dormant in some throat and blood cells for the rest of the person's life.

The clinical diagnosis of infectious mononucleosis is suggested on the basis of the symptoms of fever, sore throat, swollen lymph glands, and the age of the patient. Laboratory tests are needed for confirmation. Laboratory findings suggestive of infectious mononucleosis include an elevated white blood cell count, an increased lymphocyte count, and the presence of a significant number of atypical lymphocytes (seen when viewing a stained blood smear under the **microscope**). Diagnosis is usually made by demonstrating a positive reaction to a rapid slide test (usually referred to as a Monospot test) for the specific heterophile antibodies seen in IM.

Heterophile antibodies may be of two types, called Forssman and nonForssman. Infectious mononucleosis causes production of nonForssman heterophile antibodies. Testing for heterophile antibodies must distinguish these from the Forssman type which are not produced by IM and are present in the blood of many persons without IM. The Monospot test is based upon the principle that IM heterophile antibodies will agglutinate horse red blood cells (because they are nonForssman). First, the serum is mixed with two different antigen suspensions, guinea pig kidney antigen and beef red blood cell stroma, prior to testing with the horse red cells. The guinea pig kidney antigen absorbs (removes) Forssman heterophile antibodies while the beef red cell stroma removes

nonForssman IM antibodies. After mixing the serum with these two suspensions, the serum is mixed with the horse red cells. In infectious mononucleosis, agglutination should be seen in the serum mixed with guinea pig antigen. Little or no agglutination should be seen in the serum mixed with the beef red cell stroma.

An EBV antibody panel can be used to confirm a negative Monospot result or rule out a false positive Monospot result. The panel includes four antibody measurements: IgM viral capsid antigen (VCA), IgG VCA, Early Antigen (EA), and Epstein-Barr nuclear antigen (EBNA), which help determine the stage of the patient's EBV infection.

Preparation

To obtain the 2 mLs of blood required for this test, a nurse or phlebotomist ties a tourniquet on the person's upper arm, locates a vein in the inner elbow region, and inserts a needle into that vein. Vacuum action draws the blood through the needle into an attached tube. Collection of the sample takes only a few minutes.

Aftercare

Discomfort or bruising may occur at the puncture site. Applying pressure to the puncture site until the bleeding stops reduces bruising; warm packs relieve discomfort. Some people feel dizzy or faint after blood has been drawn and should be treated accordingly.

Complications

There are no risks beyond those of having blood drawn for any other purpose.

Results

Results of the rapid slide test are determined as positive or negative. According to the CDC, the confirmatory diagnosis of EBV infection is summarized as follows:

- **Susceptibility:** If antibodies to the VCA are not detected.
- **Primary infection:** If IgM antibody to the VCA is present in the absence of antibody to EBNA. A rising or high IgG antibody titre to the viral capsid antigen and a negative antibody test to EBNA after at least four weeks of illness are strongly suggestive of primary infection.
- **Past infection:** If antibodies to both the VCA and EBNA are present, then past infection (from four to six months to years earlier) is indicated.
- **Reactivation:** In the presence of antibodies to EBNA, an elevation of antibodies to early antigen suggests reactivation.

KEY TERMS

Heterophile antibodies—Antibodies created against one species that cross react with another.

Lymphocyte—White blood cell that fights viral and some bacterial infections by direct attack or the production of antibodies.

- **Chronic EBV infection:** Reliable laboratory evidence for continued active EBV infection is very seldom found in patients who have been ill for more than four months.

If the results are difficult to interpret, it may be necessary to retest later, after waiting one to three weeks. The change in the amounts of antibody detected between the two tests can be particularly useful, at times, in helping to make a diagnosis.

The **complete blood count (CBC)** in a patient with infectious mononucleosis typically reveals:

- a white blood cell count (WBC) of 10,000 to 20,000 cells per microliter
- more than 4,500 lymphocytes per microliter and more than 50% lymphocytes in the differential
- atypical lymphocytes (Downey cells) accounting for more than 10% of total leukocytes

Health care team roles

Physicians order and interpret the IM tests. Nurses or phlebotomists usually draw the blood needed for these tests. Clinical laboratory scientists/medical technologists or clinical laboratory technicians/medical laboratory technicians perform the antibody tests in clinical laboratories. Interpretation of EBV antibody tests is somewhat complex and requires familiarity with EBV testing and access to all the patient's clinical information.

Infertility

Definition

Infertility is the failure to conceive a **pregnancy** after attempting for at least one full year. In primary infertility, pregnancy has never occurred. In secondary infertility, one or both members of the couple have previously conceived, but are unable to conceive again after a full year of attempting.

Description

Currently, in the United States, about one in five couples struggles with infertility at any given time. Infertility has increased as a problem over the last 30 years. Some studies assign the blame for this increase on social phenomena, including the tendency for marriage to occur at a later age. Fertility in women decreases with increasing age, as illustrated by the following statistics. In one year of trying to become pregnant:

- Infertility in women at age 20 is 4%.
- Infertility in women at age 30 is 7%.
- Infertility in women at age 35 is 12%.
- Infertility in women over the age of 40 is 75%.

Many individuals have multiple sexual partners before marriage. This increase in numbers of sexual partners has led to a rise in sexually transmitted diseases. Scarring from these infections, especially from pelvic inflammatory disease (PID, a serious **infection** of the female reproductive organs, most commonly caused by chlamydia and gonorrhea), seems to be partially responsible for increases in infertility. Furthermore, use of some forms of a contraceptive called the intrauterine device (IUD) contributed to an increased rate of pelvic inflammatory disease. However, the newer IUDs do not cause infections.

To understand issues of infertility, it is first necessary to understand the basics of human reproduction. Fertilization occurs when a sperm from the male merges with an egg (ovum) from the female, creating a zygote that contains genetic material (DNA) from both the father and the mother. If pregnancy is then established, the zygote will develop into an embryo, then a fetus, and ultimately a baby will be born.

The male contribution to fertilization and the establishment of pregnancy is the sperm. Sperm are small cells that carry the father's genetic material, which is contained within the oval head of the sperm. The sperm are mixed into a fluid called semen that is discharged from the penis during sexual intercourse. The whip-like tail of sperm allows them to swim up the female reproductive tract in search of an egg (ovum).

The female makes many contributions to fertilization and the establishment of pregnancy. The ovum is the cell that carries the mother's genetic material; ova (plural of ovum) develop within the ovaries. Once a month, a single mature ovum is produced, and leaves the ovary in a process called ovulation. This ovum enters a tube leading to the uterus (the fallopian tube). If fertilization is to occur, the ovum must encounter the sperm in the fallopian tube.

When fertilization occurs, the resulting cell is called a zygote. This single cell will multiply within the fallopian tube, and the resulting cluster of cells, a blastocyst, will then move into the womb (uterus). The uterine lining (endometrium) has been preparing itself to receive a pregnancy by growing thicker. If the blastocyst successfully reaches the inside of the uterus and attaches itself to the wall of the uterus, then pregnancy has been achieved.

Causes and symptoms

Unlike most medical problems, infertility is an issue requiring the careful evaluation of two separate individuals, as well as an evaluation of their interactions with each other. In about 3–4% of couples, no cause for their infertility will be discovered.

The main factors involved in causing infertility, ranging from the most to the least common, include:

- male problems: 30-40%
- ovulation problems: 10-15%
- pelvic disease: 30-40%
- cervical factors: 10-15%
- undiagnosed: 5-10%

Diagnosis

Diagnosis of infertility involves examination of both male and female partners.

Male factors

Male infertility can be caused by a number of different characteristics of sperm. To check for these characteristics, a sample of semen is obtained and examined under a **microscope (semen analysis)**. Four basic characteristics are usually evaluated:

- Sperm count refers to the number of sperm present in a semen sample. The typical number of sperm present in just one milliliter (ml) of semen is more than 20 million. A male with only 5–20 million sperm per ml of semen is considered subfertile, while a male with less than 5 million sperm per ml of semen is considered to be infertile.
- Sperm are examined to determine how well they swim (sperm motility) and to ensure that most have normal structure (morphology). Not all sperm within a specimen of semen will be perfectly normal. Some may be immature, and others may have abnormalities of the head or tail. A typical semen sample will contain no more than 25% abnormal forms of sperm.
- Volume of the semen sample is important; an abnormal amount of semen could adversely affect the ability of the sperm to successfully fertilize an ovum.
- The ability of the sperm to penetrate the outer coat of the ovum is also evaluated. This is accomplished by observing whether sperm in a semen sample can penetrate the outer coat of a hamster ovum. Fertilization cannot occur, of course, but this test is useful in predicting the ability of an individual's sperm to penetrate a human ovum.

Any number of conditions result in abnormal findings in the semen analysis. Men can be born with testicles that have not descended properly from the abdominal cavity into the scrotal sac, or may be born with only one testicle, instead of the normal two. Testicle size might be smaller than normal. Past infection (including mumps) can affect testicular function, as can a past injury. The presence of abnormally large veins (varicocele) in the testicles can increase testicular temperature, which decreases sperm count.

History of having been exposed to various toxins, drug use, excessive alcohol use, use of anabolic steroids, certain medications, diabetes, thyroid problems, or other endocrine disturbances can have direct effects on the formation of sperm (spermatogenesis). Problems with the male anatomy can cause sperm to be ejaculated into the bladder, or scarring from past infections can interfere with ejaculation.

Female factors

OVULATORY PROBLEMS. The first step in diagnosing ovulatory problems is to make sure that an ovum is being produced each month. A woman's body temperature in the morning is slightly higher around the time of ovulation. A woman can measure and record her temperatures daily, and a chart can be drawn to show whether or not ovulation has occurred. Luteinizing hormone (LH) is released just before ovulation. A simple urine test can be done to check if LH has been released around the time that ovulation is expected.

PELVIC ADHESIONS AND ENDOMETRIOSIS. Pelvic adhesions and endometriosis can cause infertility by preventing the sperm from reaching the egg or interfering with fertilization.

Pelvic adhesions are fibrous scars. These scars can be the result of past infections, such as pelvic inflammatory disease, or infections following abortions or prior births. Previous surgeries can also leave behind scarring. Pelvic adhesions cause infertility by blocking the fallopian tubes. The ovum may be prevented from traveling down the fallopian tube from the ovary or the sperm may be prevented from traveling up the fallopian tube from the uterus.

A hysterosalpingogram (HSG) can show if the fallopian tubes are blocked. This is an x-ray exam that tests whether dye material can travel through a woman's fallopian tubes. Scarring also can be diagnosed by examining the pelvic area through the use of a scope that can be inserted into the abdomen through a tiny incision made near the navel. This technique is called **laparoscopy**.

Endometriosis may lead to pelvic adhesions. Endometriosis is the abnormal location of uterine tissue outside of the uterus. When uterine tissue is implanted elsewhere in the pelvis, it still bleeds on a monthly basis with the start of the normal menstrual period. This leads to irritation within the pelvis around the site of this abnormal tissue and bleeding, and may cause scarring.

CERVICAL FACTORS. The cervix is the opening from the vagina into the uterus through which the sperm must pass. Mucus produced by the cervix helps to transport the sperm into the uterus. Cervical mucus can be examined under a microscope to diagnose whether cervical factors are contributing to infertility. An injury to the cervix or scarring of the cervix after surgery or infection can result in a smaller than normal cervical opening, which would make it difficult for sperm to enter. Injury or infection can also decrease the number of glands in the cervix, leading to a smaller amount of cervical mucus. In other situations, the mucus produced might be the wrong consistency to allow sperm to travel through. In addition,

some women produce antibodies (immune cells) that identify sperm as foreign invaders and kill them. Finally, cervical stenosis is a rare cause of infertility.

Treatment

Treatment of infertility first involves addressing underlying conditions in the male and female partners. If these fail to produce a pregnancy, additional steps can be undertaken to assist pregnancy.

Treatment of male infertility includes first addressing known reversible factors such as discontinuing any medication known to have an effect on spermatogenesis or ejaculation, decreasing alcohol intake, or treating thyroid or other endocrine disease. Varicoceles can be treated surgically. Testosterone in low doses can improve sperm motility.

Other treatments of male infertility include collecting semen samples from multiple ejaculations, after which the semen is put through a process that allows the most motile sperm to be sorted out. These motile sperm are pooled together to create a concentrate that can be deposited into the female partner's uterus at ovulation. In cases where the male partner's sperm is proven unviable, with the consent of both partners, donor sperm may be used. Depositing the male partner's sperm or donor sperm by mechanical means into the female partner is a form of artificial insemination.

Treatment of ovulatory problems depends on the cause. If a thyroid or pituitary problem is responsible, treating that problem can restore fertility. Medication such as Clomid and Pergonal can be used to stimulate fertility. These drugs may increase the risk of multiple births (twins, triplets, etc.).

Pelvic adhesions can be excised with laparoscopy. Endometriosis can be treated with certain medications, but may also require surgery to repair any obstruction caused by adhesions.

Treatment of cervical factors includes **antibiotics** in the case of an infection, steroids to decrease production of anti-sperm antibodies, and artificial insemination techniques to completely bypass the cervical mucus.

Assisted reproductive techniques include in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), and zygote intrafallopian tube transfer (ZIFT). These are usually used after other techniques to treat infertility have failed.

IVF involves the use of a drug to induce the simultaneous release of many eggs from a female's ovaries. These are surgically retrieved. Meanwhile, several semen samples are obtained from the male partner, and a sperm

concentrate is prepared. The ova and sperm are then combined in a laboratory, where several of the ova may be fertilized. **Cell division** is allowed to take place up to the embryo stage. While this takes place, the female may be given drugs to prepare her uterus to receive an embryo. Three or four of the embryos are transferred to the female's uterus, and the wait begins to see if any or all of them implant and result in an actual pregnancy.

Success rates of IVF are still rather low. Most centers report pregnancy rates between 10–20%. Since most IVF procedures put more than one embryo into the uterus, the chance for a multiple birth is greatly increased in couples undergoing IVF.

GIFT involves retrieval of both multiple ova and semen, and the mechanical placement of both within the female partner's fallopian tubes. ZIFT involves the same retrieval of ova and semen and the fertilization and growth in the laboratory up to the zygote stage, at which point the zygotes are placed in the fallopian tubes. Both GIFT and ZIFT have higher success rates than IVF.

Prognosis

It is very difficult to obtain statistics regarding the prognosis of infertility because many different problems may exist within an individual or couple trying to conceive. In general, of all couples who undergo a complete evaluation of infertility followed by treatment, about half will ultimately have a successful pregnancy. Of those couples who do not choose to undergo evaluation or treatment, about 5% will go on to conceive after a year or more of infertility.

Health care team roles

Gynecologists who specialize in infertility lead most investigations. Registered nurses (RNs) assist throughout investigations and other associated procedures. Laboratory technicians conduct laboratory tests and evaluations of ova and sperm. Other technicians may assist in preparing eggs and sperm for IVF, or readying women for GIFT or ZIFT. Pharmacists dispense the many drugs that are required for GIFT, ZIFT, or IVF.

Prevention

Prevention of infertility involves avoiding many of the various problems that can cause infertility. Since sperm count declines with age, insemination is more likely to occur with younger men than older men. Males can preserve maximal fertility by maintaining optimal temperatures in their testicles by wearing non-binding undergarments. People should avoid exposure to coal-

based products such as tar and soot as they are associated with infertility. Protecting the testicles from trauma helps to preserve fertility. Immunization for mumps is important.

Women are maximally fertile in the beginning of their third decade of life. Thereafter, conception becomes more difficult. Avoiding or promptly treating sexually transmitted diseases lessens the possibility of endometriosis and pelvic adhesions. Limiting the number of male partners improves fertility as antibodies against sperm will not be formed. Hasty decisions to perform tubal ligations as a means of birth control may be regretted if marital arrangements change. Although tubal ligations can be reversed, subsequent pregnancy rates are not 100%.

KEY TERMS

Blastocyst—A cluster of cells representing multiple cell divisions that have occurred in the fallopian tube after successful fertilization of an ovum by a sperm.

Cervix—The opening from the vagina that leads into the uterus.

Embryo—The stage of development of a baby between the second and eighth weeks after conception.

Endometrium—The lining of the uterus.

Fallopian tube—The tube leading from the ovary into the uterus; there are two fallopian tubes.

Fetus—A baby developing in the uterus from the third month to birth.

Ovary—The female organ in which eggs (ova) are stored and mature.

Ovum (plural: ova)—The reproductive cell of the female that contains genetic information and participates in the act of fertilization. Also popularly called the egg.

Semen—The fluid that contains sperm that is ejaculated by the male.

Sperm—The reproductive cell of the male that contains genetic information and participates in the act of fertilization of an ovum.

Spermatogenesis—The process by which sperm develop to become mature sperm, capable of fertilizing an ovum.

Zygote—The result of sperm successfully fertilizing an ovum, the zygote is a single cell that contains the genetic material of both the mother and the father.

Influenza

Definition

Usually referred to as the flu or gripe, influenza is a highly infectious respiratory disease caused by certain strains of influenza virus. When the virus is inhaled it attacks cells in the upper respiratory tract causing typical flu symptoms such as fatigue, **fever** and chills, hacking cough, and body aches. Influenza victims are also susceptible to potentially life-threatening secondary infections. Although the **stomach** or intestinal upsets and **diarrhea** are commonly called “flu,” the influenza virus rarely causes gastrointestinal symptoms. Such symptoms are most likely due to other organisms such as rotavirus, *Salmonella*, *Shigella*, or *Escherichia coli*.

Description

Influenza is considerably more debilitating than the **common cold**. Influenza outbreaks occur suddenly and **infection** rapidly spreads. The annual death toll attributable to influenza and its complications averages 20,000 in the United States alone.

Influenza outbreaks occur on a regular basis. Pandemics, the most serious outbreaks, affect millions of people worldwide and last for several months. The 1918–1919 influenza outbreak serves as the primary example of an influenza pandemic. In that Spanish flu pandemic, the death toll reached a staggering 20–40 million people worldwide. Approximately 500,000 of these fatalities occurred in the United States. Pandemics also occurred in 1957 and 1968 with the Asian flu and Hong Kong flu, respectively. The Asian flu was responsible for 70,000 deaths in the United States, while the Hong Kong flu killed 34,000 people.

Epidemics are widespread regional outbreaks that occur every two to three years and affect 5–10% of the population. The Russian flu in the winter of 1977 is an example of an epidemic. A regional epidemic is shorter lived than a pandemic, lasting only several weeks. Finally, there are smaller outbreaks each winter that are confined to specific locales.

The earliest existing descriptions of influenza were written nearly 2,500 years ago by the ancient Greek physician, Hippocrates. Historically, influenza was ascribed to a number of different agents, including “bad air” and several different **bacteria**. It was not until 1933 that the causative agent was identified as a virus.

There are three types of influenza **viruses**, identified as A, B, and C. Influenza A can infect a range of species, including humans, pigs, horses, and birds, but only

humans are infected by types B and C. Influenza A is responsible for most flu cases, while infection with types B and C viruses are less common and cause a milder illness.

Causes and symptoms

Approximately one to four days after infection with the influenza virus, a person is hit with an array of symptoms. “Hit” is an appropriate term, because symptoms are sudden, harsh, and followed by overall bodily aches and a fever that may run as high as 104°F (40°C). As the fever subsides, nasal congestion and a **sore throat** become noticeable. Persons with the flu feel extremely tired and generally miserable. Typical influenza symptoms include the abrupt onset of a headache, dry cough, and chills, and a rapid onset of physical weakness. Normal energy levels typically do not return for several days, but this can extend up to two weeks.

Influenza complications usually arise from secondary bacterial infections of the lower respiratory tract. Signs of a secondary respiratory infection often appear just as a person seems to be recovering. These signs include high fever, intense chills, chest pains associated with breathing, and a productive cough with thick, yellowish-green sputum. If these symptoms appear, medical treatment is necessary. Other secondary infections, such as sinus or ear infections, may also require medical intervention. **Heart** and lung problems and other chronic diseases can be aggravated by influenza. This is a particular concern among elderly people.

With children and teenagers, it is advisable to be alert for symptoms of Reye’s syndrome, a rare but serious complication of the flu. Symptoms of Reye’s syndrome are nausea and vomiting, and—more seriously—neurological problems such as confusion or delirium. Among children Reye’s syndrome can be fatal. The syndrome has been associated with the use of aspirin to relieve flu symptoms.

Diagnosis

Although specific laboratory tests can be performed on respiratory samples to identify a flu virus strain, doctors typically rely on a set of symptoms and the presence of influenza in the community for diagnosis. Specific tests are useful to determine the type of flu in the community, but they do little to influence individual treatment. Doctors may administer tests, such as throat cultures, to identify and treat secondary bacterial infections.

Treatment

Essentially, little can be done for a case of influenza as it must simply run its course. Symptoms can be relieved with bed rest and by keeping well hydrated. A steam vaporizer may make breathing easier, and **pain** relievers such as ibuprofen and acetaminophen will relieve most aches and pains. Food may not seem appetizing, but an effort should be made to consume nourishing food. Returning to normal activities too quickly invites a possible relapse or complications.

Drugs

Since influenza is a viral infection, **antibiotics** are not an effective treatment. However, antibiotics are frequently used to treat secondary infections. Over-the-counter medications are used to treat symptoms, but it is not necessary to purchase a product marketed specifically for flu symptoms. Any medication designed to relieve pain and coughing will provide some relief. Products containing alcohol, however, should be avoided because of the dehydrating effects of alcohol. The best medicine for symptoms is simply an analgesic, such as acetaminophen or ibuprofen. Without a doctor's approval, aspirin is generally not recommended for people under the age of 18 years owing to its association with Reye's syndrome. As a precaution against the syndrome, children should receive acetaminophen or ibuprofen to treat their symptoms.

There are two **antiviral drugs** marketed for use in the United States against the influenza virus. These may be useful in treating individuals who have weakened immune systems or who are at risk for developing serious complications of influenza but may be allergic to the flu vaccine. The first is amantadine hydrochloride, which is marketed under the names Symmetrel (syrup), Symadine (capsule), and Amantadine-hydrochloride (capsule and syrup). The second antiviral is rimantadine hydrochloride, marketed under the trade name Flumandine (tablet and syrup). These two drugs are chemically related and are only effective against type A influenza viruses. Both drugs can cause side effects such as nervousness, **anxiety**, lightheadedness, and nausea. Side effects are more likely to occur with amantadine. Severe side effects include seizures, delirium, and hallucinations. These are rare and are nearly always limited to people who have kidney problems, seizure disorders, or psychiatric disorders.

Alternative treatment

There are several alternative treatments that may help in fighting off the virus, easing symptoms, and promoting recovery:

A transmission electron micrograph (TEM) of influenza viruses budding from the surface of an infected cell.

(Photo Researchers, Inc. Reproduced by permission.)

- **Acupuncture and acupressure.** Both are said to stimulate natural resistance, relieve nasal congestion and headaches, fight fever, and calm coughs, depending on the acupuncture and acupressure points used.
- **Aromatherapy.** Aromatherapists recommend gargling daily with one drop each of the essential oils of tea tree (*Melaleuca* spp.) and lemon mixed in a glass of warm water. If the patient is already suffering from the flu, two drops of tea tree oil in a hot bath may help ease the symptoms. Essential oils of eucalyptus (*Eucalyptus globulus*) or peppermint (*Mentha piperita*) added to a steam vaporizer may help clear chest and nasal congestion.
- **Herbal remedies.** Herbal remedies such as echinacea can be used to stimulate the **immune system**; as antivirals, goldenseal (*Hydrastis canadensis*) and garlic (*Allium sativum*) can be used. They can also be used to alleviate whatever symptoms arise as a result of the flu. For example, an infusion of boneset (*Eupatatorium perfoliatum*) may counteract aches and fever, and yarrow (*Achillea millefolium*) or elderflower tinctures may combat chills.
- **Homeopathy.** To prevent flu a homeopathic remedy called *Oscillocochinum* may be taken at the first sign of flu symptoms and repeated for a day or two. Other recommended homeopathic remedies vary according to the specific flu symptoms present. *Gelsemium* (*Gelsemium sempervirens*) is recommended to combat weakness accompanied by chills, headache, and nasal congestion. *Bryonia* (*Bryonia alba*) may be used to treat muscle aches, headaches, and a dry cough. For restlessness, chills, hoarseness, and achy joints, poison ivy (*Rhus toxicodendron*) is recommended. Finally, for bodily aches and a dry cough or chills, *Eupatorium perfoliatum* is suggested.

- **Hydrotherapy.** A hot bath to induce a fever will speed recovery from the flu by creating an environment in the body where the flu virus cannot survive. Taking a bath in water as hot as can be tolerated, and remain in the bath for 20–30 minutes, is recommended. While in the bath, drinking a cup of yarrow or elderflower tea helps induce sweating. However, a cold cloth should be held on the forehead or the nape of the neck to keep down the temperature of the **brain**. In case dizziness or weakness occurs, the patient should be assisted when getting out of the bath. The individual should then go to bed and cover up with layers of blankets to induce more sweating.
- **Vitamins.** For adults, 2–3 grams of **vitamin C** daily may help prevent the flu. Increasing the dose to 5–7 grams per day if infected by the flu can help overcome the infection. The dose of vitamin C should be reduced if diarrhea develops.

Prognosis

Following proper treatment guidelines, healthy people under the age of 65 years of age usually suffer no long-term consequences associated with influenza infections. While the elderly and the chronically ill are at greater risk for secondary infection and other complications, they can also recover completely. While most people fully recover from an influenza infection, the flu should not be viewed with complacency. Influenza is a serious disease. Approximately one in every 1,000 cases proves fatal.

Health care team roles

Family physicians, internists, and pediatricians most often diagnose influenza in people who seek medical attention. Nurse practitioners and physician assistants may also make such diagnoses. A physician usually prescribes over-the-counter products for symptomatic relief. Occasionally, antiviral products are prescribed for people at particular risk. Nurses administer vaccines to prevent influenza, providing education and information to those contemplating or receiving the vaccine.

Prevention

The Centers for Disease Control and Prevention recommend that people—particularly the at-risk population such as children, individuals with other diseases or disorders or a compromised immune system, and the elderly—get an influenza vaccine injection each year before the flu season starts. In the United States the flu season typically runs from late December to early March. Vaccines should be received two to six weeks prior to the

beginning of the flu season to allow people's bodies enough time to establish immunity. Adults need only one dose of the yearly vaccine, but children under nine years of age who have not previously been immunized should receive two doses with a month between each dose.

Each season's flu vaccine contains three virus strains that are the most likely to be encountered in the coming flu season. When there is a good match between the anticipated flu strains and the strains used in the vaccine, the vaccine is 70–90% effective in people younger than 65 years of age. Because **immune response** diminishes somewhat with age, people older than 65 years may not receive the same level of protection from the vaccine as do younger people. Even if they do contract the flu, the elderly benefit from vaccines, which diminish severity and help prevent complications.

The virus strains used to make the vaccine are inactivated and will not cause a case of influenza. In the past, flu symptoms following **vaccination** were associated with vaccine preparations that were not as highly purified as modern vaccines, not to the virus itself. In 1976 there was a slightly increased risk of developing Guillain-Barré syndrome, a very rare disorder associated with the swine flu vaccine. This association occurred only with the 1976 swine flu vaccine preparation and has never recurred.

Serious side effects with modern vaccines are extremely unusual. Some people experience a slight soreness at the point of injection, which resolves within a day or two. People who have never been exposed to influenza, particularly children, may experience one to two days of a slight fever, tiredness, and muscle aches. These symptoms start within 6 to 12 hours after vaccination.

It should be noted that certain people should not receive an influenza vaccine. Infants six months and younger have immature immune systems and will not benefit from the vaccine. Since the vaccines are prepared using hen eggs, people who have severe **allergies** to eggs or other vaccine components should not receive the influenza vaccine. As an alternative, they may receive a course of amantadine or rimantadine, which are also used as protective measures against influenza. Other people who might receive these drugs are those who have been immunized after the flu season has started or who are immunocompromised, such as people with advanced HIV disease. Amantadine and rimantadine are 70–90% effective in preventing influenza.

Members of certain groups are strongly advised to be vaccinated because they are at-risk for influenza-related complications:

- all people 65 years and older

- residents of **nursing homes** and chronic-care facilities, regardless of age
- adults and children who have chronic heart or lung problems, such as asthma
- adults and children who have chronic metabolic diseases, such as diabetes and renal dysfunction, as well as severe anemia or inherited hemoglobin disorders
- children and teenagers receiving long-term aspirin therapy
- pregnant women who will be in the second or third trimester during flu season, or women who are nursing
- anyone who is immunocompromised, including HIV-infected people with CD4 count over 200; people with **cancer**; organ transplant recipients; and people receiving steroids, **chemotherapy**, or radiation therapy
- anyone in contact with people in these groups, such as teachers, care givers, health-care personnel, and family members
- travelers to foreign countries

An individual need not be in one of the at-risk categories listed above, however, to receive a flu vaccination. Anyone who wants to avoid the discomfort and inconvenience of a case of influenza should receive the vaccine.

L. Fleming Fallon, Jr., M.D., Dr.P.H.

Informed consent

Definition

Informed consent is a legal document in all 50 states, prepared as an agreement for treatment, nontreatment, or for an invasive procedure that requires physicians to disclose the benefits, risks, and alternatives to said treatment, nontreatment, or procedure. It is the method by which a fully informed, rational patient may be involved in choices about his or her health care.

Description

Informed consent stems from the legal and ethical right the patient has to decide what is done to his or her body, and from the physician's ethical duty to make sure that the patient is involved in decisions about his or her own health care. The process of securing informed consent has three phases, all of which involve information exchange between doctor and patient and are part of **patient education**. First, in words the patient can understand, the physician must convey the details of a planned procedure or treatment, its potential benefits and serious risks, and any feasible alternatives. The patient should be presented with information on the most likely outcomes of the treatment. Second, the physician must evaluate whether or not the person has understood what has been said, must ascertain that the risks have been accepted, and that the patient is giving consent to proceed with the procedure or treatment with full knowledge and forethought. Finally, the patient must sign the consent form, which documents in generic format the major points of

consideration. The only exception to this is securing informed consent during extreme emergencies.

It is critical that the patient receive enough information on which to base informed consent, and that the consent is wholly voluntary and has not been forced in any way. It is the responsibility of the physician who discusses the particulars with the patient to detail the conversation in the patient's record. A physician may, at his or her discretion, appoint another member of the health care team to obtain the patient's signature on the consent form, with the assurance that the physician has satisfied the requirements of informed consent.

Paul H. Ting, M.D., Assistant Professor of Anesthesiology at the University of Virginia and editor of the "About Anesthesiology" web site discusses why patients are apprehensive. "I think that people's greatest concerns are...whether they will live or die...whether they will feel any **pain** or be uncomfortable...whether they will be well taken care of (and I include in this whether their care will lead to a successful result and whether they will be treated with dignity)...."

"The boilerplate consent form has good intentions; it is comprehensive and therefore should reflect that a comprehensive discussion was completed," said Dr. Ting. "The actual form itself is in place to protect the hospital and the physician. Legally, it is proof that things have been covered and the patient agrees to the procedure, risks, benefits, options, etc. However, the informed consent process (which the form merely is supposed to document) is in place for the protection of the patient. The process is in place to make sure that everything is discussed with the patient—all of the options, all of the common risks, the worst thing that can happen, etc."

The law requires that a reasonable physician standard be applied when determining how much information is considered adequate when discussing a procedure or treatment with the patient. There are three approaches to making this discussion: what the typical physician would say about the intervention (the reasonable *physician* standard); what the average patient would need to know to be an informed participant in the decision (the reasonable *patient* standard); and what the patient would need to know/understand to make a decision that is informed (*subjective* standard).

Viewpoints

There is a theory that the practice of acquiring informed consent is rooted in the post-World War II Nuremberg Trials. At the war crimes tribunal in 1949, 10 standards were put forth regarding physicians' requirements for experimentation on human subjects. This

established a new standard of ethical medical behavior for the post-WW II human rights age, and the concept of voluntary informed consent was established. A number of rules accompanied voluntary informed consent. It could only be requested for experimentation for the gain of society, for the potential acquisition of knowledge of the pathology of disease, and for studies performed that avoided physical and mental suffering to the fullest extent possible.

As of 2001, most of the 50 United States had legislation that spells out the required standards for informed consent. For example, the State of Washington employs the second approach outlined as the *reasonable patient* standard. This ensures that the doctor fulfills all professional responsibilities and provides the best care possible and that the patient has a choice in decisions about his or her health care. However, the patient's competence in making a decision is considered. This points to the issue of the patient's "capacity." Anyone suffering from an illness, anticipating surgery, or undergoing treatment for a disease is under a great deal of **stress and anxiety**. It may be natural for a patient to be confused or indecisive. When the attending physician has serious doubts about the patient's understanding of the intervention and its risks, the patient may be referred for a psychiatric consultation. This is strictly a precaution to ensure that the patient understands what has been explained; declining to be treated or operated on does not necessarily mean the person is incompetent. It could mean that the person is exercising the right to make his or her own health care decisions.

Although it is the law to formally present the procedure or treatment to the patient, physicians do express doubt as to its wisdom. Some believe that informing patients of the risks of treatment might scare them into refusing it when the risks of non-treatment are even greater. But patients might have a different view. Without the complete story, for example, a patient might consent to beginning a particular course of **chemotherapy**. Convinced by the pressures from a pharmaceutical company, it is conceivable that a doctor will use an agent less effective than a newer treatment. By withholding information about treatment alternatives, the physician may be denying the patient a choice and a chance of an extended life of greater quality.

The international community has also had much to say in this regard. Martin Tattersall, professor at the Sydney University Cancer Medicine Department, and Alan Langslands, professor in Radiation Oncology at Westmead, said in the August 1995 issue of the *Medical Journal of Australia*, "Our findings indicate the extent of variation in the practice of providing information to **cancer** patients commencing treatment.... The current dou-

ble standard between former clinical trials (where ethics committees require that patients be given a 'plain language statement,' as well as giving their signed consent) and the 'usual' practice outside such trials, is apparently narrowing. The reasons for this may relate to the fear of litigation, rather than recognition of the need to provide full information." A litigious society such as the United States might be plagued by an even greater number of lawsuits than at present if informed consent were not legally mandated.

Professional implications

Undeniably, physicians in surgery, anesthesia, oncology, infectious disease—the list is endless—are faced with issues regarding Informed Consent. As the federal government takes a more active role in deciding the extent to which patients must be informed of treatments, procedures, and clinical trials in which they voluntarily become enrolled, more and more health care providers must become educated in what needs to be conveyed to patients. This is emphasized by the report of a case in which a federal court (Hutchinson vs. United States [91 F2d 560 (9th Cir. 1990)]) ruled in favor of the physician, despite his failure to advise his asthmatic patient (for whom he had prescribed the steroid, prednisone), of the well-known risk of developing aseptic necrosis (bone death), which did occur. The practitioner neglected to inform the patient that there were other drugs available with a much less serious side effect profile that could have treated the **asthma**. However, and despite this "neglect," a higher, appellate court reversed the ruling and found the physician guilty. Apparently the patient had used more conservative drugs in the past with good results. The court believed that if the physician had merely advised the patient of the more serious side effects of prednisone and offered the patient more conservative treatment, the physician would have avoided liability.

Nursing professionals have a greater role in evaluating whether the consent is informed or not than they might believe. When a nurse witnesses the signature of a patient for a procedure, or surgery, he or she is not responsible for providing its details. Rather, the role is to be the patient's advocate; to protect the patient's dignity; identify any fears; and determine his or her degree of comprehension and approval of care to be received. Each patient is an individual, and each one will have a different and unique response depending on his or her personality, level of education, emotions, and cognitive status. If the patient can restate the information that has been imparted to him or her, then that will help to confirm that he or she has received enough information and has understood it. The nurse is obligated to report any doubts about the patient's

understanding regarding what has been said, or any concerns about his or her capacity to make decisions.

Inheritance, principles of

Definition

The patterns governing how genetic information is transmitted from generation to generation are collectively known as the principles of inheritance.

Description

Single-gene inheritance

Genes are composed of DNA (deoxyribonucleic acid), whose building blocks, the nucleotides, code for the multitude of **proteins** in the human body, including enzymes and structural proteins. In 2001, estimates place the number of human protein-coding genes between 25,000 and 35,000. A single-gene disorder is one caused by an alteration (mutation) in a specific gene that normally plays an important role in the human body. The protein product of a mutated gene is either abnormal in function, reduced in amount, or missing entirely.

Genes are passed down from parent to child in predictable patterns, discussed below. Knowledge of these patterns allows health care providers to explain to patients why a certain genetic disease is present in members of the family, and to predict the possibility that another family member will also be affected. As of 2001 more than 10,000 traits or diseases had been identified as following a single-gene pattern of inheritance. These are catalogued in the Online Mendelian Inheritance in Man (OMIM) at <<http://www.ncbi.nlm.nih.gov/omim/>>. In the following discussion, the MIM numbers associated with each disease example are the OMIM catalogue numbers.

In order to understand single-gene inheritance, it is necessary to be familiar with several terms and concepts. With some exceptions, discussed later, genes are present in pairs. Each member of the pair is termed an allele. An individual is said to be homozygous (a homozygote) at a certain gene locus if the two alleles of a pair are the same (i.e., if both alleles are either normal or carry the same mutation). In contrast, if the two alleles are different, the person is heterozygous (a heterozygote). For example, a person is heterozygous if he or she has one normal and one mutant allele; or if he or she has two abnormal alleles, each of which has a different mutation. The word "genotype" refers to an individual's allelic makeup at a gene. "Phenotype" refers to the observable result of having a certain genotype. Hair color is an example of a phenotype. Phenotype can be affected by other genes or by environmental influences.

Genetic traits caused by single genes are often referred to as Mendelian traits, in tribute to the Austrian monk Gregor Mendel, who in 1865 reported the results of his painstaking work on the transmission of traits such as color and shape in the garden pea. His three laws of heredity are:

- Unit inheritance. Prior to Mendel, many believed that traits were blended as they were passed from generation to generation. Although genes would not be "dis-

covered” until the next century, Mendel clearly spelled out that inheritance is a matter of passing on discrete traits.

- **Segregation.** The two alleles of a gene are never transmitted together from one parent to an offspring. This means that, in humans, an individual egg or sperm is formed with only one allele of each gene.
- **Independent assortment.** Alleles of different genes pass randomly to offspring. This law was later found to have important exceptions: If two genes are very close to each other on a chromosome, they tend to be passed down together.

Mendel’s laws went unnoticed until 35 years later, when they were simultaneously and independently discovered by Hugo De Vries in the Netherlands, Erich von Tschermak in Austria, and Carl Correns in Germany. These rediscoveries marked the real beginning of genetics as a science. Over the years many other scientists and physicians have contributed to our current understanding of inheritance in humans.

AUTOSOMAL INHERITANCE. The transmission of single-gene traits from generation to generation follows one of several basic patterns, depending on the location of the particular gene. A gene on one of the 22 pairs of autosomes—that is, the non-sex-determining chromosomes—is called an autosomal gene. Similarly, a trait or disease associated with that gene is an autosomal trait. Autosomal conditions are the most common and are equally likely to occur in males or females. Autosomal traits are further classified as either dominant or recessive.

Autosomal-dominant inheritance. Dominant conditions are those that are expressed in heterozygotes. For example, in a dominant disorder, if the two alleles of the gene are labeled A for the mutant (disease-producing) copy and B for the normal copy, an individual who is AB at that gene locus will have the disease, as will the individual who is AA. However, because a mutant allele is much less common than its normal counterpart, it is very unlikely that an affected individual would be AA.

The inheritance pattern of dominant traits is distinctive. If one parent has a particular dominant trait (e.g., an AB genotype), he or she has a 50% chance of passing the mutant allele (A) to each offspring, and, similarly, a 50% chance of passing the normal allele. Since most mutant alleles are very rare, there is usually little chance that the other parent would have the same mutant allele. Therefore, the total risk of having a child with the same disorder is 50% with each **pregnancy**. However, depending on the particular trait or disease, there are often circumstances in which the actual risk is less than 50%. For example, whether or not a person with the mutant gene

Gregor Mendel. (Archive Photos, Inc. Reproduced by permission.)

exhibits the trait may depend on a phenomenon called penetrance. If an autosomal-dominant disorder is fully penetrant, every individual with a mutant copy of the gene will have the disease. An allele is said to have reduced penetrance if only some individuals with the allele ever develop signs of the disorder. Similarly, expressivity refers to the degree to which someone who has inherited the mutant gene will be affected. For example, one person with a particular mutant allele might be severely affected, while another will have only mild features of the disease. The degree to which penetrance and expressivity play a role in autosomal-dominant disorders varies with the particular gene. In addition, some mutant alleles cause disease only later in life; these are the so-called adult-onset single-gene disorders.

Of the 10,000 genetic traits and diseases currently known, more than half are autosomal-dominant. When considered individually, the majority are rare, with the most common being present in only 1 in 500 to 1,000 individuals. However, taken together, they have an important impact on health. One of the most common is familial hypercholesterolemia (MIM 143890), a cause of early-onset **heart** disease. Mutations in the gene for this condition disrupt the normal **metabolism** of **fats** in the body and lead to a significant buildup of cholesterol

deposits in the arteries. Huntington disease (MIM 143100), a progressive neurological disorder affecting approximately 1 in 20,000 individuals, is an example of an autosomal-dominant disorder that does not usually appear until well into adulthood. Individuals with a mutant copy of this gene typically begin to show symptoms between ages 30 and 50, with death occurring approximately 15 years later. Neurofibromatosis (von Recklinghausen disease, MIM 162200), a commonly encountered autosomal-dominant condition (1 in 3,000 individuals), is a good example of a disease exhibiting variable expressivity. Signs and symptoms can vary from extremely mild ones such as pigmentary changes of the skin (cafe-au-lait spots) to more severe complications (including learning disabilities and multiple disfiguring tumors).

Autosomal-recessive inheritance. The genes for autosomal-recessive traits are also located on the autosomes, but the mutant, disease-causing alleles are recessive to the normal alleles; thus, if one normal allele is present, it is usually sufficient to prevent any expression of the disease. If the normal allele is designated A and the mutant allele is designated a, individuals who are AA or Aa will be phenotypically normal. Only those with an aa genotype will exhibit signs of the disease. Aa individuals are termed carriers, because they carry one mutant copy without showing symptoms themselves. Except for extremely rare cases of new mutations, both parents of an individual (aa) with an autosomal recessive disorder are carriers (Aa). Each time they make a germ cell (egg or sperm), that germ cell can receive only one allele. Thus, each parent always has a 50% (1 in 2) chance of passing on the mutant allele. If both parents pass the mutant allele to their germ cells, at fertilization the resulting embryo will have two mutant alleles (aa) and no normal allele. Thus, the chance that two parents who are both carriers of a mutant allele at the same gene locus will have a child with the disease is 25% (50% x 50%), or 1 in 4 with each pregnancy. Similarly, the probability of their having a child who is a carrier (Aa) is 50%, and the chance of having a child (AA) who did not inherit the disease allele from either parent is 25%.

Because an individual who carries one copy of a gene for an autosomal-recessive disorder is usually symptom-free, he or she can unknowingly transmit the disease allele to offspring. However, because of the rarity of most autosomal-recessive disorders, it is unlikely that both members of a couple will be carriers for the same disease gene and have a risk for producing children with the disorder. An exception to this is when parents are consanguineous (**blood** relatives), because they are both at risk of being carriers for the same disease allele present in their family. Consanguinity is a hallmark of

autosomal-recessive traits, and couples who are related may be at an increased risk over nonconsanguineous couples for an autosomal-recessive disorder in their offspring if a disease allele is carried in their family.

X-LINKED INHERITANCE. In addition to the 22 pairs of autosomes, humans have two sex chromosomes, X and Y, which determine an individual's sex (gender). Females have two X chromosomes (XX) and males have an X and a Y (XY). Because the smaller Y chromosome has only a very few genes as compared to the larger X, X-linked inheritance is often referred to as sex-linked inheritance. The pattern of inheritance of X-linked traits is very different from that of autosomal conditions. A distinguishing feature is the lack of male-to-male transmission, because a father transmits only his Y chromosome, not his X, to his sons. There are examples of both X-linked recessive and X-linked dominant diseases, although the former are far more common.

X-linked recessive inheritance. Another hallmark of X-linked recessive traits is that they are almost exclusively seen in males, while females are the carriers. This is explained by the fact that males only have one X chromosome and females have two Xs. The rarity of a particular mutant allele (X_m) in the general population means that a female's other allele at that gene locus is likely to be normal (X_n). Because the mutant allele is recessive, females with one mutant allele and one normal allele ($X_m X_n$) are rarely affected. However, on average, one half, or 50%, of the sons of a carrier female will have the particular disease as a result of inheriting the mother's X chromosome with the mutant allele ($X_m Y$). Similarly, half of a carrier female's daughters will be carriers. Since a male with an X-linked recessive trait has only one X chromosome and he transmits that X to all of his daughters, all of his daughters will be carriers.

X-linked dominant inheritance. An X-linked disease is considered dominant if it is expressed in heterozygotes ($X_m X_n$). All of the daughters of an affected male, but none of his sons, will have the disease. All offspring, female or male, of an affected female will be affected. However, because of a phenomenon called X-inactivation, some females may have a milder disease. In all females, one X in each cell is normally inactivated, and most genes on that X are nonfunctioning in that cell. The process is usually random, meaning that in females with one mutant and one normal allele, approximately half of the cells will have an active normal allele, which is often enough to ensure a milder course of the disease. In some severe X-linked disorders, most affected individuals are females, and it is rare to see a male with the disease. This is explained by the fact that males do not have another X with a normal allele. Rett syndrome (MIM 312750), a severe mental-retardation syndrome, is an X-linked dom-

inant disorder seen only in females. It is proposed that male fetuses with the abnormal Rett syndrome gene do not survive to birth.

MITOCHONDRIAL INHERITANCE. The above-described patterns of inheritance are applicable to genes present on the chromosomes in the nucleus of the cell. However, cells have additional genes in their mitochondria, the energy-producing organelles in the cytoplasm, the non-nuclear portion of the cell. Leber hereditary optic atrophy (MIM 535000), a severe type of midlife **vision** loss, is one of the rare disorders traced to mutations in mitochondrial DNA. Because mitochondria are almost exclusively passed from parent to child in the egg and not in the sperm, a hallmark of mitochondrial inheritance is transmission from an affected woman to all of her children. Although mitochondrial diseases are single-gene disorders, they are not considered Mendelian.

Chromosome abnormalities

In humans, the 35,000 or so nuclear genes are located on 46 chromosomes: 22 pairs of autosomes and 1 pair of sex chromosomes. Unlike single-gene diseases that are due to mutations in the DNA, chromosomal disorders are the result of too little or too much normal DNA. These disorders are usually divided into two types, numerical and structural.

NUMERICAL CHROMOSOME ABNORMALITIES. Numerical disorders are the result of either a missing or an extra whole chromosome. Although classified as genetic disorders, they are not transmitted through families. Rather, they are usually the result of an error in the specialized cell divisions (meiosis) that produce eggs and sperm. **Down syndrome**, a condition involving mental retardation and characteristic physical features, with an incidence of approximately 1 in 800 live births, is perhaps the most familiar example of a chromosome disorder. In 95% of individuals with Down syndrome, the condition is due to an extra, free-standing chromosome 21 (trisomy 21). More than 90% of trisomy 21 is due to an extra chromosome being packaged into the egg. In less than 10% of individuals, the sperm is the source of the extra 21. The only known risk factor for trisomy 21 is the age of the mother. Women have an increasingly greater risk for having a child with trisomy 21 as they get older. The reason for this is not known. Other examples of clinically important conditions that result from either a missing or an extra chromosome are Turner syndrome, Klinefelter syndrome, trisomy 13, and trisomy 18.

STRUCTURAL CHROMOSOME ABNORMALITIES. Structural chromosome abnormalities are caused by chromosome breakage and rearrangement. Among the more common types are inversions, translocations, dele-

tions, and duplications. If the rearrangement preserves all of the genetic material, it is called balanced. Individuals who carry balanced rearrangements are not affected themselves, but their altered chromosomes are at risk for further breakage and rearrangement during egg and sperm formation. This can result in offspring with extra or missing portions of chromosomes. In approximately 5% of individuals with Down syndrome, the extra chromosome 21 is not free-standing, as in trisomy 21, but is attached to another chromosome as the result of an unbalanced translocation. Often one parent will carry the balanced form of the translocation and be at risk for having other children with Down syndrome. Unbalanced structural chromosome abnormalities are found in about 1 in 17,000 live births. In the majority of cases, the resulting imbalance in the amount of genetic material results in serious physical and developmental abnormalities.

Multifactorial inheritance

Instead of one single gene being of paramount importance in producing disease, a multifactorial disorder results from the interaction of a number of genes plus influences in the environment. Despite the fact that multifactorial disorders are among the most common causes of disease in humans, the specific genes and environmental factors are still poorly understood. In contrast to single-gene disorders, multifactorial diseases do not exhibit a clear-cut pattern of inheritance within families. After one affected individual in the family, the risk of a second affected with the disorder may be somewhat increased, but that increase is more in the range of 2–10% percent than the 25–50% seen in single-gene disorders.

Nontraditional inheritance

In addition to the well-known patterns of inheritance described above, some important clinical disorders exhibit variations on these patterns. Several of these nontraditional types of inheritance are introduced briefly here. The reader is referred to other sources listed in the references for more detailed treatments.

- Triplet-repeat disorders. These are caused by genes that change in size and function from parent to child. Fragile X syndrome (MIM 309550), primarily affecting males, is caused by a gene on the X chromosome that can expand when passed from parent to child. The expansion disrupts gene function and results in mental retardation, characteristic facial features, and enlarged testes. There are a number of other triplet-repeat disorders, including the autosomal-dominant Huntington disease.

KEY TERMS

Allele—A member of a pair of genes.

Autosomes—Non-sex-determining chromosomes.

Chromosomes—Structures in the nucleus of a cell consisting of a thread of DNA containing the genetic information (genes). Humans have 46 chromosomes in 23 pairs.

Enzyme—A protein catalyst that promotes chemical reactions within the body.

Hemoglobin—The iron-containing protein of the red blood cells. Its function is to carry oxygen from the lungs to the tissues.

- **Imprinting disorders.** Most genes are expressed the same in an individual whether that gene was contributed by the mother or the father. However, there are exceptions in which the allele from one parent is normally imprinted and inactive. If the allele from the other parent is missing, for example, due to a deletion of a portion of the chromosome containing the gene, the individual is left with no functioning gene. Two very different conditions involving mental retardation, Prader-Willi syndrome (MIM 176270) and Angelman syndrome (MIM 105830), have been found to involve the phenomenon of imprinting.
- **Uniparental disomy.** This is the presence of both members of a chromosome pair from one parent and no copy from the other parent. The reader is referred to other sources for a more detailed treatment of this rare phenomenon. Uniparental disomy in combination with imprinting can also result in clinically important disorders, including some cases of Prader-Willi and Angelman syndromes.

Role in human health

Although genetics plays a role in the majority of human diseases, the contribution of genes may be primary or secondary in the pathophysiology of diseases. A British Columbian survey of more than one million individuals estimated that by age 25, at least 53 of 1,000 will have a disease with a significant genetic component.

Common diseases and disorders

Most genetic disorders fall into one of three main types; single gene, chromosomal, and multifactorial. Each type has its important hallmarks, and a basic knowl-

edge of the distinguishing factors of each is important for those who work in a clinical setting.

Single-gene disorders

Cystic fibrosis (CF, MIM 602421) is a typical autosomal-recessive disease. CF is often said to be the most common serious autosomal-recessive condition in the Caucasian population, with a frequency of about 1 in 2,000 children. Its clinical features include chronic respiratory disease, pancreatic insufficiency, and a decreased life expectancy. At present there is no cure, but because a great deal is being learned about the function of the CF gene, CF is a disease for which treatment at the gene level (also known as gene replacement or **gene therapy**) is being considered. Carrier parents who have had one child with CF have a 25% risk, with each subsequent pregnancy, of having another affected child. It is customary to offer these couples the option of prenatal diagnosis in future pregnancies to determine if the fetus is affected.

Sickle-cell anemia (MIM 603903), another autosomal-recessive disorder, is due to a specific mutation in one of the genes that codes for hemoglobin. The resulting abnormalities in the hemoglobin-rich red blood cells lead to multiple clinical symptoms in affected (aa) individuals, including increased risks for infections, blood clots, strokes, and painful swelling of the joints. Sickle cell is more common in those who can trace their ancestry to the African continent. About 1 in 500 African Americans is born with this disease. Approximately 8% are carriers (Aa) but remain symptom-free.

Perhaps the best-known example of an X-linked recessive disease is **hemophilia A** (MIM 306700). Seen almost exclusively in males, this is a failure of the blood to clot normally because of a mutation in the gene for one of the clotting factors, factor VIII. Affected males require life-long treatment with blood transfusions and factor VIII concentrates. In recent years research has been directed toward being able to offer gene therapy for males with this disorder. Duchenne **muscular dystrophy** (DMD, MIM 310200) is another X-linked recessive condition affecting the muscle fibers; it results in death usually by age 20. Since most males with DMD do not survive to reproduce, their abnormal genes are not passed on. Nevertheless, the frequency of DMD does not decline over time, because approximately one third of all cases are due to new mutations and not to the transmission of the gene from a carrier mother.

Multifactorial inherited disorders

Spina bifida, or open-spine defect, is a multifactorial birth defect, as are many cases of cleft lip/palate.

Recent studies have suggested that a deficiency of **folic acid**, one of the **B vitamins**, may play a role in causing spina bifida, and women who are planning a pregnancy are urged to take supplemental folic acid. Notwithstanding the important part that multifactorial inheritance plays in the etiology of birth defects, perhaps its greatest role is in the common diseases that are adult-onset. For example, most coronary heart disease is thought to be multifactorial, with genes plus dietary habits playing a part in determining an individual's risk for atherosclerosis, a narrowing of the arteries of heart caused by lipid (fat) deposits. A variety of cancers are also thought to be due to a combination of genetic and environmental factors. An enormous challenge awaits the next generation of geneticists as they attempt to unravel the complex interactions of genes and environment in these clinically important multifactorial disorders.

Integumentary system

Definition

The integumentary system includes the skin and the related structures that cover and protect the body. The human integumentary system is composed of the skin, and includes glands, hair, and nails. The largest organ in the body, the skin protects the body, prevents water loss, regulates body temperature, and senses the external environment.

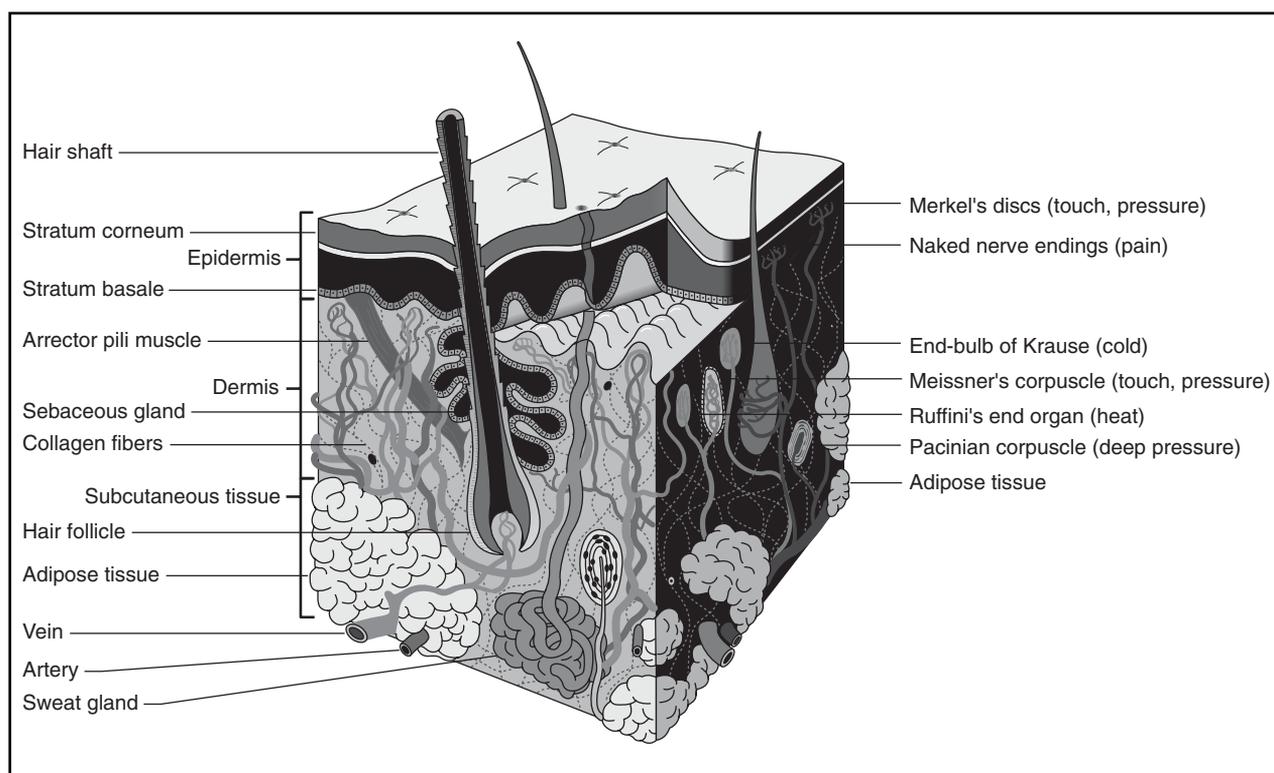

Description

The integumentary system serves many protective functions for the body. It acts as a mechanical barrier, simultaneously preventing water from entering the body and excessive water loss. It also limits access of microorganisms that could cause illness, and protects underlying tissues from mechanical damage. Pigments in the skin called melanin, give skin its color, and absorb and reflect the sun's harmful ultraviolet radiation.

Function

In addition to serving as a protective barrier, the skin helps to regulate the body temperature by several mechanisms. If heat builds up in the body, sweat glands in the skin produce more sweat that evaporates and cools the skin. When the body overheats, **blood vessels** in the skin dilate (expand), bringing more **blood** to the surface, and allowing body heat to dissipate. When the body is too cold, the blood vessels in the skin constrict, shunting blood away from the body surface, thus conserving heat. Along with temperature regulation, the skin serves as a minor excretory organ, since sweat removes small, clinically insignificant amounts of nitrogenous wastes produced by the body. The skin also functions as a sense organ since it contains millions of nerve endings that detect touch, heat, cold, **pain** and pressure. Finally, the skin produces **vitamin D** in the presence of sunlight, and renews and repairs damage to itself.

In an adult, the skin covers about 21.5 sq. ft (2 sq. m), and weighs about 11 lb. (5 kg). Depending on location, the skin thickness ranges from 0.02-0.16 in (0.5-4.0 mm). Skin is composed of an outer layer, or epidermis, and a thicker inner layer, the dermis. A subcutaneous layer of fatty or adipose tissue is immediately below the dermis. Fibers from the dermis attach the skin to the subcutaneous layer, and the underlying tissues and organs also connect to the subcutaneous layer.

Human skin. (Diagram by Hans & Cassidy. Courtesy of Gale Group.)

The epidermis

Ninety percent of the epidermis, including the outer layers, contains keratinocytes, cells that produce keratin, a protein that helps waterproof and protect the skin. Melanocytes are pigment cells that produce melanin, a brown-black pigment that adds to skin color and absorbs ultraviolet light, thereby shielding the genetic material in skin cells from damage. Merkel's cells disks are touch-sensitive cells found in the deepest layer of the epidermis of hairless skin.

In most areas of the body, the epidermis consists of four layers. On the soles of the feet and palms of the hands where there is considerable friction, the epidermis has five layers. Calluses, abnormal thickenings of the epidermis, occur on skin subject to constant friction. At the skin surface, the outer layer of the epidermis constantly sheds the dead cells containing keratin. The uppermost layer consists of about 25 rows of flat dead cells that contain keratin.

The dermis

The dermis is made up of connective tissue that contains protein, collagen, and elastic fibers. It also contains blood and lymph vessels, sensory receptors, related nerves, and glands. The outer part of the dermis has fin-

gerlike projections, called dermal papillae, that indent the lower layer of the epidermis. Dermal papillae cause ridges in the epidermis above it, which in the digits give rise to fingerprints. The ridge pattern of fingerprints is inherited, and is unique to each individual. The dermis is thick in the palms and soles, but very thin in other places, such as the eyelids.

The blood vessels in the dermis contain a volume of blood. When a part of the body, such as a working muscle, needs more blood, blood vessels in the dermis constrict, shifting blood from the skin to supply muscles and other body parts. Sweat glands with ducts that pass through the epidermis and open on the skin surface through pores are embedded in the deep layers of the dermis. Hair follicles and hair roots also originate in the dermis, and the hair shafts extend from the hair root through the skin layers to the surface. The dermis also contains sebaceous glands associated with hair follicles. Sebaceous glands produce an oily substance called sebum. Sebum softens the hair and prevents it from drying, but if sebum blocks a sebaceous gland, a whitehead appears on the skin. A blackhead results if the material oxidizes and dries. Acne pimples are caused by infections of the sebaceous glands.

The skin is an important sense organ and as such includes a number of types of nerves, which are mainly

in the dermis, with a few reaching the epidermis. Nerves carry impulses to and from hair muscles, sweat glands, and blood vessels, and receive messages from touch, temperature, and pain receptors. Some nerve endings are specialized such as sensory receptors that detect external stimuli. The nerve endings in the dermal papillae, known as Meissner's corpuscles, detect light touch, or the feel of clothing on the skin. Pacinian corpuscles, located in the deeper dermis, are stimulated by stronger pressure on the skin. Receptors near hair roots detect displacement of the skin hairs by stimuli such as touch or wind. Bare nerve endings throughout the skin supply information to the **brain** about temperature change (both heat and cold), texture, pressure, and trauma.

Role in human health

Along with its vital roles as shield against microorganisms and regulating body temperature, skin often provides information about overall health and a variety of medical conditions. The color, texture, temperature, and elasticity of skin can aid in diagnosing a variety of disorders. For example, patients with hepatitis may have a characteristic yellow tinge to their skin. Similarly, cold sores and **fever** blisters are indications of **infection** with herpes simplex virus, and warts (intraepidermal skin tumors) result from infection with human papilloma virus (HPV).

Skin testing is an important diagnostic tool in the evaluation of **allergies**. Skin testing involves a series of superficial injections of one or more suspected allergens. A positive response, such as redness, or inflammation, at the site of the skin test, helps to pinpoint the culprit.

Common diseases and disorders

Acne, caused by clogged pores and bacterial infection, is commonly diagnosed in teenagers and young adults. Acne may be mild, moderate, or severe and is characterized by blackheads, whiteheads, papules, pustules, and cysts on the face, shoulders, chest, and back. Mild acne may be treated with topical antimicrobial agents to kill the **bacteria** on the skin and topical retinoids to open the pores. Moderate and severe acne often respond to treatment with systemic **antibiotics** such as tetracycline or doxycycline.

Common bacterial skin infections are impetigo, folliculitis, and cellulitis. Impetigo is a contagious skin infection caused by streptococci or staphylococcus. It produces crusty patches on the skin. Local outbreaks may be treated with antibacterial ointment, and patients with widespread infections are given oral antibiotics. Infectious folliculitis produces erythema (redness) and pustules. It is caused by staphylococcus and treated with oral antibi-

otics. Cellulitis is swelling, erythema, warmth, and pain caused by infection of the dermis and subcutaneous tissue often near a wound site. Cellulitis is usually caused by Group A streptococci or staph aureus and is treated with a course of anti-strep or anti-staph antibiotics.

Common viral skin disorders include infection with herpes simplex or herpes zoster. Herpes simplex is responsible for cold sores, fever blisters, and lesions on the genitals and buttocks. Herpes zoster produces a painful rash characterized by vesicles. Both conditions are treated with acyclovir, or other orally administered anti-viral agent.

Skin reactions include eczema, allergic contact dermatitis (rashes), such as those resulting from contact with poison ivy, sumac, or oak, and **hives**. Contact dermatitis, an eruption of itchy skin vesicles, is an allergic skin reaction. Patients are advised to avoid contact with the suspected allergen, and mild cases may be treated with warm soaks and topical ointments to reduce inflammation and soothe inflamed skin.

Cosmetic damage as well as potentially fatal skin disorders may result from overexposure to the ultraviolet (UV) rays in sunlight. At first, overexposure to sunlight results in injury known as sunburn. UV rays damage skin cells, blood vessels, and other dermal structures. Continual overexposure produces leathery skin, wrinkles, and discoloration and may also lead to skin **cancer**. Anyone excessively exposed to UV rays runs a risk of skin cancer, regardless of the amount of pigmentation normally in the skin. Seventy-five percent of all skin cancers are basal cell carcinomas that arise in the epidermis and rarely metastasize (spread) to other parts of the body. Physicians can surgically remove basal cell cancers. Squamous cell carcinomas also occur in the epidermis, and these may metastasize. Malignant melanomas are life-threatening skin cancers that metastasize rapidly. There can be a 10 to 20 year delay between exposure to sunlight and the development of skin cancers.

Dermatology is the medical specialty devoted to the diagnosis and treatment of skin disorders. In addition to the disorders previously described, primary care physicians and dermatologists are frequently called upon to diagnose and treat the following conditions:

- alopecia (hair loss)
- athlete's foot (fungus infection)
- moles
- psoriasis (scaly skin on the scalp, trunk, arms and legs)
- rosacea (symmetrically distributed papules and pustules on the nose and cheeks)

KEY TERMS

Chitin—Polysaccharide that forms the exoskeleton of insects, crustaceans, and other invertebrates.

Dermis—Thicker layer of skin lying below the epidermis.

Epidermis—Thinner outermost layer of the skin.

Keratin—Insoluble protein found in hair, nails, and skin.

Melanin—Brown-black pigment found in skin and hair.

- scabies (skin infestation with mites that produces inflammatory papules in the wrists, web spaces, and sides of feet)
- seborrheic dermatitis (facial redness and scaling)
- spider veins, varicose veins
- vitiligo (loss of skin color on patches of skin, usually affects the face and extremities)

Today, many dermatologists also provide a range of cosmetic services to reduce the signs of aging, such as wrinkles, sagging skin and discoloration, and reverse some of the effects of sun damage to skin. Microdermabrasion, laser skin resurfacing, and injections of collagen are among the techniques used to improve the appearance of skin.

Intensive care unit equipment

Definition

Intensive care unit (ICU) equipment includes patient monitoring, respiratory and cardiac support, **pain man-**

agement, emergency resuscitation devices, and other life support equipment designed to care for patients who are seriously injured, have a critical or life-threatening illness, or have undergone a major surgical procedure, thereby requiring 24-hour care and monitoring.

Purpose

An ICU may be designed and equipped to provide care to patients with a range of conditions, or it may be designed and equipped to provide specialized care to patients with specific conditions. For example, a neuromedical ICU would care for patients with acute conditions involving the nervous system or for patients who have just had neurosurgical procedures and would require equipment for monitoring and assessing the **brain and spinal cord**. A neonatal ICU is designed and equipped to care for infants who are ill, born prematurely, or have a condition requiring constant monitoring.

Patient monitoring equipment

Patient monitoring equipment includes the following:

- Acute care physiologic monitoring system—Continuously measures and displays data on **vital signs**, such as **heart rate**, **blood pressure**, cardiac output, and **blood oxygen levels**.
- Pulse oximeter—Monitors the oxygen saturation in the blood.
- Intracranial pressure monitor—Measures the pressure of fluid in the brain in patients with head trauma or other conditions affecting the brain (such as tumors, **edema**, or hemorrhaging).
- Apnea monitor—Continuously monitors breathing to detect cessation in infants and adults at risk of respiratory failure.

Life support and emergency resuscitative equipment

ICU equipment for life support and emergency resuscitation include the following:

- Ventilator (also called a respirator)—Assists with or controls pulmonary ventilation in patients who cannot breathe on their own.
- Infusion pump—Device that delivers fluids intravenously or epidurally, including continuous anesthesia, drugs, and blood infusions.
- Crash cart—Portable cart containing emergency resuscitation equipment for patients who are “coding” (that is, their vital signs are in a dangerous range), including

a defibrillator, airway intubation devices, resuscitation bag/mask, and medication box.

- **Intra-aortic balloon pump**—A device that helps reduce the heart's workload and helps blood flow to the coronary arteries for patients with unstable angina, **myocardial infarction**, or patients awaiting transplants.

The use of diagnostic equipment is also required in the ICU. Mobile x-ray units are used for bedside radiography, particularly of the chest. Portable clinical laboratory devices, called point-of-care analyzers, are used for blood analysis at the bedside to provide results much faster than if samples were sent to the central laboratory.

Disposable ICU equipment includes urinary (Foley) catheters, catheters used for arterial and central venous lines, Swan-Ganz catheters, chest and endotracheal tubes, gastrointestinal and nasogastric feeding tubes, and monitoring electrodes.

Description

ICU equipment includes patient monitoring, life support and emergency resuscitation devices, and diagnostic devices.

Patient monitoring equipment

- Acute care physiologic monitoring systems are comprehensive patient monitoring systems that can be configured to measure and display various parameters, such as an electrocardiogram (ECG), respiratory rate, blood pressure (noninvasive and invasive), body temperature, cardiac output, arterial hemoglobin oxygen saturation, mixed venous oxygenation, and end-tidal carbon dioxide, via electrodes and sensors connected to the patient. Each patient bed in an ICU has a physiologic monitor, and all monitors are networked to a central nurses' station.
- Pulse oximeters measure the arterial hemoglobin oxygen saturation of the patient's blood with a sensor clipped over the finger or toe. Pulse oximetry is usually a capability included in a physiologic monitoring system, but the ICU also uses dedicated pulse oximeters for some patients.
- Intracranial pressure monitors are connected to sensors inserted into the brain through a cannula or bur hole. These devices warn of elevated pressure and record or display pressure trends. Intracranial pressure monitoring may be a capability included in a physiologic monitor.
- Apnea monitors use electrodes or sensors placed on the patient to detect cessation of breathing, display respira-

tion parameters, and trigger an alarm if a certain amount of time passes without a patient's breath being detected. Apnea monitoring may be a capability included in a physiologic monitor.

Life support and emergency resuscitative equipment

- **Ventilators** consist of a flexible breathing circuit, gas supply, heating/humidification mechanism, monitors, and alarms. They are microprocessor-controlled and programmable, and regulate the volume, pressure, and flow of patient respiration. Ventilator monitors and alarms may be interfaced to a central monitoring system or information system.
- **Infusion pumps** employ automatic, programmable pumping mechanisms to supply the patient with fluids intravenously or epidurally through a catheter. The pump is hung on an intravenous pole, which is located next to the patient's bed.
- **Crash carts**, also called resuscitation carts or code carts, are strategically located in the ICU for immediate availability when a patient experiences cardiorespiratory failure. The cart holds a defibrillator, which is used to apply an electric shock to a patient in ventricular fibrillation. Two paddles are placed on the patient's chest and buttons are pressed to discharge an electrical shock of approximately 2,000 to 4,000 volts. The cart also holds a resuscitator, which is inserted into the patient's airway, and a bag is pressed to push air into the **lungs**.
- **Intra-aortic balloon pumps** use a balloon placed in the patient's aorta to help the heart pump. The balloon is on the end of a catheter that is connected to the pump's console, which displays heart rate, pressure, and ECG readings. The patient's ECG is used to time the inflation and deflation of the balloon.

Diagnostic devices most commonly used in the ICU are mobile x-ray units, which can be pushed to the patient's bedside to take x rays using a battery-operated generator that powers an x-ray tube, and point-of-care blood analyzers, which are handheld devices that require a small amount of whole blood and display blood chemistry parameters.

Operation

The ICU is a demanding environment due to the critical condition of patients and the variety of equipment necessary to support and monitor patients. Therefore, when operating ICU equipment, staff should pay attention to the types of devices and the variations between different models of the same type of device, so as not to make an error in operation or adjustment. Although many

KEY TERMS

Apnea—Cessation of breathing.

Arterial line—A catheter inserted into an artery and connected to a physiologic monitoring system to allow direct measurement of oxygen, carbon dioxide, and invasive blood pressure.

Edema—An abnormal accumulation of fluids in intercellular spaces in the body; causes swelling.

Central venous line—A catheter inserted into a vein and connected to a physiologic monitoring system to directly measure venous blood pressure.

Chest tube—A tube inserted into the chest to drain fluid and air from around the lungs.

Endotracheal tube—A tube inserted through the patient's nose or mouth that functions as an airway and is connected to the ventilator.

Gastrointestinal tube—A tube surgically inserted into the stomach for feeding a patient unable to eat by mouth.

Nasogastric tube—A tube inserted through the nose and throat and into the stomach for direct feeding of the patient.

Ventricular fibrillation—An irregular cardiac rhythm characterized by contractions of the ventricular muscle of the heart and signaling impending cardiac arrest; treated by using a defibrillator and medications.

hospitals make an effort to standardize equipment, for example, using the same manufacturer's infusion pumps or patient monitoring systems, older devices and non-standardized equipment may still be used, particularly when the ICU is busy. Clinical staff should be sure to check all devices and settings to ensure patient safety.

ICU patient monitoring systems are equipped with alarms that sound when the patient's vital signs deteriorate, for instance, when breathing stops, blood pressure is too high or too low, or when heart rate is too fast or too slow. Usually, all patient monitors connect to a central nurses' station for easy supervision. ICU staff should be sure that all alarms are functioning properly and that the central station is staffed at all times.

For reusable patient care equipment, clinical staff should be sure to properly disinfect and sterilize devices that contact patients. Disposable items, such as catheters and needles, should be disposed of in an appropriately labeled container.

Maintenance

Since ICU equipment is used continuously on critically ill patients, it is essential that equipment be properly maintained, particularly those devices used for life support and resuscitation. ICU staff should perform daily checks on equipment and inform **biomedical engineering** staff when equipment needs maintenance, repair, or replacement. For mechanically complex devices, service and preventive maintenance contracts are available from the manufacturer or third-party servicing companies.

Health care team roles

ICU equipment is used by an ICU care team, which consists of a critical care attending physician, ICU nurses, respiratory therapists, pharmacists, physical therapists, and nutritionists. Physicians trained in other specialties, such as anesthesiology, cardiology, radiology, surgery, neurology, pediatrics, and orthopedics, may be consulted and called to the ICU to treat patients who require their expertise. Radiologic technologists perform mobile x-ray examinations (bedside radiography). Either nurses or clinical laboratory personnel perform point-of-care blood analysis. ICU equipment is maintained and repaired by the hospital biomedical engineering staff and/or the equipment manufacturer.

Some studies have shown that patients in the ICU following high-risk surgery are at least three times as likely to survive when cared for by "intensivists," physicians trained in critical care medicine.

Training

Manufacturers of more sophisticated ICU equipment, such as ventilators and patient monitoring devices, provide clinical training for all involved staff when the device is purchased. All ICU staff must have undergone specialized training in the care of critically ill patients and must be trained to respond to life-threatening situations, since ICU patients are in critical condition and may experience respiratory or cardiac emergencies.

Intestine, large

Definition

The large intestine is located in the abdominal cavity. It is the site of the last phases of digestion and consists of three segments: the cecum, the colon, and the rectum. The colon divides into ascending colon, transverse colon, descending colon, and sigmoid colon. The large intestine is called large because its diameter is considerably greater than the diameter of the **small intestine**.

Description

The large intestine is the terminal part of the **digestive system**. This important system is responsible for the ingestion and digestion of foodstuffs. Along the digestive tract, food is broken down into nutrient molecules small enough to pass into the bloodstream. Nutrient molecules are mostly absorbed in the small intestine, with the remainder being absorbed in the large intestine, which also prepares waste for elimination from the body through the anus.

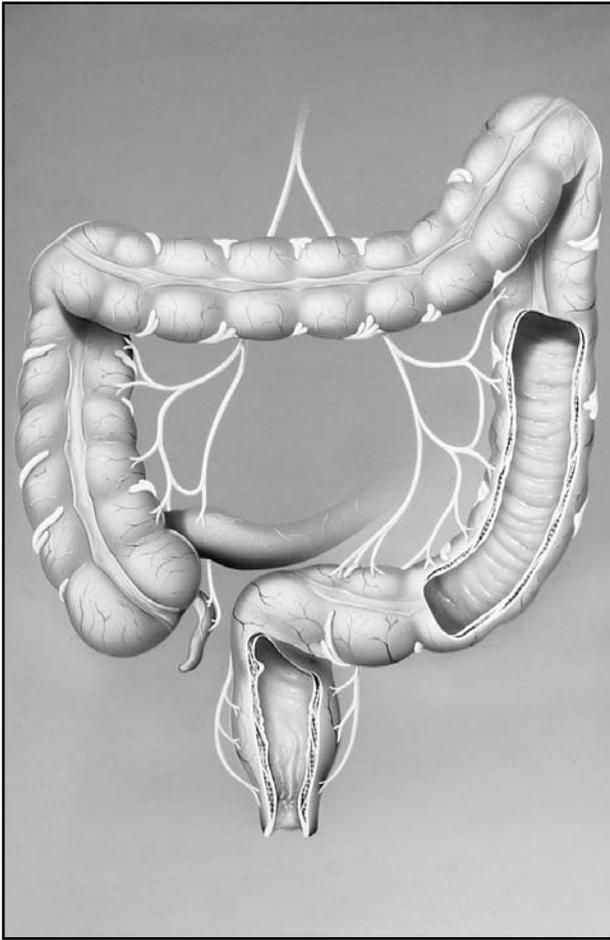

The large intestine is called the ascending colon as it starts from the cecum, which marks the end of the small intestine. The caecum contains the worm-shaped appendix. The ascending colon then passes along the right abdominal wall to the inferior surface of the **liver** and bends sharply at a right angle to the left at a curve called the hepatic flexure. At this point, it crosses the abdominal cavity, passing to the left abdominal wall and is known as the transverse colon. Under the spleen, it bends again at the splenic flexure, and is known as the descending colon, passing along the left abdominal wall to the pelvic region. The colon then forms an S-shaped curve and is called the sigmoid colon. The rectum marks the end of the colon. It is a storage site for solid waste which can then exit the body through an external opening called the anus, controlled by muscles called sphincters.

The large intestine is about 6 ft (1.8 m) long and about 2 in (5 cm) wide in the average, normal adult.

Function

The large intestine has three major functions:

- Recovery of water and essential ions. When the partially digested foodstuffs reach the end of the small intestine (ileum), roughly 80% of their water contents has been absorbed, but considerable water and small ions, such as sodium and chloride, still remain and must be recovered by further absorption. The colon then absorbs most of the remaining water and ions and additionally secretes bicarbonate ions as well as mucus, an important lubricant that protects the intestinal lining.
- Formation and storage of feces. As matter moves through the colon, it is dehydrated, mixed with **bacteria** and mucus, and formed into feces for subsequent storage and elimination. The composition of normal feces is approximately 75% water and 25% solid waste, mostly consisting of bacteria and roughage, that is, undigested protein, fat, fibers, dried digestive juices, and dead cells. Its typical brown color is due to pigments resulting from the bacterial degradation of bilirubin and fecal odor results from gases released by bacteria.

The large intestine consists of four sections: the ascending (left), transverse (top), descending (right), and sigmoid (bottom) colon. (Photograph by John Bavosi. Science Source/Photo Researchers. Reproduced by permission.)

- **Bacterial fermentation.** Fermentation refers to the enzymatic decomposition and utilization of foodstuffs by bacteria. The large intestine has a rich bacterial life that produces a wide variety of enzymes capable of fermenting many of the nutrient molecules that would otherwise not be absorbed. A normal adult harbors some 450 different species of bacteria in the colon and most of these are anaerobes, meaning bacteria that survive only in oxygen-free environments. Bacterial populations in the large intestine digest **carbohydrates, proteins, and lipids** that escape digestion and absorption in the small intestine and they also manufacture **vitamin K** and certain B vitamins.

The movement of bulk matter in the colon is referred to as large intestinal motility and it consists of four different types of muscle-assisted contractions:

- **Segmentation contractions.** These contractions mash and mix the partially digested foodstuff, exposing it to the mucous membrane where nutrient absorption occurs.
- **Peristaltic contractions.** These contractions are wave-like contractions that allow material to advance from the small intestine through the colon.
- **Antiperistaltic contractions.** These contractions occur in a backwards direction toward the ileum, so as to slow down the forward movement of matter through the colon. This provides more residence time for the absorption of nutrients.
- **Giant migrating contractions.** These contractions represent a type of motility only seen in the colon. Giant migrating contractions are a type of very intense and prolonged peristaltic contraction that can strip a large segment of colon free of contents.

Following the ingestion of food, large intestinal motility increases significantly, triggered by the duodenocolic reflex, which is stimulated by the presence of fat in the small intestine. Additionally, giant migrating contractions push feces into the empty rectum. Stretching of the rectum in turn stimulates the defecation reflex. This is a reflex controlled by the pelvic nerves, and it results in relaxation of the ring-like internal anal sphincter, the muscle that constricts or closes the anus. This is followed by voluntary relaxation of the external anal sphincter and defecation.

Role in human health

The importance of the large intestine in human health is mostly derived from its role in removing water from food residues and transporting it into the bloodstream. Along with this water, dissolved **minerals** and ions, notably sodium, potassium, and chlorine, are also transported to the bloodstream. Without these chemicals, the **blood** is chemically unbalanced, a condition that can lead to serious illness and even death.

Common diseases and disorders

- **Appendicitis.** Appendicitis is an inflammation of the appendix. It occurs due to accumulated waste material that cannot move out of the appendix easily because it only has one opening. The symptoms of appendicitis are muscular rigidity, sharp **pain** in the right lower abdomen, and vomiting.
- **Colitis.** Colitis is commonly known as irritable bowel or spastic colon. It refers to the inflammation of the inner lining of the colon. Colitis is related to **stress** and

KEY TERMS

Abdomen—A part of the body that lies between the thorax and the pelvis. It contains a cavity (abdominal cavity) that holds organs such as the pancreas, stomach, intestines, liver, and gallbladder. It is enclosed by the abdominal muscles and the vertebral column (spine).

Abdominal cavity—The hollow part of the body located between the diaphragm, which is the thin muscle below the lungs and heart, and the pelvis, the basin-shaped cavity that contains the reproductive organs, bladder, and rectum. The abdominal cavity contains the abdominal organs.

Anaerobes—Bacteria that live only in environments that are virtually oxygen-free.

Anal sphincter—The ring-like band of muscle that constricts or closes the anus.

Anus—The terminal opening of the digestive tract.

Appendix—A worm-shaped structure projecting from the cecum.

Bilirubin—A waste product from the breakdown of heme, the active group of hemoglobin, the molecule that carries oxygen in the blood. Bilirubin is produced in the liver and excreted in bile.

Cecum—The pouch-like start of the large intestine that links it to the small intestine.

Colon—Part of the large intestine, located in the abdominal cavity. It consists of the ascending colon, the transverse colon, the descending colon, and the sigmoid colon.

Digestion—The conversion of food in the stomach and in the intestines into substances capable of being absorbed by the blood.

Digestive system—Organs and paths responsible for processing food in the body. These are the mouth, the esophagus, the stomach, the liver, the gallbladder, the pancreas, the small intestine, the large intestine, and the rectum.

Feces—Waste product of digestion formed in the large intestine. About 75% of its mass is water, the remainder is protein, fat, undigested roughage, dried digestive juices, dead cells, and bacteria.

Fermentation—Enzymatic breakdown and utilization of foodstuffs by bacteria, as occurs in the large intestine.

Goblet cells—Mucus-secreting cells found scat-

tered among other cells in the epithelium of many organs, especially in the intestinal and respiratory tracts. They are most abundant in the colon.

Hepatic flexure—Sharp right-angle bend of the ascending colon under the liver as it becomes the transverse colon.

Ion—Elements consist of positively charged nuclei surrounded by negatively charged electrons. These charges are balanced and the overall charge of an element is zero. An element becomes an ion, that is a charged species, if it gains or losses electrons. Many small ions are essential for the functioning of the body. The major ones include: the potassium ion (K⁺), the sodium ion (Na⁺), the chlorine ion (Cl), and the HCO₃⁻ ion.

Large intestinal motility—Muscle-assisted contractions occurring in the colon to facilitate movement of intestinal contents. There are four type of motility: segmentation contractions, peristaltic contractions, antiperistaltic contractions and giant migrating contractions.

Large intestine—The terminal part of the digestive system, site of water recycling, nutrient absorption, and waste processing located in the abdominal cavity. It consists of the caecum, the colon, and the rectum.

Mucous membrane—The lubricated lining of several body organs that contains mucus-secreting glands.

Mucus—The slimy secretion of glands found on mucous membranes composed of various proteins, salts, and white blood cells.

Pelvis—The basin-shaped cavity located below the abdomen that contains the reproductive organs, the bladder, and rectum.

Peristalsis—A pattern of wave-like muscle contractions that allows material to advance through the digestive tube.

Peritoneum—The thin membrane that lines the abdominal and pelvic cavities, and covers most abdominal organs.

Rectum—The rectum is a short, muscular tube that forms the lowest portion of the large intestine and connects it to the anus.

KEY TERMS [CONTINUED]

Small intestine—The part of the digestive tract located between the stomach and the large intestine. It consists of the duodenum, the jejunum, and the ileum.

Splenic flexure—Sharp right-angle bend of the transverse colon under the spleen as it becomes the descending colon.

can lead to ulcerative colitis, in which open sores appear in the mucous membrane of the colon.

- **Colorectal cancers.** Colorectal cancers start in the innermost layer of the tissues of the large intestine and can grow through some or all of the layers. They can develop in any of the four sections of the colon or in the rectum.
- **Constipation.** Constipation is caused primarily by insufficient fiber in the diet, lack of **exercise**, or not drinking enough fluids. As a result, fecal matter hardens and large intestinal motility is impaired.
- **Diarrhea.** Diarrhea is a condition characterized by frequent, loose, watery stools that range from yellowish to light brown to green in color. If enough water is lost, **dehydration** occurs.
- **Diverticulosis.** Diverticulosis is characterized by outward ballooning (diverticula) of the large intestine wall caused by chronic constipation.
- **Dysentery.** Dysentery is a general term for various disorders characterized by severe diarrhea, inflamed intestines, and intestinal bleeding. Some forms of dysentery may clear up by themselves, while other forms may continue for years without treatment.
- **Hemorrhoids.** Hemorrhoids are commonly known as piles. They are dilated veins in the anus and rectum.
- **Peritonitis.** Peritonitis refers to inflammation of the peritoneum, the membrane that lines the abdominal and pelvic cavities. It can occur as a result of a ruptured appendix, which empties its contents of fecal matter and waste into the abdominal cavity. This condition is extremely serious.
- **Ptosis of the colon.** Also known as prolapsed colon, this is a common condition that occurs when the colon falls from its normal position to a lower position.

Intestine, small

Definition

The small intestine is a long coiled tube located in the abdominal cavity. It is the major site of chemical digestion and absorption of nutrients by the body and consists of three sections: the duodenum, the jejunum, and the ileum.

Description

The small intestine is the longest section of the **digestive system**. This important body system digests food by breaking it down into nutrient molecules small enough to pass into the bloodstream. Nutrient molecules are absorbed in the small intestine and sent into the **blood** circulatory system. The digestive system also eliminates solid waste, recycles water, and absorbs **vitamins** from nutrients in the large intestines. Even though some starch breakdown takes place in the mouth and some breakdown of protein is done in the **stomach**, most of the digestion occurs in the duodenum.

The small intestine is a coiled, tube-like organ held in place by two membrane sheets attached to the walls of the abdominal cavity and referred to as the mesentery. Nerves, blood and lymph vessels to and from the small

KEY TERMS

Abdomen—A part of the body that lies between the thorax and the pelvis. It contains a cavity (abdominal cavity) that holds organs such as the pancreas, stomach, intestines, liver, and gallbladder. It is enclosed by the abdominal muscles and the vertebral column (spine).

Abdominal cavity—Hollow part of the body located between the diaphragm, which is the thin muscle below the lungs and heart, and the pelvis, which is the basin-shaped cavity that contains the reproductive organs, the bladder, and the rectum. The abdominal cavity contains the abdominal organs.

Acid—Refers to a compound that is acid or sour. When dissolved in water, acids yield hydrogen ions.

Amino acids—Organic compounds containing mostly the elements carbon, nitrogen, and oxygen that combine to form peptides and proteins.

Base—Refers to a compound that is caustic (soda, lime). Bases dissolve in alcohol and in water, and can combine with fats.

Bile—A greenish yellow fluid produced by the liver and stored in the gallbladder that is secreted in the small intestine to assist in the absorption of fats.

Bile ducts—Passages external to the liver for the transport of bile.

Digestion—The conversion of food in the stomach and in the intestines into substances capable of being absorbed by the blood.

Digestive system—Organs and paths responsible for processing food in the body. These are the mouth, the esophagus, the stomach, the liver, the gallbladder, the pancreas, the small intestine, the colon (large intestine), and the rectum.

Duodenum—The first section of the small intestine, extending from the stomach to the jejunum, the next section of the small intestine.

Epithelial cells—Cells covering the surface of the body and the lining of its cavities. In the small intestine, the epithelial cells cover the villi and contain microvilli.

Epithelium—The covering of the internal and external surfaces of the body and of the lining of blood vessels and small cavities. It consists of cells joined by cementing substances.

Gastric juice—An acidic secretion of the stomach

that breaks down the proteins contained in the ingested food, prior to digestion.

Gland—An organ that produces and releases substances for use in the body, such as fluids or hormones.

Ileum—The last section of the small intestine located between the jejunum and the large intestine.

Jejunum—The section of the small intestine located between the duodenum and the ileum.

Lymph—Colorless liquid that bathes body tissues and circulates in the lymph vessels.

Mesentery—The membrane that connects the jejunum and the ileum to the abdominal cavity walls.

Mucosal folds—Mucosal folds are circular folds found on the inner surface of the small intestine. They increase surface area and help mix the partially broken down foods by acting as baffles.

Mucous membrane—The lubricated lining of several body organs that contains mucus-secreting glands.

Mucus—Slimy secretion of glands found on mucous membranes composed of various proteins, salts, and white blood cells.

Pancreas—The pancreas is a flat, glandular organ lying below the stomach. It secretes the hormones insulin and glucagon that control blood sugar levels and also secretes pancreatic enzymes in the small intestine for the breakdown of fats and proteins.

Peritoneum—Thin membrane that lines the abdominal and pelvic cavities and covers most abdominal organs.

Pylorus—The opening from the stomach into the small intestine.

Small intestine—The part of the digestive tract located between the stomach and the large intestine.

Villi intestinales—Microscopic hair-like structures covered with epithelial cells measuring 1–1.5 mm that line the mucous inner membrane of the small intestine. The epithelial cells of the villi contain microvilli and are responsible for the absorption of nutrients. Being so small and numerous, they effectively increase the absorptive surface area of the small intestine.

intestine lie between the two sheets of the mesentery. In the adult, the small intestine measures on average about 22 ft (6.7 m) with a diameter of 1–2 in (2.5–5 cm). It consists of three segments: the short duodenum, the jejunum, which represents 40% of the small intestine, and the terminal ileum, which accounts for the remaining 60% and which empties into the **large intestine**. The small intestine thus forms a passage going from the pylorus (opening from the stomach) to the large intestine.

The inner mucous membrane of the small intestine is not flat and uniform but folded to such a great extent that its inner lining is referred to as the mucosal folds. The mucosal folds are covered with approximately 20,000 tiny hair-like projections called villi that are lined with epithelial cells studded with microvilli. One villus contains about 500 microvilli and in one square inch of small intestine, there are some ten billion microvilli.

Function

Together, the intestines process 2–3 gal (7.6–11.4 l) of food, liquids, and bodily waste every day. The small intestine is the major site of absorption of almost all nutrients into the blood.

The stomach delivers foodstuffs to the duodenum that it has reduced to a liquid pulp with gastric juices, called the chyme, for further breakdown. The duodenum also receives pancreatic enzymes from the **pancreas** and bile from the **liver** via the pancreatic and common bile ducts. The pancreatic enzymes are required for the chemical breakdown of **fats**, sugars, and **proteins**, and the bile plays an important role in the absorption of fats. To assist the process, the villi sway constantly so as to stir up the chyme for nutrient removal and transport across their membranes into the blood and lymph vessels. The fatty molecules are transferred to the lymph, while sugar (glucose) and amino acids go into the blood and are carried to the liver. The muscles that encircle the small intestine constrict about seven to twelve times a minute to shake, knead, and mix the chyme with its secretions and the gastric juices of the stomach. The small intestine also absorbs enormous quantities of water. Normal water intake for an adult is about 0.5 gal (2 l) of dietary fluid per day. An additional 1.6–1.8 gal (6–7 l) of fluid is delivered to the small intestine by secretions from salivary glands, stomach, pancreas, liver, and its own secretions. Of these 2.1–2.3 gal (8–9 l), the small intestine absorbs 80% on a daily basis.

The absorption of nutrients across the epithelial cell boundary of the small intestine is made possible by maintaining a “sodium electrochemical gradient.” The interior of all cells maintains a low concentration of sodium. The epithelial cells lining the small intestine (enterocytes)

achieve this using a large number of enzymes (Na_+/K_+ ATPases), called sodium pumps. These pumps export sodium ions from the cell in exchange for potassium ions, thus establishing a gradient of both charge and sodium concentration across the cell membrane that facilitates transport. This constant flow of sodium is ultimately responsible for the absorption of water, amino acids, and **carbohydrates** by the small intestine. It is known that each intestinal enterocyte has some 150,000 such sodium pumps, which allow each cell to transport about 5 billion sodium ions out of each cell per minute.

Role in human health

The passage of foodstuffs through the small intestine results in the absorption of most of the water and electrolytes (sodium, chloride, potassium) as well as almost all nutrient molecules, such as glucose, amino acids, and fatty acids. The small intestine not only provides the nutrients required for the functioning of the body, but also plays a critical role in water and acid-base equilibrium. Acid-base equilibrium refers to a condition by which the net rate of acid or base production by the body is balanced by the net rate of acid or base elimination from the body, resulting in stable amounts of hydrogen ions in body fluids.

Common diseases and disorders

The common diseases and disorders of the small intestine include:

- **Adenocarcinoma.** Adenocarcinomas are cancers of the gland cells that line the small intestine. They tend to occur in the duodenum.
- **Adenomas.** Adenomas are non-cancerous gland cell tumors often found in the intestinal villi.
- **Atresia of small intestine.** Atresia of the small intestine is characterized by the absence or closure of parts of the small intestine. Duodenal atresia is diagnosed in 1:5,000 live births and is frequently associated with **Down syndrome**. Jejuno-ileal atresia occurs less frequently (1:1,500 to 1:20,000 live births).
- **Carcinoid tumors.** Carcinoid tumors develop from the neuroendocrine cells that are found in the numerous secretions entering the intestine. About 2,500 carcinoid tumors are diagnosed each year in the United States and they account for about one-third of all tumors that develop in the small intestine and appendix.
- **Crohn’s disease.** Crohn’s disease causes inflammation in the small intestine. It usually occurs in the ileum.
- **Cytomegalovirus (CMV).** CMV is a herpes-type virus that can infect the epithelial cells of the small intestine.

- Duodenal ulcer. Gastric and duodenal ulcers afflict approximately 4 million people in the United States. They are associated with **alcoholism**, chronic lung and kidney disease, and thyroid disorders.
- Dysentery. Dysentery is a general term for various disorders characterized by severe **diarrhea**, inflamed intestines, and intestinal bleeding. Some forms of dysentery may clear up by themselves while other forms may continue for years without treatment.
- Protein-losing enteropathy. Disease of the small intestine characterized by excessive loss of plasma proteins.
- Gastrointestinal stromal tumor (GIST). GIST is most commonly diagnosed in the muscular wall of the jejunum and ileum.
- Gluten sensitive enteropathy. Disease of the small intestine characterized by impaired absorption of nutrients due to loss of villi because of an adverse immune reaction to gluten, a protein found in wheat and other related foods.
- Small intestinal hemorrhages. The major causes of small intestinal hemorrhage are infections, vascular anomalies, and bleeding disorders.
- Small intestinal infarction. Small intestinal infarction is caused by the partial or complete obstruction to blood flow. It usually occurs in people over age 50–55.

Intracranial ultrasound see **Ultrasonic encephalography**

Intradermal injections

Definition

Intradermal injections are injections given to a patient in which the goal is to empty the contents of the syringe between the layers of the skin.

Purpose

Intradermal injection is often used for conducting skin **allergy tests** and testing for antibody formation.

Precautions

This is a painful procedure and is used only with small amounts of solution. The nurse should ensure that the needle is inserted into the epidermis, not subcutaneously, as absorption would be reduced. It is imperative that the following information is reviewed prior to administration of any medication: the right patient, the right medicine, the right route, the right dose, the right site, and the right time. Because this method of injection is often used in allergy testing, it is important that latex-free syringes are used.

Description

With the intradermal injection, a small thin needle of 25 or 27 gauge and 3/8 to 3/4 inch (1-2 cm) is inserted into the skin parallel with the forearm, with the bevel facing upward. These injections are normally given in the inner palm-side surface of the forearm, with the exception of the human diploid cell rabies vaccine, which is given in the deltoid muscle.

Preparation

After washing his or her hands, the nurse should put on latex-free gloves to complete the procedure. A sterile syringe and a needle should be prepared. If a sterile multiple-dose vial is used, the rubber-capped bottle should be rubbed with an antiseptic swab. The needle is then inserted through the center of the cap, and some air from the syringe inserted to equalize the pressure in the container. Slightly more of the required amount of drug is should then be removed. The syringe should be held vertically at eye level, then the syringe piston should be pushed carefully to the exact measurement line.

If a small individual vial containing the correct amount of drug is used, the outside should be wiped with an antiseptic swab and held in the swab while the top is snapped off. The needle is then inserted into the vial, tak-

Skin must be spread taut for an intradermal injection.
(Delmar Publishers, Inc. Reproduced by permission.)

ing care that the tip of the needle does not scratch against the sides of the vial, thereby becoming blunt.

The **syringe and needle** containing the drug should be placed on a tray with sterile cotton swabs and cleaning disinfectant. If the patient is unfamiliar with the procedure, the nurse should explain what he or she is about to do, and let the patient know that the medication was prescribed by the doctor. As with all drugs prescribed for a patient, the dose on the patient's prescription sheet should be checked prior to administration.

A screen should be drawn around the patient to ensure privacy. The injection site is then rubbed vigorously with a swab, and disinfectant applied to cleanse the area and increase the **blood** supply. With the bevel of the needle facing upwards, the needle is inserted into the skin, parallel with the forearm. The syringe piston should then be pushed in steadily and slowly, releasing the solution into the layers of the skin. This will cause the layers of the skin to rise slightly.

Aftercare

Monitor the patient's reaction and provide reassurance, if required. Dispose of all waste products carefully and place the syringe and needle in a puncture-resistant receptacle.

Complications

If the circulation is depleted, absorption of the drug administered may be slow.

Results

Check for any adverse reactions if the drug is being administered for the first time.

KEY TERMS

Bevel—The flat aperture on one side of a needle at the tip.

Deltoid muscle—A large muscle covering the shoulders.

Sterile—Free from living microorganisms.

Subcutaneous—Beneath the skin.

Health care team roles

As this procedure is often used as a diagnostic tool, the process should be explained fully to the patient.

The health care team should record any side effects or negative reactions to the drug that has been injected; medical staff should be notified.

Intramuscular injection

Definition

An intramuscular injection is an injection given directly into the central area of a specific muscle. In this

Angles of insertion for injections. (Delmar Publishers, Inc. Reproduced by permission.)

way, the **blood vessels** supplying that muscle distribute the injected medication via the **cardiovascular system**.

Purpose

Intramuscular injection is used for the delivery of certain drugs not recommended for other routes of

administration, for instance intravenous, oral, or subcutaneous. The intramuscular route offers a faster rate of absorption than the subcutaneous route, and muscle tissue can often hold a larger volume of fluid without discomfort. In contrast, medication injected into muscle tissues is absorbed less rapidly and takes effect more

slowly that medication that is injected intravenously. This is favorable for some medications.

Precautions

Careful consideration in deciding which injectable route is to be used for the prescribed medication is essential. The intramuscular route should not be used in cases where muscle size and condition is not adequate to support sufficient uptake of the drug. Intramuscular injection should be avoided if other routes of administration, especially oral, can be used to provide a comparable level of absorption and effect in any given individual's situation and condition. Intramuscular injections should not be given at a site where there is any indication of **pain**.

Description

Intramuscular (IM) injections are given directly into the central area of selected muscles. There are a number of sites on the human body that are suitable for IM injections; however, there are three sites that are most commonly used in this procedure.

Deltoid muscle

The deltoid muscle located laterally on the upper arm can be used for intramuscular injections. Originating from the Acromion process of the scapula and inserting approximately one-third of the way down the humerus, the deltoid muscle can be used readily for IM injections if there is sufficient muscle mass to justify use of this site. The deltoid's close proximity to the radial nerve and radial artery means that careful consideration and palpation of the muscle is required to find a safe site for penetration of the needle. There are various methods for defining the boundaries of this muscle.

Vastus lateralis muscle

The vastus lateralis muscle forms part of the quadriceps muscle group of the upper leg and can be found on the anteriolateral aspect of the thigh. This muscle is more commonly used as the site for IM injections as it is generally thick and well formed in individuals of all ages and is not located close to any major arteries or nerves. It is also readily accessed. The middle third of the muscle is used to define the injection site. This third can be determined by visually dividing the length of the muscle that originates on the greater trochanter of the femur and inserts on the upper border of the patella and tibial tuberosity through the patella ligament into thirds.

Palpation of the muscle is required to determine if sufficient body and mass is present to undertake the procedure.

Gluteus medius muscle

The gluteus medius muscle, which is also known as the ventrogluteal site, is the third commonly used site for IM injections. The correct area for injection can be determined in the following manner. Place the heel of the hand of the greater trochanter of the femur with fingers pointing towards the patient's head. The left hand is used for the right hip and vice versa. While keeping the palm of the hand over the greater trochanter and placing the index finger on the anterior superior iliac spine, stretch the middle finger dorsally palpating for the iliac crest and then press lightly below this point. The triangle formed by the iliac crest, the third finger and index finger forms the area suitable for intramuscular injection.

Determining which site is most appropriate will depend upon the patient's muscle density at each site, the type and nature of medication you wish to administer, and of course the patient's preferred site for injections.

Preparation

Before **administering medication**, a health care practitioner verify the medication order for accuracy and prepare the medication from the vial or ampule.

- First, ensure you have identified the patient and assist them into a position which is comfortable and practical for access to the injection site you have chosen.
- Locate the correct area for injection using the above guidelines or those taught during medical training. Clean the site with an alcohol swab or other cleansing agent.
- Prepare the syringe by removing the needle cover, inverting the syringe, and expelling any excess air. Approximately 0.1–0.2 ml of air should be left in the syringe so that the air in the top of the syringe chamber, when the **syringe and needle** are pointing down, forces the entire amount of medication to be delivered. This also prevents medication residue from being left in the needle, where it can leak into the subcutaneous and dermal layers when the syringe and needle are removed from the muscle.
- When ready to inject, spread the skin using the fingers of the non-dominant hand. Holding the syringe with the thumb and forefinger of the dominant hand, pierce the skin and enter the muscle. This process should be done quickly with sufficient control so as to lessen the discomfort of the patient. If there is little muscle mass, particularly in infants or the elderly, then you may need

to pinch the muscle to provide more volume of tissue in which to inject.

- Aspirate at the injection site (while syringe and needle are within the muscle) by holding the barrel of the syringe with the non-dominant hand and pulling back on the syringe plunger with the dominant hand. If **blood** appears in the syringe, it is an indication that a blood vessel may have been punctured. The needle and syringe should be immediately withdrawn and a new injection prepared. If no blood is aspirated, continue by slowly injecting the medication at a constant rate until all medication has been delivered.
- Withdraw the needle and syringe quickly to minimize discomfort. The site may be briefly massaged, depending on the medication given. Some medication manufacturers advise against massaging the site after injection, as it reduces the effect and intention of the medication by dispersing it too readily or over too large an area. Manufacturers' recommendations should be checked.
- Discard the used syringe and needle intact as soon as possible in an appropriate disposal receptacle.
- Check the site at least once more a short time after the injection to ensure that no bleeding, swelling or any other signs of reaction to the medication are present. Monitor the patient for other signs of side effects, especially if it is the first time the patient is receiving the medication.
- Document all injections given and any other relevant information.

Aftercare

Monitor for signs of localized redness, swelling, bleeding, or inflammation at injection site. Observe the patient for at least 15 minutes following the injection for signs of reaction to the drug.

Complications

Most complications of intramuscular injections are a result of the drug injected and not the procedure. However, it is possible that localized trauma of the injection site may result as part of the process. Minor discomfort and pain is common for a short period following the injection, but usually resolves within a few hours.

Results

The optimal outcome is a situation in which the medication is safely and effectively delivered to the patient via intramuscular injection without signs of com-

A doctor gives a vaccine by intramuscular injection.

plications or discomfort. Safety for the health care provider is also paramount.

Health care team roles

The health care provider is obliged to undertake the following when administering an intramuscular injection:

- Inform and educate the patient on the need and effect of the medication being delivered.
- Ensure the correct identification and verification procedures are followed.
- Provide privacy for the patient during the procedure.
- Understand the theory behind selecting appropriate injection sites.
- Demonstrate correct technique when undertaking the procedure.
- Monitor for complications.

- Document all relevant information and ensure safe disposal of equipment.

Intraoperative care

Definition

The term “intraoperative” refers to the time during surgery. Intraoperative care is patient care during an operation and ancillary to that operation.

Activities such as monitoring the patient’s **vital signs**, **blood** oxygenation levels, fluid therapy, medication transfusion, anesthesia, radiography, and retrieving samples for laboratory tests, are examples of intraoperative care. Intraoperative care is provided by nurses, anesthesiologists, nurse anesthetists, surgical technicians, surgeons, and residents, all working as a team.

Purpose

The purpose of intraoperative care is to maintain patient safety and comfort during surgical procedures. Some of the goals of intraoperative care include maintaining homeostasis during the procedure, maintaining strict sterile techniques to decrease the chance of cross-infection, ensuring that the patient is secure on the operating table, and taking measures to prevent hematomas from safety strips or from positioning.

Precautions

Patients undergoing surgery most often are given some type of anesthesia. The administration of **general anesthesia** has a relaxing effect on the patient’s body, which can suppress cardiovascular function or heighten cardiovascular irritability. It may also result in respiratory depression, loss of consciousness, **paralysis**, and lack of sensation. These effects, some of which are intentional for the period of the surgery, mean the patient is in a very vulnerable position. It is the responsibility of the

health care team in the operating room to maintain the patient’s safety and yet facilitate surgery.

In 1992 the American Association of Nurse Anesthetists (AANA) established guidelines for monitoring patients undergoing general anesthesia. The guidelines call for continuous observation of the patient by the nurse assigned to the patient. Ventilation should be assessed by continuous auscultation of breath sounds, and oxygenation should be monitored by continuous pulse oximetry. Continuous electrocardiograph (ECG) showing the patient’s cardiac function should be in place, and the patient’s **heart** rate and **blood pressure** should be monitored at least every five minutes. A means to monitor the patient’s temperature must be available immediately for use. In case of an emergency backup personnel who are experts in **airway management**, emergency intubation, and advanced cardiac life support (ACLS) must be available. An emergency cart containing the necessary supplies and equipment must be immediately accessible. The ACLS equipment should be checked daily to ensure proper function.

Total analgesia is a goal of general anesthesia in order to facilitate surgery. This means that the patient does not have the normal “pain” sensations that warn of potential injury. The health care team must keep this in mind when they are positioning the patient for a surgical procedure. Although it may be necessary for a patient to be positioned in an unusual way for access to a particular area during surgery, care must be taken to ensure that the patient’s body is in proper alignment and that joints and muscles are not in such an unnatural position that they will be damaged if they remain in that position for a lengthy procedure. Areas of the operating table that come into contact with the patient’s bony prominences must be padded to prevent skin trauma and hematomas.

During a surgical procedure many instruments, drapes, and sponges are used. Also, a multitude of care providers may be working in the operative field performing different tasks. These factors, combined with the complexity and length of some surgical procedures, may provide extensive opportunity for patient trauma from equipment malfunction or the failure of the surgical team to avoid using full weight on the sedated patient. Additionally, it is the responsibility of the nurses working in the operating room to maintain an accurate count of all sponges, instruments, and sharps that may become **foreign bodies** upon incision closure. Nurses who fail to make accurate counts can be held legally liable.

Most surgical procedures are invasive and compromise a patient’s skin integrity. This increases the risk of

infection. To decrease the risk, strict asepsis (sterile technique) must be followed at all times. It is recommended that the ventilation system in an operative area provide a minimum of fifteen exchanges of filtered air per hour. The temperature in the intraoperative area should be maintained at 68–73°F (20–23°C), and the relative humidity should be maintained at 30%–60%. Health care personnel who work in the operating room must not be permitted to work if they have open lesions on the hands or arms, eye infections, **diarrhea**, or respiratory infections. Scrub attire must be worn by all personnel entering the operating room. Fresh scrub attire must be donned daily and, if heavily soiled during one case, should be changed before the next case. Most facilities provide personnel with scrub attire that is professionally laundered. Shoe covers are required and should be changed often. Head and facial hair must be completely contained in a lint-free cap or hood. Properly fitting disposable surgical masks must be worn at all times and discarded immediately after use. Sterile gloves and sterile gowns must be worn by those working in, and in proximity to, the sterile field. Careful skin preparation with appropriate antiseptic solutions is preformed on the patient's arrival to the operating area.

Patients who have a known or suspected allergy to latex should be scheduled for surgery as the first case of the day whenever possible to avoid contact with airborne latex particles (often attached to powder granules from the gloves) that may be in the room from a previous surgery. These patients should also be identified (some facilities use special colored identification bands and colored tapes on the patient's medical record) so that all health care personnel can recognize them. Special care must be taken to limit the uses of equipment containing latex that will contact the patient's skin. This includes anesthesia masks, adhesive tape and dressings, injections drawn from multidose vials with rubber stoppers, adhesive ground plates for electrocautery or diathermy, and pad coverings on the operating table and arm extensions.

Description

Intraoperative care includes the activities performed by the health care team during surgery that ensure the patient's safety and comfort, implement the surgical procedure, monitor and maintain vital functions, and document care given. The intraoperative time period can vary greatly from less than one hour to 12 hours or more, depending on the complexity of the surgery being performed.

Preparation

Prior to surgery the patient or legal guardian must have the surgical procedure explained to them in great detail, including the expected outcomes and all possible complications, in order to give **informed consent**. The explanation should be given to the patient at a time when he or she is relaxed, but when judgment is not clouded by the use of any **pain** medication or anesthesia, which would invalidate the consent. A consent form must be signed by the patient or guardian and witnessed by a staff member as well as the surgeon performing the procedure. It is the duty of the RN admitting the patient to the surgical suite to check the patient's ID band and ensure that all records are intact and accounted for.

After consent is given the patient may be taken to a holding area where a large-bore intravenous catheter is inserted into the patient's arm for use in fluid replacement and to infuse medications during the procedure. The area of the body where the incision will be made is meticulously prepared using drapes, and a skin preparation that is antiseptic and may include the use of alcohol solutions and iodophor. Monitoring devices such as continuous ECG nodes, pulse oximetry probes, and a blood pressure cuff are usually applied prior to skin preparation. Anesthesia, also, is begun before skin prep. Surgery is then ready to begin.

Aftercare

The time after surgery is referred to as the postoperative period and includes the recovery and convalescence phases. The recovery phase is the time immediately after surgery when the effects of anesthesia are wearing off and the patient is waking up. The convalescence phase is spent either in the hospital, in an interim care facility, or at home—depending on the procedure and the preferences of the physician and patient.

Complications

Intraoperative complications are surgery related, anesthesia related, or position related. One complication occurring during the intraoperative period that is not common but can be life threatening is an anaphylactic (allergic) reaction to anesthesia. The intraoperative staff is trained extensively in the treatment of such a reaction, and emergency equipment should always be available in the event it is needed for this purpose. Another anesthesia-related complication is called "awareness under anesthesia." This occurs when the patient receives sufficient muscle relaxant (paralytic agent) to prohibit voluntary motor function but insufficient sedation and analgesia to block pain and the sense of **hearing**. Patients are aware

KEY TERMS

Anaphylactic reaction (anaphylaxis)—A hypersensitive reaction to an antigen resulting in life-threatening, progressive symptoms.

Anesthesia—A classification of medications that are intended to cause the loss of normal sensation.

Aseptic technique—Strict sterile procedures instilled to decrease the risk of contamination of a surgical site or open wound.

ECG—Abbreviation for electrocardiograph. Electro-cardiograph is a tracing of the electrical activity of the heart obtained through electrodes placed on a person's skin in certain areas where electrical activity can be easily be detected.

Hypovolemic shock—A state of shock caused by the sudden loss of large amounts of blood.

Informed consent—Written or oral permission given by a patient or guardian for medical or surgical treatment after a complete explanation is given and any questions the patient has are answered. If consent is given orally, documentation must have two witnesses.

Intraoperative care—Care provided to a patient during surgery that is ancillary to the surgery.

Malignant hyperthermia—A chain reaction triggered in susceptible people by commonly used general anesthetics. Signs include greatly increased body metabolism, muscle rigidity, and eventual hyperthermia which may exceed 110°F (43.3°C). Death may be caused by cardiac arrest, brain damage, internal hemorrhage, or failure of other body systems.

Pulmonary function tests—Tests used to determine ventilation and perfusion capabilities of the lungs.

Pulse oximetry—A method of measuring a patient's blood oxygenation status. A measure of 100% is optimal.

of being “awake” because they hear the sounds and conversation in the room and, in some cases, can feel the pain associated with the skin incision and surgery. However, they cannot respond to these sensations in a way—not even with so small a motion as blinking the eyelid—that will tell someone what they are sensing. This condition creates an exaggerated fear response that can affect hemodynamics and vital signs. Another com-

plicating reaction may be that of malignant hyperthermia. This is a chain reaction triggered in susceptible people by commonly used general anesthetics. Signs include greatly increased body **metabolism**, muscle rigidity, and eventual hyperthermia which may exceed 110°F (43.3°C). Death may be caused by cardiac arrest, **brain** damage, internal hemorrhage, or failure of other body systems.

Complications of surgery include, but are not limited to, hypovolemic **shock** (due to blood loss during surgery), injuries from poor positioning during surgery, infection of the surgical wound, fluid and electrolyte imbalances, aspiration **pneumonia**, blood clots, and paralytic ileus (paralysis of the intestines, causing distention).

Results

The results of a surgical procedure depend greatly on the procedure performed, the skill of the surgeon, the general health of the patient preoperatively, and the ability of the patient's body to recover from the procedure. Some surgeries cure a condition (e.g., an appendectomy for an inflamed appendix). Others are only one step in a long process to cure a disease or repair an injury (e.g., discectomy for a patient suffering from back pain). Still others are performed as palliative measures rather than as a cure. An example of palliative surgery would be the removal of a metastatic abdominal tumor to relieve abdominal pressure. In this example removing the abdominal tumor is not going to cure the **cancer** that exists in other parts of the patient's body; it is simply going to relieve the discomfort caused by the abdominal mass.

Health care team roles

Nurses may fill two different roles in the operating room. The scrub nurse is responsible for providing the surgeon with instruments and supplies and maintaining the sterile field. This role also may be assumed by a scrub or surgical technician. The second role nurses have in the operating room is that of circulating nurse. The circulating nurse is first the patient's advocate, with primary concern and responsibility for the patient's safety and welfare. In addition, the circulating nurse is responsible for anything related to the patient that is not directly contingent to the sterile field. That means all activities necessary to prepare the patient and the operative site for surgery, and assistance required by anesthesia personnel. Of crucial import is that the circulating nurse must be certified to give intravenous medication to the patient in case of an emergency. Finally, nurses must document and process tissue specimens for pathology.

Intravenous fluid regulation

Definition

Intravenous (IV) fluid regulation refers to the manual or automatic pump control of the rate of flow of IV fluids as they are delivered to a patient through a vein.

Purpose

The purpose of intravenous fluid regulation is to control the amount of fluid that a patient is receiving, usually within a given hour of IV therapy. Without fluid regulation, the IV would run in by gravity at a rapid rate and could cause fluid or drug overload.

Precautions

There are varied types of IV administration sets, and they deliver fluid at different amounts per drop. Nurses should always determine the type of drip chamber that they are using and calculate the IV flow per minute based upon the amount of fluid that the administration set delivers per drop.

There are varied types of IV pumps and IV tubing used to deliver IV fluids. Nurses should be sure to use the correct tubing for the pump selected. The specific directions for the use of each individual pump should be followed.

Description

Manual regulation of IV fluids is performed by adjusting the roller adaptor on the IV tubing until it reaches the appropriate drip rate per minute. To manually regulate the IV rate, the nurse looks at her watch and times the number of drops that fall into the drip chamber over one full minute. If the rate is too slow, the adapter should be rolled to a looser position to speed the dripping of the IV. If the rate is too fast, the roller adapter should be tightened to decrease the dripping of the IV. Nurses should adjust the roller until the IV rate is set at the correct amount of drops per minute to deliver the IV fluids as ordered. The IV rate must be checked every hour or more often according to the policy of the medical setting to be certain that the rate remains accurate.

To regulate the IV fluid to be delivered by an IV pump, the tubing should be threaded into the machine correctly. Nurses should dial in the hourly IV rate (cc to be delivered over an hour) and start the pump following the manufacturers guidelines. IVs must be checked hourly when on a pump to be sure that the rate remains accurate and that the correct amount of fluid is delivered. Most pumps have a reading that shows how much fluid has been delivered over the past hour.

Preparation

The physicians order for IV therapy should be reviewed. An IV therapy order will include the type of IV fluid to be delivered over a specific amount of time. Some physicians will order IV therapy in terms of an hourly rate. (Example: Lactated Ringers IV, run at 125 cc/hour.) More commonly the physician will order IV therapy in terms of eight, 12, or 24 hour time periods. (Example: One liter of D5W IV over the next eight hours.)

If the fluid is ordered by the shift (every eight hours) or for a 24-hour period, the first calculation must be to

KEY TERMS

Diaphoresis—Profuse sweating.

Phlebitis—An inflammation of a vein.

Tachycardia—A condition where the heart rate is faster than normal, usually over 100 beats a minute in an adult.

determine how much fluid is ordered per hour. This can be determined by dividing the total amount of fluid by the total time ordered for delivery. For example, if the doctor ordered 1000 cc to be given over eight hours, divide the 1000 cc by the time (eight hours) to obtain the rate per hour. The hourly rate for the IV would be 125 cc for each hour. Another example would be that the doctor orders 3 liters of IV fluid to be given over 24 hours. Divide 3 liters (3000 cc) by the time (24 hours) to obtain the hourly rate of 125 cc per hour. When using an IV pump, the only calculation needed is the rate per hour because IV pumps when set will deliver an hourly rate of IV fluid automatically. The machine does the calculation and drip control. Nurses should be sure to select the specific tubing that the manufacturer recommends for use with each pump.

When not using an automatic IV pump, an administration set should be selected, and the nurse should look on the packaging for the calibration of the drip rate. Standard IV administration sets have a drip factor of 10, 15, or 20 drops/cc. A microdrip or minidrip administration set has a drip factor of 60 drops/cc and is used primarily for low IV rates, such as those used for pediatric clients. The calibration of the administration set must be known in order to calculate the flow of the IV fluids correctly.

The next step is to convert the drops per hour into drops per minute so that the nurse can literally count the drops delivered each minute to set the IV flow. To calculate the drops per minute, the drip factor of the administration set must be used. The nurse should divide the number of ccs to be delivered per hour by the number of minutes in an hour (60) and multiply by the drip factor of the IV administration set to find the drops per minute. For example, if the patient should receive 125 cc per hour using a set that delivers 10 drops/cc, the nurse would multiply the fraction $125/60$ times 10 to get a drip rate per minute of 20.8 drops/minute. The number should be rounded to 21 drops per minute. Another example would be if the patient should receive 150 cc per hour using a set that delivers 20 drops/cc, the nurse would multiply the fraction $150/60$ times 20 to get a drip rate of 50 drops

per minute. The easiest calculation is using an administration set that delivers 60 drops/cc, because the drops and the minutes cancel each other out. For example, to give 50 cc/hr using a 60 drops/cc administration set, the fraction $50/60$ should be multiplied by 60 to get a drip rate per minute of 50. Once the drip rate per minute is determined, the flow of the IV is ready to be regulated according to the doctor's order.

Aftercare

Regulating IV fluid is an ongoing process from the time that an IV is started until it is completed. Hourly checks of an IV should include assessing the client's response to the IV, the rate of the IV flow, how much fluid has infused, how much fluid remains to be infused, and the condition of the IV insertion site. Adjust the rate if the IV is not flowing at the rate that was ordered. If IV fluid is flowing in slowly, the nurse should check for a kink in the tubing or a positional problem. In addition, the IV could be out of the vein, or a small clot, phlebitis, or **infection** at the site could be slowing the IV down. If an IV is flowing too rapidly, it may be leaking out around the IV insertion site or may run faster when the patient extends the extremity. The whole system, from the insertion site to the IV bag, should be examined. The physician will assess IV fluid needs and reorder IV therapy daily according to client needs.

Complications

Circulatory overload can occur if an IV is not regulated and IV fluids infuse too rapidly for the patient's body to handle. Signs of fluid overload include tachycardia, elevated **blood pressure**, headache, **anxiety**, wheezing or other signs of respiratory distress, diaphoresis, restlessness, distended neck veins, or chest **pain**. If these signs occur, slow the IV rate and contact the physician.

Sluggish IV flow or mechanical failure can also occur, which results in the IV fluid not being delivered as ordered. The sign of sluggish IV flow is an IV rate that is persistently behind in spite of constant regulation. Sluggish IV flow can be caused by kinked tubing; small clots, phlebitis, or infection at the site; infiltration of the IV cannula; or a problem with the needle leaning against the wall of the vessel and cutting off IV flow. If the problem is not positional or equipment related, the IV will need to be restarted in a new vein in order to deliver the IV therapy safely and effectively.

Results

IV fluids when regulated to flow according to the physicians orders have positive therapeutic effects such

as rehydration, restoration of **electrolyte balance**, restoration of **acid-base balance**, replacement of **vitamins, proteins**, and calories, and safe rapid medication administration.

Health care team roles

IV fluid regulation is delegated to registered nurses in most medical settings. Paramedics, LPNs, and IV team technicians who have received special IV training may regulate IV flow rates according to the policies in some medical settings. Patients and their families can be trained to use IV therapy in the home setting. The equipment for home IV therapy, however, will usually include a pump that automatically controls the IV rate. This setting is usually locked so that it cannot be accidentally altered. Patients are taught the signs of complications and learn to trouble-shoot IV alarms. IV nurses visit daily or every few days to change the IV tubing and are on-call to assist the patients and their families 24 hours a day when problems arise.

Intravenous medication administration

Definition

Intravenous (IV) medication administration refers to the process of giving medication directly into a patient’s

vein. Methods of administering IV medication may include giving the medication by rapid injection (push) into the vein using a syringe, giving the medication intermittently over a specific amount of time using an IV secondary line, or giving the medication continuously mixed in the main IV solution. IV medications are most often given through a peripheral line or saline IV lock, but may also be administered direct IV, through an implanted vascular access port or through a central line.

Purpose

The primary purpose of giving IV medications is to initiate a rapid systemic response to medication. It is one of the fastest ways to deliver medication. The drug is immediately available to the body. It is easier to control the actual amount of drug delivered to the body by using the IV method and it is also easier to maintain drug levels in the **blood** for therapeutic response. The IV route for medication administration may be used if the medication to be delivered would be destroyed by digestive enzymes, is poorly absorbed by the tissue, or is painful or irritating when given by intra-muscular (IM) or subcutaneous (SQ) injection.

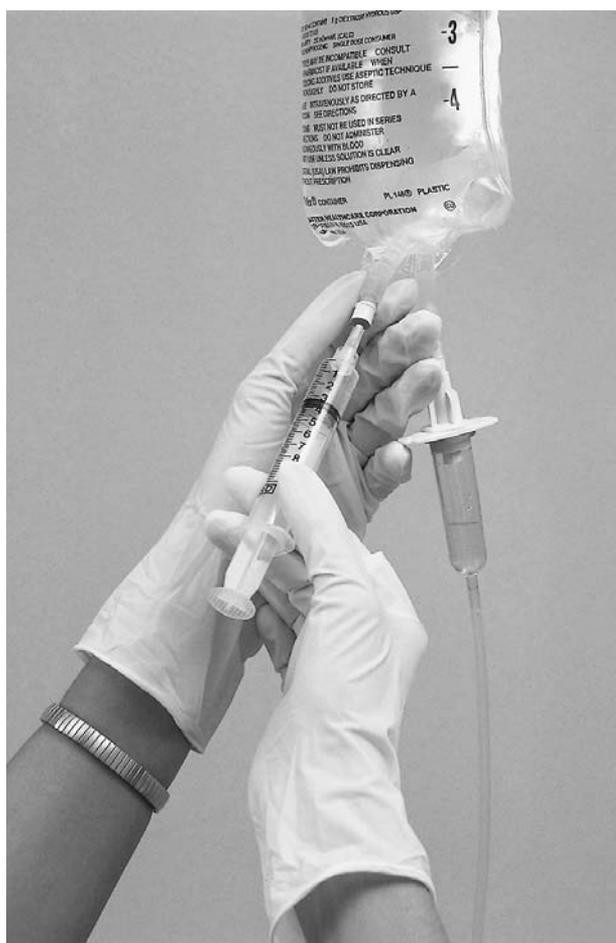

Precautions

Proper IV administration should follow the five “rights” of medication administration to avoid medication errors: be sure it is the right patient, the right drug, the right dose, the right time, and the right route before giving any medication.

The IV line must be intact before any IV medication can be administered. Some IV medications can cause severe tissue damage if injected into the tissue through an infiltrated IV site.

Some IV push medications must be diluted before injection. The health care professional must check the directions for giving the specific drug IV before performing the injection. Administration guidelines for giving IV medications must be followed to avoid serious complications from the drug injection. Most medical settings have an approved IV drug list and instructions for injecting each drug IV. Other resources include the PDR guide, drug administration handbooks, or printed inserts from the pharmaceutical company.

The drug delivery rate is an important factor when administering IV medication. Some IV drugs are meant to be delivered rapidly over several minutes to obtain therapeutic effect. Other drugs are most effective when delivered slowly and intermittently throughout the day. Each drug delivery rate is unique. Administration guide-

Adding medication to an intravenous fluid bag. (Delmar Publishers, Inc. Reproduced by permission.)

lines for giving IV medications must be followed to achieve the therapeutic effect desired.

IV drugs may not be compatible with certain IV fluids or other drugs. Drug incompatibility is a true risk to the patient because it can cause crystallization of the medication that may at the least clog the IV line or at the worst have an embolus effect on the patient. The health care professional must check compatibility warnings that are included in IV drug administration guidelines. The line must be flushed with saline before and after giving medications IV to avoid contact of incompatible solutions or medications.

The effects of medication appear rapidly after an IV injection. The health care professional must know the indications, actions, and adverse effects of the medication that is to be delivered and must observe the patient closely for adverse medication reactions or allergic reactions and be prepared to respond with supportive therapy or drug reversing agents.

Description

IV push medication techniques deliver a bolus (a dose of medication injected all at once intravenously) of medication directly into a vein or access port to produce an immediate peak drug level in the patient's bloodstream. Large quantities of fluid IV push can cause severe complications; follow the recommendations of the drug administration guidelines. To deliver an IV bolus medication, draw the appropriate amount of medication that has been prepared, diluted, and/or reconstituted according to IV drug administration guidelines into a syringe. A bolus injection is most often given through a peripheral IV line, a saline lock, directly into a vein, or through a vascular access port.

When giving an IV bolus medication through a peripheral line with compatible fluid, the health care professional must shut off the IV line using the control clamp. The Y-port closest to the insertion site is cleaned with an alcohol or povidone-iodine pad to prevent bacterial contamination. The health care professional must then connect the medication needle or needle-less system connector to the port. The medication is injected over the period of time ordered, after which the syringe is disconnected and removed. The IV line is reopened using the control clamp and the IV flow is reset to the appropriate setting. If the peripheral line fluid is not compatible with the IV bolus medication, two syringes with 3cc of normal saline are prepared before giving the medication. The line is flushed before and after the IV medication administration with the prepared saline syringes. The Y-port is quite vulnerable to contamination when switching syringes. After the IV line is flushed the second time, the line can be reopened and the IV flow rate reset to the appropriate setting.

A saline (heparin) lock is a peripheral IV device. It is a short IV line that has been locked off to prevent venous fluid from flowing out. It is primarily used to access a vein for intermittent IV drug therapy. A latex cap that can be accessed by a needle or needle-less system connector to deliver drugs or IV fluids intermittently covers the distal tip. When giving an IV bolus medication through a saline lock, prepare two syringes with 3 cc of normal saline as well as the IV bolus medication syringe. (The health care professional should check the medical institution policy because some institutions require the use of heparin to flush IV locks.) The health care professional wipes off the cap of the saline lock with an alcohol or povidone-iodine swab to prevent bacterial contamination. The needle or needle-less system connector is connected to the latex cap of the lock and the patency of the lock is checked by pulling back on the syringe. A flashback of blood into the tubing indicates that the IV

catheter or needle is in the vein. If no blood appears, a tourniquet is applied above the IV site for about one minute and then the line is aspirated again. Medication should not be given unless the IV is patent (open and unblocked). To continue, the saline is injected into the lock and the insertion site is examined for signs of leaking or puffiness. If the IV lock appears intact, the saline syringe is removed. The medication syringe is connected to the cap using a needle or needle-less connector and the IV push medication is administered over the amount of time that was ordered. The medication syringe is removed and then the second saline syringe is connected to flush the line. Care is taken not to contaminate the cap when switching syringes. Finally the saline syringe is removed and the saline lock apparatus is left well secured to the patient's skin.

In an emergency when a patient has no IV line in and an IV bolus medication needs to be given, the nurse or physician may elect to insert a temporary butterfly IV apparatus connected to a needle. This is not a common situation. In most cases the staff will attempt to insert a regular IV catheter line to enable them to have a stable line for follow-up infusions of medications or fluids. To insert a temporary butterfly IV apparatus, the health care professional washes his/her hands and puts on gloves. A tourniquet is applied and a large vein is selected. The skin over the vein is swabbed with a povidone-iodine swab and the needle is inserted into the skin and then into the vein. When the IV is in place and a blood flashback is visible in the tubing, the tourniquet is removed and the distal end of the line is connected to a syringe of normal saline. The wings of the apparatus are secured with a piece of tape, and the line is aspirated with a syringe to assure proper line placement. If a blood return occurs, the line is slowly injected with 3 cc of normal saline to flush it. The insertion site is checked for puffiness or signs of leakage. Then the saline syringe is removed and rapidly replaced with the medication syringe. The prepared bolus of medication is given over the amount of time ordered. When the medication administration is complete, the syringe is removed and quickly replaced with another 3cc syringe filled with normal saline. The line is flushed

with the saline and the butterfly apparatus is removed from the vein. Pressure is applied to the site using a sterile 2 x 2 gauze pad. This method is not recommended for more than one dose of medication because of the temporary nature of the apparatus. If a patient may require further IV therapy a regular IV catheter should be inserted and connected to an IV line or capped off for use as a saline lock.

IV bolus medication may be given through a vascular access port that has been surgically implanted in the chest. When giving IV medication into an access port follow the procedures for accessing and giving IV medications through the port that are defined by the medical setting. A special needle apparatus is required that will not damage the port or the skin over the port. PICC line and mid-line catheters are not usually used for IV bolus medications because of the length of their tubing. Central lines must be used cautiously when giving IV bolus medication. Since the bolus will be pouring into a large central vein, the effect of the medication will be immediate and can be overwhelming to the patient's body.

IV medication may be given intermittently using a larger amount of fluid to be administered over a longer period of time (such as 50 cc over 20 minutes). Intermittent infusions may be administered through a secondary IV set (piggy back set) using an IV pump or a volume control set using an automatic IV syringe pump. There are many types of tubing and apparatus that can be used to deliver intermittent IV therapy. When administering intermittent IV therapy the instructions as defined on the administration set or in the medical center's IV policies are followed. The basic principles include: ensuring that the IV secondary set (piggy back) is positioned into the correct port on the main IV line and verifying that the pump is set to deliver the IV medication over the correct amount of time that was ordered by the physician. All lines are primed before they are connected to the IV to avoid delivering air through the lines. If the IV medication to be given is not compatible with the IV solution that is hanging, the line is flushed with normal saline before and after running the IV medication. The patient is observed carefully as the medication is delivered for

KEY TERMS

Embolus—An air bubble, blood clot, or foreign matter that lodges in a blood vessel, occluding blood flow.

Necrosis—Tissue destruction or death of tissue cells that is caused by injury, infection, or disease.

Venous thrombosis—A condition in which a vein is clogged off by foreign matter or a blood clot that results in decreased blood flow and oxygen to specific parts of the body.

signs of medication reaction or allergic reaction. When the IV medication has run in, the main IV solution is switched back on and the pump is reset for the maintenance rate as ordered by the physician.

Some IV medications, such as potassium chloride, are mixed into the main IV solution bag and run continuously. These medications are injected into the IV bag by the pharmacy or the nurse prior to hanging the IV solution. They run continuously at the rate of flow ordered by the physician.

Preparation

The patient is placed in a comfortable position, the procedure is explained, and the patient is told the name of the drug to be administered. The patient also should be instructed to alert the health care professional immediately if he/she has unusual feelings or discomfort after medication administration. The patency of the IV line is checked to insure that the line is intact and not leaking. The physician's order is reviewed and the five rights of medication administration are checked. The label on the medication is checked to be sure that it is not outdated. (Outdated medication should not be given.) The IV administration guidelines for the specific drug are reviewed, and the health care professional verifies that the drug is approved for IV administration according to the policies of the medical setting. After washing his/her hands, the health care professional calculates and prepares the drug according to drug administration guidelines. Any necessary equipment is assembled and ready access to emergency response equipment (such as contained in a crash cart) is verified.

The health care professional determines the amount of time over which the drug should be delivered according to the physician's order and/or the IV drug administration guidelines. For IV push medications this is calculated in cc to be delivered per minute. This number is

calculated by dividing the amount to be delivered (in cc) by the time over which the drug should be delivered (in minutes). For example, if the order is to give 10 mg of drug X over 5 minutes, first determine that 10 mg of drug X comes prepared in 6 cc of liquid. Divide 6 cc by 5 minutes to determine that the rate of IV injection should be 1.2 cc per minute. If the drug must be reconstituted, the rate is calculated using the total amount of drug in cc after reconstitution. For example, give 25 mg of drug Y over 5 minutes. Drug Y is a powder that is reconstituted with 5 cc of sterile water. When reconstituted, the medication has a fluid volume of 6 cc. Divide 6 cc by 5 minutes to determine that the drug should be given at 1.2 cc per minute. Intermittent IV drug doses are usually calculated in cc per hour. They are given in larger amounts of fluid that are usually given with an IV pump and most IV pumps are set in cc per hour, not cc per minute. To calculate the cc per hour rate, the cc per minute rate is multiplied by 60. For example, if the order reads give drug Z in 50 cc of normal saline over 20 minutes, calculate the cc to be delivered per minute by dividing 50 cc by 20 minutes and then multiply times 60 minutes. The rate would be 150 cc per hour to deliver the IV medication in 20 minutes.

Aftercare

After an IV medication has been delivered, the patient is observed for adverse or allergic reactions. Used needles are discarded without recapping them in a puncture proof, contaminated needle container. Used IV tubing, bags, gloves, and disposable supplies are discarded in a plastic bag that can be sealed and discarded in the contaminated trash. The health care professional washes his/her hands and documents that the medication that has been given. If reverting to a primary IV line, the health care professional must be sure to reset the IV flow rate to the correct hourly rate that is ordered for the IV fluids.

Complications

Complications of IV medication administration may include:

- infiltration of the IV line when a drug is injected IV bolus
- tissue necrosis when drugs are injected into infiltrated IV sites
- thrombophlebitis of the vein
- injection of air embolism
- serious adverse drug reactions such as hypotension, cardiac arrhythmias, and cardiac arrest
- allergic reaction to the medication

- venous thrombosis
- pain at the IV site

Results

When administered according to the physicians orders, following drug administration guidelines, and using the correct technique and IV apparatus, IV medications can have immediate positive therapeutic effects. The effects of the medication will vary depending upon the type of medication given.

Health care team roles

IV medication administration is delegated to registered nurses in most medical settings. Paramedics, LPNs, and IV team technicians who have received special IV training may give certain medications IV according to the policies of some medical settings. Patients and their families can be trained to use IV therapy pumps that automatically deliver IV medications in the home setting. IV nurses visit the home daily or every few days to change the medication cartridge and check the status of the IV line. The settings for the IV pump delivering IV medications are usually locked so that they cannot be accidentally altered. Patients are taught the signs of complications and learn to trouble-shoot IV alarms. IV nurses remain on-call to assist the patient and the family 24 hours a day when problems arise.

Intravenous tubing and dressing change

Definition

Intravenous (IV) infusion is the process whereby fluids, medications, **blood** products, and nutritional substances are administered into a vein by means of an intravascular device. The most commonly used device is the short peripheral venous catheter, which is usually inserted into the veins of the forearm or hand. IV fluids are supplied in plastic bags and delivered via an administration set, i.e., tubing. The fluid to be infused and the flow rate are prescribed by a physician or nurse practitioner.

Purpose

IV infusion is a method of fluid replacement used most often to maintain fluid and **electrolyte balance**, or to correct fluid volume deficits after excessive loss of body fluids, or in patients unable to take sufficient volumes by mouth. Many medications are also given by IV infusion and it is used for prolonged nutritional support of patients with gastrointestinal dysfunction.

Precautions

The insertion of an IV access device creates an open wound and the continued presence of the catheter within the wound keeps it “open,” which provides easy access for opportunistic **bacteria**. These bacteria may be present on a patient’s skin or may come from touch contamination by a practitioner. Technically, the administration of IV solutions takes place within a “closed-system,” but the delivery system usually has a number of connections, which may allow entry of bacteria. Strict adherence to handwashing and **aseptic technique** must always be followed while obtaining venous access and the equipment must be handled carefully to prevent contamination. Before using any materials, the practitioner must ensure that all packaging is intact prior to opening, that expiration dates have not passed, and that there are no visible signs of contamination. The site at which a catheter is placed has been shown to influence the subsequent risk of catheter-related infections; and in adults, hand vein insertions have a lower risk of problems than do upper arm or wrist vein insertions. Similarly, there is a greater risk with insertions in the legs than the arms, but the choice of a site may be limited by patient factors, e.g., preexisting catheters, anatomic deformity, present illness, or trauma. The practitioner must also be aware of any patient **allergies** to latex, iodine, or other substances. For

KEY TERMS

Catheter—A hollow tube that is flexible and used for withdraw or introduce fluids into the body.

Dehydration—A condition that results from a loss of water in the body.

Intravascular—Within a vessel, as a blood vessel.

Semipermeable—Permitting passage of only certain molecules.

Peripheral—That portion of the body that is outside the main region, as arms or legs.

Povidone—A synthetic polymer used as a dispersing and suspending agent as in povidone-iodine, a topical anti-infective agent.

selection of catheters, the Centers for Disease Control (CDC) recommend the use of a Teflon catheter, a polyurethane catheter, or a steel needle. The choice depends on the intended purpose, duration of use, and known complications. Transparent, semipermeable, polyurethane dressings reliably secure the site, permit continuous visual inspection of it, allow patients to bathe or shower without saturating the dressing, and require less frequent changes than standard gauze and tape dressings. Research has shown no clinically important differences between the two with regard to rate of **infection** or occurrence of inflammation.

Description

The initial insertion of a catheter with transparent dressing or sterile gauze should be labeled as to the time and date of insertion in an obvious location near the site (e.g. on dressing or on the bed) and the IV administration set should likewise be labeled as to time and date of hanging. CDC recommendations for care and management of peripheral venous catheter sites, IV administration sets, and dressing changes include the following:

- Hands must be washed before and after palpating, inserting, replacing, or changing dressing.
- The catheter site must be visually inspected and palpated for redness, tenderness, or warmth (phlebitis) daily.
- Sites must be replaced and rotated every 48–72 hours to minimize risk of phlebitis. Catheters inserted under emergency conditions must be replaced with new catheters within 24 hours due to possible break-in aseptic technique. Heparin locks must be replaced within 96 hours. Catheters with signs of phlebitis should be removed immediately or as soon as its use is no longer

clinically indicated. Do not routinely apply topical antimicrobial ointment to site.

- When the catheter is removed or replaced, the site dressing should be replaced. The dressing should also be replaced when it becomes damp, loosened, or soiled. Dressings are changed more frequently for patients that sweat. Avoid touching the site when dressing is replaced.
- The IV tubing, including piggyback tubing and stopcocks, is replaced no more frequently than at 72-hour intervals, unless clinically indicated. Tubing used to infuse blood, blood products, or lipid emulsions is replaced within 24 hours of initiation.
- Injection ports are cleaned with 70% alcohol or povidone-iodine before accessing the system. Heparin locks require a routine flush with normal saline solution, unless they are used to obtain blood specimens, in which case a dilute heparin (10 units/ml) flush solution should be used.

Preparation

- All needed materials must be assembled prior to approaching the patient for catheter insertion or IV tubing and dressing change.
- Hands must be washed before and after the procedure.
- The procedure is explained to the patient and he/she is encouraged to ask questions.
- If the patient's veins are difficult to access, warm soaks can be applied to the area prior to attempted insertion to increase blood flow to that area and facilitate the process.
- Nonlatex or latex gloves are worn for insertion of the catheter and for changing the dressing.
- The site or dressing should be marked with labels carrying the date, time, and initials of the individual performing the procedure.

Aftercare

Follow-up care includes:

- The site is inspected and palpated daily.
- IV fluids and additives are monitored to ensure that they are those ordered by the physician or nurse practitioner.
- The infusion rate is checked to make sure that it is correct as ordered.

Complications

The use of IV devices is frequently complicated by a variety of local or systemic infectious complications to include:

- bloodstream infection
- inflammation and/or infection of the lining of the cavities of the heart
- inflammation of the vein sometimes associated with a clot
- infections in other areas of the body

The risk of complications in IV therapy is actually higher on the second day of therapy and was believed to increase with time, which made routine restarts after three days a common practice. Recent research has shown, however, that a restarted catheter has a significantly higher risk of complication in its first 24 hours than does an initial catheter. Thus, restarting catheters routinely at 72 hours does not reduce the risk of complication in the next 24 hours when compared to simply continuing therapy with the original catheter, provided the site or the original has no signs of inflammation. Once additional studies confirm these data, the recommendations may change.

Results

The results obtained from IV therapy should primarily serve to improve the condition of the patient. A dehydrated patient's fluid volume and electrolyte balance should improve. Any patient ill from an infection should feel improved with IV antibiotic therapy. The purpose of an IV is to alleviate symptoms and assist with enhancing well-being.

Health care team roles

The **registered nurse** is the primary provider of IV catheter insertion, IV fluids, tubing, and dressings. It is the role of this nurse to ensure that the recommended procedures, protocols, and written orders for IV therapy are followed. It is also the duty of the nurse to maintain her skills for IV therapy and keep updated on any changes in recommendations in providing care. Available data suggest that personnel specially trained or designated with the responsibility for insertion and maintenance of IV devices provide a service that reduces the rate of infections and overall costs.

Intravenous urography

Definition

Intravenous urography is a radiographic study of the **urinary system** using an intravenous contrast agent (dye).

Of the many ways to obtain images of the urinary system, the intravenous injection of a contrast agent has been traditionally considered the best, although other modalities, such as computed tomography (CT) or ultrasound, are better for some disease processes. The **kidneys** excrete the contrast into the urine, which becomes visible when x rayed (radiopaque), creating images of the urinary collection system.

The procedure has several variations and many names, including:

- Intravenous pyelography (IVP).
- Intravenous urography (IVU).
- Pyelography.
- Antegrade pyelography differentiates this procedure from retrograde pyelography, which injects the contrast agent directly into the lower end of the system. The contrast agent flows backward, hence the name "retro-

grade.” Retrograde pyelography is used to better define problems in the lower ureters and is the only way to get x rays if the kidneys are non-functional.

- Nephrotomography, or tomographic slices of the kidneys, is taken by a moving x-ray source emitting x rays onto a film moving in the opposite direction. Images above and below the level of the kidneys are blurred, allowing a more detailed image of the kidneys with no overlying material, such as gas or fecal material.

There are numerous exams available for detecting kidney abnormalities, with varying risks and costs.

- Nuclear renal scans rely on the radiation given off by certain atoms (isotopes), which are injected into the bloodstream. They reach the kidneys, where images are constructed by measuring the radiation emitted. The radiation is no more dangerous than standard x rays. This exam has limited applications, including the evaluation of reflux, chronic obstruction, and renal function. It is also used to evaluate high **blood pressure** that is refractory to treatment, and is commonly used to evaluate the kidney of a renal transplant patient for early rejection where renal artery stenosis is suspected as the cause.
- Ultrasound is a quick, safe, simple, and inexpensive way to obtain views of internal organs. Renal size can be measured as well as the visualization of hydronephrosis, cysts, tumors, and renal calculi. Small stones in the ureters are not as well visualized and the function of the kidneys can not be determined.
- Retrograde pyelography is better able to define problems in the lower part of the ureters, and is the only way to completely opacify the ureters in patients with reduced kidney function. This exam is performed in an operating room by a urologist. A cystoscope is placed into the bladder and a catheter is placed into each ureter to inject the contrast agent. The advantage of this method is that small stones can be removed immediately by the urologist.
- Computed tomography scans (CT or CAT scans) use a fine beam of x rays creating images at precise levels in the body. The information is processed by a computer and imaged onto film with a laser printer. Three-dimensional images can be constructed from this method of imaging. An injection of a contrast agent is necessary to visualize the kidneys in detail. The CT scan is done without IV contrast to look for stones (calculi). In some centers, this modality has replaced IVPs and ultrasound for this application. Special equipment is necessary and the exam can be costly.
- Magnetic resonance imaging (MRI) uses magnetic fields and radio frequency signals instead of ionizing

radiation to create computerized images. This form of energy is entirely safe as long as the patient has no metal in his or her body. It has limited applications and usually is not done for common problems, such as **pain** and hematuria (**blood** in the urine). MRI usually is done if other tests are inconclusive. MRA (magnetic resonance **angiography**) may be done to evaluate the renal arteries, particularly if renal artery stenosis is suspected as a cause of **hypertension** that is refractory to treatment. MRI requires special apparatus and installation and is a very costly exam.

Purpose

An intravenous urogram is ordered to demonstrate the structure and function of the kidneys, ureters, and bladder. Patients complaining of abdominal pain radiating to the back may require this exam to rule out **kidney stones**. Hematuria may also be an indication of kidney stones, **infection**, or tumors. Patients with high blood pressure (hypertension) and recurrent bladder infections may also require an intravenous urogram (but hypertension usually is imaged with MRA or nuclear medicine imagery and this exam is done when renal artery stenosis is the suspected cause of refractory hypertension). Sometimes the exam is ordered to evaluate the function of the kidney in a renal transplant patient. The transplanted kidney is located in the iliac fossa, so special films of the pelvis area are done instead of the normal routine views. The radiographic technologist may also be required to take x rays in the operating room when a retrograde pyelogram is ordered by a urologist during a C and P (**cystoscopy** and pyelography).

Emergency patients with blunt abdominal trauma are usually evaluated with a CT scan or occasionally ultrasound instead of an intravenous urogram.

Precautions

A serious complication of an intravenous urogram is an allergic reaction to the iodine-containing contrast agent. Severe reactions are rare, but can be dramatic and even lethal. For this reason all radiology departments performing this exam are equipped with emergency drugs and oxygen in the x-ray room itself.

Description

The patient will be required to change into a hospital gown and empty his or her bladder. The x-ray technologist will verify that the patient has followed the bowel preparation and complete a detailed questionnaire on the current medical history of the patient. This includes previous contrast reactions, known **allergies**,

risks of **pregnancy**, and current medications. The x-ray technologist will explain the exam in detail to the patient as well as the risks of the contrast material that will be injected intravenously. All departments require that the patient sign a consent form before the examination is started. The x-ray technologist will relay this information to the radiologist who will decide on what type of contrast will be used. Patients who have had an injection with no reaction can be given less expensive iodine-based contrast, whereas patients who take various **heart** medications or those with known allergies or **asthma** will be injected with a more expensive contrast agent (known as non-ionic contrast) that has fewer side effects. Some departments use the non-ionic contrast exclusively.

The patient will be instructed to lie supine (face-up) on the x-ray table and a preliminary KUB will be done. This is an abdominal view of the kidneys, ureter, and bladder used to verify patient preparation, centering, and the radiographic technique needed to demonstrate all the required structures.

Kidney stones may or may not be visualized on the preliminary film. The x-ray technologist prepares the required amount of contrast to be used depending on the weight of the patient (1 ml per pound). This is normally 50–75 cc of contrast for an average-sized patient. The contrast will be injected all at once (bolus injection) or in some cases, through an intravenous drip. Some radiologists prefer to start an intravenous drip with saline as a precautionary measure while others inject with a small butterfly needle. The needle usually remains in place for 10–15 minutes, in case more contrast is needed or in case drugs need to be administered because of an allergic reaction. Most reactions occur immediately but some can take place 10 or 15 minutes after the injection.

The first film is taken immediately after the injection to see a detail of the renal outline (nephrogram). Films are usually taken at five-minute intervals depending on the routine of the radiologist. Compression may be applied to the lower abdomen with a wide band to keep the contrast material in the kidneys longer. This creates a more detailed image of the renal collecting system. When the compression is released after approximately 10 minutes the contrast material drains quickly and a detailed, filled image of the ureters is obtained. Films done in the upright or prone (face-down) position may also be ordered to better visualize the lower ureters. Some departments require routine renal tomographic images to be done as well when the kidneys are well visualized. This allows the kidneys to be seen free of gas or fecal shadows. Sometimes the radiologist requires oblique views of the kidneys or bladder to determine the exact location of calculi (stones). At approximately 20 minutes after the injection a film centered on the bladder may be

required. The x-ray tube is angled slightly caudad (towards the feet) so that there is no superimposition of the pubic area of the pelvis over the bladder. The films are shown to the radiologist and if no further films are necessary the patient will be asked to void (urinate) and a post-void film will be taken. The exam can take from 30 minutes to one hour depending on the number of films required. If the kidney is obstructed, delayed films may be required to complete the exam.

Preparation

In order to obtain the best visualization of the kidneys, ureters, and bladder, the intestines must be free of gas and fecal material. Every radiology department has their own specific requirements. Most include a laxative such as X-Prep or Dulcolax tablets taken around 4 p.m. the day preceding the exam. This is followed with a light fat-free dinner which includes lean meats, noodles, white rice, bread with no butter, and tea or black coffee. Fluids are permitted until midnight, after which no food or liquid is allowed until after the intravenous urogram is completed. Patients who are diabetic are sometimes done early in the morning to avoid any complications. Patients who have had a previous reaction to a contrast material can be given a series of steroids and **antihistamines** the day before the exam as well as the morning of the exam. The patient must consult with their physician before this is administered. In patients with known or suspected renal failure, lab tests, including BUN and creatinine, may be ordered prior to the IVP.

Complications

An allergic reaction to the contrast agent is the primary risk, although kidney damage is also a potential complication. Patients with a possible iodine allergy or a previous reaction to a radiographic contrast agent should inform the x-ray technologist. A detailed history of known allergies, risk of pregnancy, and current medications is required before an intravenous urogram. All radiology departments have consent forms that must be signed by the patient before starting the exam. Emergency equipment and specific drugs such as antihistamines (Benadryl), adrenaline, and atropine are kept in the x-ray room. All radiography technologists must have specific training and education on the various signs and symptoms of an allergic reaction. A mild reaction consists of a skin rash or **hives**, whereas a more serious reaction includes swelling of the larynx, difficulties in breathing, asthmatic attacks, and a severe drop in blood pressure (hypotension).

Since x-rays are involved during this procedure, there is a minimal risk due to radiation. This exam is not

KEY TERMS

Contrast agent—A radiopaque substance used in radiology to permit visualization of body structures.

Intravenous—Into a vein.

done on pregnant women or women who think they may be pregnant.

Results

A normal intravenous urogram indicates no visible abnormality in the structure or function of the urinary system. The radiologist looks for a smooth non-lobulated outline of each kidney, no clubbing or other abnormality of the renal calyces (collecting system), and no abnormal fluid collection in the kidneys that could suggest obstruction. The ureters must contain no filling defects (stones) or deviations due to an adjacent tumor. The bladder must have a smooth outline and empty normally as visualized on the post-void film.

Abnormal results include hydronephrosis (distension of the renal pelvis and calices due to obstruction) as a result of tumors or calculi (stones). Cysts or abscesses may also be present in the urinary system. A delay in renal function can also indicate renal disease. An abnormal amount of urine in the bladder after voiding may indicate prostate or bladder problems.

Intravenous urograms are often done on children to rule out a rapid developing tumor in the kidneys, called a Wilm's tumor. Children are also prone to infections of the bladder and kidneys due to urinary reflux (return back-flow of urine).

Health care team roles

The x-ray technologist must work in conjunction with the doctors and nurses in making sure the patient has not had a previous allergic reaction to a contrast agent. All hospitals have an emergency team ready to react in such a situation, so the technologist must be aware of the procedure to follow when assistance is necessary due to a severe reaction. Details of patient preparation must also be communicated to the hospital wards. In some hospitals the radiologic technologists are trained to give injections, but if this is not the case nurses may be asked to install an intravenous drip before the patient is brought to the radiology department.

Patient education

The x-ray technologist must explain the risks of an allergic reaction to each patient even though severe reactions are extremely rare due to the advances made in the preparation of contrast agents. The x-ray technologist explains to the patient that a warm, flushed feeling or a metallic **taste** in the mouth are normal reactions in some patients. Breathing instructions are also important since the kidneys change position depending on the phase of respiration and to prevent motion artifacts. Sometimes an emergency patient with renal colic (acute abdominal pain) is asked to urinate through a special filter used to trap small stones. All radiographic technologists must be certified and registered with the American Society of Radiologic Technologists or an equivalent organization. Continued education credits are mandatory to remain registered.

Ipecac

Description

There are two categories of ipecac preparations—a syrup used in standard medical practice and a homeopathic remedy. They are given for different purposes. The medicinal effects of ipecac were recognized centuries ago by the Portuguese who settled in South America. They found a plant that can make people vomit and appropriately named it *Caephalis ipecacuanha*, meaning sick-making plant. Nowadays, ipecac is used to treat a variety of conditions. Its most widely accepted use is to induce vomiting in cases of accidental **poisoning**. When ipecac is swallowed, a substance in it called cephaeline irritates the **stomach** and causes vomiting. Syrup of ipecac is now considered the safest drug to treat poison-

ing and is often the most effective. There are different types of ipecac preparations that vary greatly in strength. Syrup of ipecac is best for use at home to treat accidental poisoning. Ipecac fluid extract and ipecac tincture should be avoided as they are much stronger compounds and can be toxic.

Ipecacuanha is a homeopathic remedy made from ipecac by a process of dilution and succussion (shaking). In contrast to syrup of ipecac, it is given to relieve vomiting.

General use

Treatment of poisoning

Standard medical practice uses ipecac to cause vomiting in cases of poisoning in order to remove the toxic substance from the stomach before absorption occurs. It can be used on animals as well as humans. Ipecac is safer and more effective than many other methods for inducing vomiting, such as sticking a finger down a child's throat or using salt water. There are times, however, when ipecac should not be used because it can make certain kinds of poisoning worse. Syrup of ipecac should not be used if the poison is one of the following.

- strychnine
- alkalis (lye)
- strong acids
- kerosene
- fuel oil
- gasoline
- coal oil
- paint thinner
- cleaning fluid

Poisoning is a potentially serious condition. It is best to contact a local poison control center, local hospital emergency room, or the family doctor for instructions before using syrup of ipecac.

Ipecac's reputation for inducing vomiting has encouraged some bulimics to take it on a regular basis in order to purge the contents of the stomach after an eating binge. This misuse of ipecac is extremely dangerous; it can cause **heart** problems, tears in the esophagus or stomach lining, vomiting **blood**, seizures, or even death.

Homeopathy

The homeopathic remedy made from ipecac is called *Ipecacuanha*. Homeopathic preparations are given for a reason completely opposite from that of standard allopathic treatment. In **homeopathy**, ipecac is given to stop

Ipecac plant (*Cephaelis ipecacuanha*). (PlantaPhile Germany. Reproduced by permission.)

vomiting rather than to induce it. According to Hahnemann's law of similars, a substance that would cause vomiting in large doses when given to a healthy person will stimulate a sick person's natural defenses when given in extremely dilute and carefully prepared doses. *Ipecacuanha* is a favorite homeopathic remedy for morning sickness associated with **pregnancy**. It is also given to stop nausea that is not relieved by vomiting; when the vomitus is slimy and white; when there is gagging and heavy salivation; when the tongue is clean despite the patient's feelings of nausea; and when the patient is not thirsty. The nausea may be accompanied by a headache, cough, or heavy menstrual bleeding. The modalities (circumstances) that suggest *Ipecacuanha* as the appropriate homeopathic remedy is that the patient feels worse lying down; in dry weather; in winter; and when exercising or moving about.

A homeopathic practitioner would not necessarily prescribe ipecac for all cases of nausea. *Arsenicum* would be given when the nausea is caused by **food poisoning** and accompanied by strong thirst, *Nux vomica* when the nausea is the result of overindulgence in food or alcohol and accompanied by gas or heartburn. A sick child might be given *Pulsatilla*, particularly if rich foods have been eaten.

On the other hand, a homeopathic practitioner may prescribe ipecac for any of the following conditions that are not related to nausea and vomiting:

- Nosebleeds producing bright red blood.
- Dental bleeding.
- Diarrhea with cramping abdominal **pain**. The stools are green with froth or foam.

KEY TERMS

Bulimia nervosa—An eating disorder characterized by episodic binge eating followed by self-induced vomiting or laxative abuse.

Cephaeline—A chemical compound found in ipecac that irritates the stomach lining and triggers the vomiting reflex.

Fluid extract—A concentrated preparation of a drug.

Law of similars—A principle of homeopathic treatment according to which substances that cause specific symptoms in healthy people are given to sick people with similar symptoms.

Modality—A factor or circumstance that makes a patient's symptoms better or worse. Modalities include such factors as time of day, room temperature, the patient's level of activity, sleep patterns, etc.

Tincture—An alcoholic solution of a chemical or drug.

- Asthma of sudden onset. The patient has to sit up in order to breathe, but cannot bring up any mucus in spite of violent coughing.
- Hoarseness or loss of voice following a cold.
- Physical or mental exhaustion.

Preparations

Syrup of ipecac

Syrup of ipecac is made from the dried roots and rhizomes (underground stems) of *Cephaelis ipecacuanha*. It is available over the counter in 0.5–1 oz bottles. Larger bottles require a doctor's prescription. The dosage for infants under 6 months old should be prescribed by the family doctor or poison control center. For children six months to one year, the usual dose is 5–10 ml or 1–2 tsp. One-half or one full glass (4–8 oz) of water should be taken immediately before or after the dose. The dose may be repeated once after 20–30 minutes if vomiting does not occur. For children one to 12 years of age, the usual dose is 15 ml (1 tbsp) to be taken with one full glass (8 oz) of water. Adults and teenagers should take 15–30 ml of ipecac with at least 1 full glass of water. Syrup of ipecac should not be taken with milk or soda drinks as these foods may prevent it from working properly. If vomiting does not occur within 20–30 minutes after the

first dose, a second dose may be needed. If the second dose fails to induce vomiting, the patient should be taken to a hospital emergency room.

If both activated charcoal and syrup of ipecac are recommended to treat poison, ipecac must be used first. Activated charcoal should not be taken until 30 minutes after taking syrup of ipecac, or until the vomiting caused by ipecac stops.

Homeopathic preparations

Ipecacuanha is available as an over-the-counter remedy in 30x potency. This is a decimal potency, which means that one part of ipecac has been mixed with nine parts of alcohol or water; 30x means that this decimal dilution has been repeated 30 times. The dilute solution of ipecac is then added to sugar tablets so that the remedy can be taken in tablet form.

Precautions

Syrup of ipecac

For inducing vomiting in cases of accidental poisoning, only the syrup form of ipecac should be used. Syrup of ipecac should not be mixed with milk or carbonated drinks as they may prevent vomiting.

Syrup of ipecac should not be used in the following situations (contact poison control center or family doctor for alternative treatments):

- Poisoning caused by strychnine; sustained-release theophylline; such corrosive substances as strong alkalis (lye); strong acids (such as toilet bowl cleaner); and such petroleum products as kerosene, gasoline, coal oil, fuel oil, paint thinner, or cleaning fluids.
- Overdoses of medications given for depression.
- Excessive vomiting.
- A serious heart condition.
- Timing. Do not give ipecac more than 4–6 hours after the poison was ingested.
- Pregnancy.
- Very young children (less than six months old). Infants and very young children may choke on their own vomit or get vomit into their lungs.
- Drowsy or unconscious patients.
- Seizures.

Homeopathic preparations

Ipecacuanha should not be given after *Arsenicum* or *Tabac* because these remedies will counteract it.

Side effects

The following side effects have been associated with the use of syrup of ipecac.

- Loose bowel movements.
- Diarrhea.
- Fast irregular heartbeat.
- Inhaling or choking on vomit.
- Stomach cramps or pains.
- Coughing.
- Weakness.
- Aching.
- Muscle stiffness.
- Severe heart problems often occur in cases of ipecac abuse. Because ipecac stays in the body for a long time, damage to the heart frequently occurs in persons who repeatedly take ipecac to induce vomiting.
- Seizures. These are most likely to occur in patients who accidentally swallow ipecac or in ipecac abusers.
- Death. Deaths have been reported due to ipecac abuse in bulimic persons.

Homeopathic *Ipecacuanha* has been highly diluted and is relatively nontoxic.

Interactions

Ipecac should not be given together with other drugs because it can decrease their effectiveness and increase their toxicity. If both syrup of ipecac and activated charcoal are needed to treat suspected poisons, ipecac should be given first. Activated charcoal should not be given until vomiting induced by ipecac has stopped. Soda pop should also be avoided because it can cause the stomach to swell. The person should lie on the stomach or side in case vomiting occurs.

Homeopathic *Ipecacuanha* is considered complementary to *Arnica* and *Cuprum*. It is counteracted by *Arsenicum* and *Tabac*.

Iron-binding capacity test see **Iron tests**

Iron

Description

Iron is a mineral that the human body uses to produce the red **blood** cells (hemoglobin) that carry oxygen throughout the body. It is also stored in myoglobin, an oxygen-carrying protein in the muscles that fuels cell growth.

General use

Iron is abundant in red meats, vegetables, and other foods, and a well-balanced diet can usually provide an adequate supply of the mineral. But when there is insufficient iron from dietary sources, or as a result of blood loss in the body, the amount of hemoglobin in the bloodstream is reduced and oxygen cannot be efficiently transported to tissues and organs throughout the body. The resulting condition is known as iron-deficiency anemia, and is characterized by fatigue, shortness of breath, pale skin, concentration problems, dizziness, a weakened **immune system**, and energy loss.

Iron-deficiency anemia can be caused by a number of factors, including poor diet, heavy menstrual cycles, **pregnancy**, kidney disease, **burns**, and gastrointestinal disorders. Individuals with iron-deficiency anemia should always undergo a thorough evaluation by a physician to determine the cause.

Children two years old and under also need adequate iron in their diets to promote proper mental and physical development. Children under two who are not breastfeeding should eat iron-fortified formulas and cereals. Women who breastfeed need at least 15 mg of dietary or supplementary iron a day in order to pass along adequate amounts of the mineral to their child in breast milk. Parents should consult a pediatrician or other healthcare

KEY TERMS

Chelation—The use of a medication or herbal substances to inactivate toxic substances in the body. Chelation is used to treat iron overload in some patients.

Decoction—An herbal extract produced by mixing an herb in cold water, bringing the mixture to a boil, and letting it simmer to evaporate the excess water. The decoction is then strained and consumed hot or cold. Decoctions are usually chosen over infusion when the botanical in question is a root or berry.

Ferritin—An iron storage protein found in the blood. High levels of serum ferritin may indicate iron overload.

Hemochromatosis—Also known as iron overload; a genetic condition in which excess iron is stored in the tissues and organs by the body where it can build up to toxic amounts.

Homeopathic remedy—Used to treat illnesses that manifest symptoms similar to those that the remedy itself causes, but administered in extremely diluted doses to prevent any toxic effects.

Infusion—An herbal preparation made by mixing boiling water with an herb, letting the brew steep for 10 minutes, and then straining the herb out of the mixture. Tea is made through infusion.

Thalassemia—A group of several genetic blood diseases characterized by absent or decreased production of normal hemoglobin. Individuals who have thalassemia have to undergo frequent blood transfusions, and are at risk for iron overload.

Tincture—A liquid extract of an herb prepared by steeping the herb in an alcohol and water mixture.

professional for guidance on iron supplementation in children.

It has been theorized that excess stored iron can lead to atherosclerosis and ischemic **heart** disease. Phlebotomy, or blood removal, has been used to reduce stored iron in patients with iron overload with some success. Iron chelation with drugs such as desferrioxamine (Desferal) that help patients excrete excess stores of iron can be helpful in treating iron overload caused by multiple blood transfusions.

Iron levels in the body are measured by both hemoglobin and serum ferritin blood tests.

Normal total hemoglobin levels are:

- neonates: 17-22 g/dl
- one week: 15-20 g/dl
- one month: 11-15 g/dl
- children: 11-13 g/dl
- adult males: 14-18 g/dl (12.4-14.9 g/dl after age 50)
- adult females: 12-16 g/dl (11.7-13.8 g/dl after menopause)

Normal serum ferritin levels are:

- neonates: 25-200 ng/ml
- one month: 200-600 ng/ml
- two to five months: 50-200 ng/ml
- six months to 15 years: 7-140 ng/ml
- adult males: 20-300 ng/ml
- adult females: 20-120 ng/ml

Preparations

Iron can be found in a number of dietary sources, including:

- pumpkin seeds
- dried fruits (apricots)
- lean meats (beef and liver)
- fortified cereals
- turkey (dark meat)
- green vegetables (spinach, kale, and broccoli)
- beans, peas, and lentils
- enriched and whole grain breads
- molasses
- sea vegetables (blue-green algae and kelp)

Eating iron-rich foods in conjunction with foods rich in **vitamin C** (such as citrus fruits) and lactic acid (sauerkraut and yogurt) can increase absorption of dietary iron. Cooking food in cast-iron pots can also add to their iron content.

The recommended dietary allowances (RDA) of iron as outlined by the United States Department of Agriculture (USDA) are as follows:

- children 0–3: 6-10 mg/day
- children 4–10: 10 mg/day
- adolescent and adult males: 10 mg/day
- adolescent and adult females: 10-15 mg/day

- pregnant females: 30 mg/day
- breastfeeding females: 15 mg/day

A number of herbal remedies contain iron, and can be useful as a natural supplement. The juice of the herb stinging nettle (*Urtica dioica*) is rich in both iron and vitamin C (which is thought to promote the absorption of iron). It can be taken daily as a dietary supplement. Dandelion (*Taraxacum officinale*), curled dock (*Rumex crispus*), and parsley (*Petroselinum crispum*) also have high iron content, and can be prepared in tea or syrup form.

In Chinese medicine, dang gui (dong quai), or *Angelica sinensis*, the root of the angelica plant, is said to both stimulate the circulatory system and aid the **digestive system**. It can be administered as a decoction or tincture, and should be taken in conjunction with an iron-rich diet. Other Chinese remedies include foxglove root (*Rehmannia glutinosa*), Korean ginseng (*Panax ginseng*), and astragalus (*Astragalus membranaceus*).

Ferrum phosphoricum (iron phosphate), is used in homeopathic medicine to treat anemia. The remedy is produced by mixing iron sulfate, phosphate, and sodium acetate, which is administered in a highly diluted form to the patient. Other homeopathic remedies for anemia include *Natrum muriaticum*, *Chinchona officinalis*, *Cyclamen europaeum*, *Ferrum metallicum*, and *Manganum aceticum*. As with all homeopathic remedies, the type of remedy prescribed for iron deficiency depends on the individual's overall symptom picture, mood, and temperament. Patients should speak with their homeopathic professional or physician, or healthcare professional before taking any of these remedies.

Iron is also available in a number of over-the-counter supplements (i.e., ferrous fumarate, ferrous sulfate, ferrous gluconate, iron dextran). Both heme iron and non-heme iron supplements are available. Heme iron is more efficiently absorbed by the body, but non-heme iron can also be effective if used in conjunction with vitamin C and other dietary sources of heme iron. Some multivitamins also contain supplementary iron. Ingesting excessive iron can be toxic, and may have long-term negative effects. For this reason, iron supplements should only be taken under the recommendation and supervision of a doctor.

Precautions

Iron deficiency can be a sign of a more serious problem, such as internal bleeding. Anyone suffering from iron-deficiency anemia should always undergo a thorough evaluation by a healthcare professional to determine the cause.

Iron **overdose** in children can be fatal, and is a leading cause of **poisoning** in children. Children should never take supplements intended for adults, and should only receive iron supplementation under the guidance of a physician.

Individuals with chronic or acute health conditions, including kidney **infection**, **alcoholism**, liver disease, rheumatoid arthritis, **asthma**, heart disease, colitis, and **stomach** ulcer should consult a physician before taking herbal or pharmaceutical iron supplements.

If individuals taking homeopathic dilutions of *Ferrum phosphoricum* experience worsening of their symptoms (known as a homeopathic aggravation), they should stop taking the remedy and contact their healthcare professional. A homeopathic aggravation can be an early indication that a remedy is working properly, but it can also be a sign that a different remedy is needed.

Patients diagnosed with hemochromatosis, a genetic condition in which the body absorbs too much iron and stores the excess in organs and tissues, should never take iron supplements.

Side effects

Taking herbal or pharmaceutical iron supplements on an empty stomach may cause nausea. Iron supplementation may cause hard, dark stools, and individuals who take iron frequently experience constipation. Patients who experience dark bowel movements accompanied by stomach pains should check with their doctor, as this can also indicate bleeding in the digestive tract.

Other reported side effects include stomach cramps and chest **pain**. These symptoms should be evaluated by a physician if they occur.

Some iron supplements, particularly those taken in liquid form, may stain the teeth. Taking these through a straw, or with a dropper placed towards the back of the throat, may be helpful in preventing staining. Toothpaste containing baking soda and/or hydrogen peroxide can be useful in removing iron stains from teeth.

Signs of iron overdose include severe vomiting, racing heart, bloody **diarrhea**, stomach cramps, bluish lips and fingernails, pale skin, and weakness. If overdose is suspected, the patient should contact poison control and/or seek emergency medical attention immediately.

Interactions

Iron supplements may react with certain medications, including **antacids**, acetohydroxamic (Lithostat), Dimercaprol, Etidronate, Fluoroquinolones. In addition,

they can decrease the effectiveness of certain tetracyclines (**antibiotics**). Individuals taking these or any other medications should consult their healthcare professional before starting iron supplements.

Certain foods decrease the absorption of iron, including some soy-based foods, foods with large concentrations of **calcium**, and beverages containing **caffeine** and tannin (a substance found in black tea). These should not be taken within two hours of using an iron supplement. Some herbs also contain tannic acid, and should be avoided during treatment with iron supplements. These include allspice (*Pimenta dioica*) and bayberry (*Myrica cerifera*, also called wax myrtle).

Individuals considering treatment with homeopathic remedies should also consult their healthcare professional about possible interactions with certain foods, beverages, prescription medications, aromatic compounds, and other environmental elements—factors known in **homeopathy** as remedy antidotes—that could counteract the efficacy of treatment for iron deficiency.

Iron deficiency anemia

Definition

Anemia can be caused by **iron** deficiency, folate deficiency, **vitamin B₁₂** deficiency, and other causes. Iron deficiency anemia is due to a shortage of iron. It is characterized by the production of red **blood** cells that are smaller than normal (microcytic) and appear pale or light colored (hypochromic) when viewed under a **microscope**. For this reason, the anemia that occurs with iron deficiency is also called hypochromic microcytic anemia.

Description

Iron deficiency anemia is the most common type of anemia throughout the world. In the United States, iron deficiency anemia occurs to a lesser extent than in developing countries because of the higher consumption of red meat and the practice of food fortification (addition of iron to foods by manufacturers). In the United States, iron deficiency anemia is caused by a variety of factors, including excessive losses of iron in menstrual fluids and excessive bleeding into the gastrointestinal tract. In developing countries located in tropical climates, the most common cause of iron deficiency anemia is infestation with hookworm.

Causes and symptoms

Infancy is a period of increased risk for iron deficiency. A human infant is born with a built-in supply of iron, which can be tapped during periods of drinking low-iron milk or formula. Both human milk and cow milk contain rather low levels of iron (0.5-1.0 mg iron/liter). However, about 50% of the iron in human milk is absorbed by an infant, while only 10% of the iron in cow milk is absorbed. During the first six months of life, growth of an infant is made possible by milk in the diet and by the infant's built-in supply. **Premature infants** have a lower supply of iron. For this reason, it is recommended that pre-term infants (beginning at two months of age) be given oral supplements of 7 mg iron/day, in the form of ferrous sulfate. Iron deficiency can develop when infants are fed formulas that are based on cow milk that has not been fortified. For example, unfortified cow milk is given free of charge to mothers in Chile. This practice prevents general malnutrition, but results in the development of mild iron deficiency.

The normal rate of blood loss in the feces is 0.5-1.0 ml per day. About 60% of persons with **cancer** of the colon and rectum experience further blood loss in the range of 10 ml/day, which can lead to iron deficiency anemia. The **fecal occult blood test** is widely used to screen for the presence of cancer of the colon or rectum. In the absence of testing, **colorectal cancer** may be first detected because of the resulting iron deficiency anemia.

Infection with hookworm can also cause iron deficiency anemia. The hookworm is a parasite that thrives in warm climates, including in the southern United States. A hookworm enters the body through the skin, very commonly through bare feet. The hookworm then migrates to the small intestines where it attaches itself to the villi (small, finger-like structures found on the walls of the intestines, which are used for the absorption of nutrients). Hookworms damage the villi, resulting in

blood loss. Further, they produce anticoagulants which promote continued bleeding. Each hookworm can cause the loss of up to 0.25 ml of blood per day.

Bleeding and blood loss through the gastrointestinal tract can also be caused by hemorrhoids, anal fissures, irritable bowel syndrome, aspirin-induced bleeding, blood clotting disorders, and diverticulosis (a condition caused by an abnormal opening from the intestine). Several genetic diseases are characterized by **bleeding disorders**. These include **hemophilia A**, **hemophilia B**, and **von Willebrand's disease**. Of these, only von Willebrand's disease leads to gastrointestinal bleeding.

The symptoms of iron deficiency anemia include weakness and fatigue. These symptoms result from the lack of function of red blood cells, and the reduced ability of red blood cells to carry iron to exercising muscles. Iron deficiency can also affect other tissues, including the tongue and fingernails. Prolonged iron deficiency can result in changes of the tongue, which may become smooth, shiny, and reddened, a condition known as **glossitis**. Fingernails may grow abnormally and acquire a spoon-shaped appearance.

Decreased iron intake is a contributing factor in iron deficiency and the resulting iron deficiency anemia. The iron content of some common foods is:

- whole wheat bread (43 mg/kg)
- spinach (33 mg/kg)
- beef (28 mg/kg)
- raisins (20 mg/kg)
- eggs (20 mg/kg)
- lima beans (15 mg/kg)
- potatoes (14 mg/kg)
- canned tuna (13 mg/kg)
- chicken (11 mg/kg)
- peanut butter (6.0 mg/kg)
- tomatoes (3.0 mg/kg)
- cabbage (1.6 mg/kg)
- apples (1.5 mg/kg)
- corn oil (0.6 mg/kg)

It is readily apparent that apples, tomatoes, and corn oil are relatively low in iron, while whole wheat bread, spinach, and beef are relatively high in iron. The assessment of whether a food is low or high in iron can also be made by comparing the amount of that food eaten per day with the recommended dietary allowance (RDA) for iron. The RDA for iron for an adult male is 10 mg/day, while that for an adult woman is 15 mg/day. The RDA during

pregnancy is 30 mg/day. The RDA for infants of 0-0.5 years of age is 6 mg/day, while that for infants of 0.5-1.0 year of age is 10 mg/day. RDA values are based on the assumption that a person eats a mixture of plant and animal foods.

The above list of iron values alone may be deceptive, because bioavailability varies. Bioavailability means the percent of iron in the food that is absorbed via the gastrointestinal tract to the bloodstream. Non-absorbed iron is lost in the feces. The bioavailability of iron in fruits, vegetables, and grains is very low, but is much higher in meats. The bioavailability of iron in plants ranges from only 1-10%, while that in meat, fish, chicken, and liver is 20-30%. The most readily absorbable source of iron is human milk, which has a 50% bioavailability.

Interactions between various foods also influence the absorption of dietary iron. **Vitamin C**, for example, increases the absorption of dietary iron. Thus, if rice is consumed with a vitamin C-rich food such as orange juice, then the absorption of the rice's iron is enhanced. The increased use of formulas fortified with both iron and vitamin C has led to a marked reduction in anemia in infants and young children in the United States. In contrast, if rice is consumed with tea, certain chemicals (tannins) in the tea reduce the absorption of iron. Another potent inhibitor of iron absorption is phytic acid, a chemical that occurs naturally in legumes, cereals, and nuts.

Diagnosis

Iron deficiency anemia in infants is defined as a hemoglobin level below 109 mg/ml of whole blood, and a **hematocrit** of under 33%. Anemia in adult males is defined as hemoglobin under 130 mg/ml and a hematocrit of under 38%. Anemia in adult females is defined as hemoglobin under 120 mg/ml and a hematocrit of under 32%. Anemia in pregnant women is defined as hemoglobin of under 110 mg/ml and a hematocrit of under 31%.

When an abnormally high presence of blood is found in feces during a fecal occult blood test, a physician needs to examine the gastrointestinal tract to determine the cause or source of bleeding. For this, a sigmoidoscope may be used. This is an instrument that consists of a flexible tube with a light at the end and allows an examiner to directly visualize and examine the interior of the large bowel or colon to a distance of 60 cm from the anus. A **barium enema**, with an x ray, may also be used to detect abnormalities that can cause bleeding.

KEY TERMS

Barium—An element used in liquid suspension with radiography (x rays) due to its high contrast with human tissue.

Diverticulitis—A disease caused by abnormal outpocketings in the walls of the intestines.

Ferrous—A form of iron that has two electrons available for chemical reactions and is readily absorbed by humans; ferrous iron is also referred to as reduced.

Gastroenterology—The study of the structures of the gastrointestinal tract, commonly including the stomach, small intestines and large intestines.

Glossitis—A condition of the tongue in which the tongue becomes red, smooth, and shiny.

Hematocrit—The proportion of whole blood in the body, by volume, that is composed of red blood cells.

Heme—A protein comprising most of the mass of red blood cells that transports oxygen and carbon dioxide.

Hemoglobin—An iron-containing protein within red blood cells. Hemoglobin accounts for about 95% of the protein in the red blood cell.

Hypochromic—Having less than normal color.

Microcytic—Cells that are smaller than normal size.

Occult—Hidden or difficult to observe.

Protoporphyrin IX—A protein. Measuring protoporphyrin IX is useful to assess iron status. Hemoglobin consists of a complex of a protein plus heme. Heme consists of iron plus protoporphyrin IX. Normally during the course of red blood cell formation, protoporphyrin IX acquires iron to generate heme. Protoporphyrin IX builds up to abnormally high levels when iron is deficient.

Recommended Dietary Allowance (RDA)—Quantities of nutrients in the diet that are required to maintain human health. RDAs are established by the Food and Nutrition Board of the National Academy of Sciences and may be revised every few years.

Villi—Small, finger-like structures found on the walls of the intestines that are used for the absorption of nutrients.

If evidence suggests that oral iron supplements are failing in treating anemia, a test for oral iron absorption is indicated. The oral iron absorption test is conducted by ingesting 64 mg iron (325 mg ferrous sulfate) in a single dose. Blood samples are then taken after two hours and four hours. The iron content of the person's serum is then measured. If iron absorption is normal, the concentration of iron should rise by an increment of about 22 micro-moles. Smaller increases in concentration mean that iron absorption is abnormal, and that therapy should involve injections or infusions of iron.

Treatment

Oral iron supplements (pills) may contain various chemical compounds containing iron, often called iron salts. Iron salts include ferrous sulfate, ferrous gluconate, or ferrous fumarate. Injections and infusions of iron can be given using a preparation called iron dextran. In patients with poor gastrointestinal absorption of iron, therapy with injection or infusion is preferable over oral supplements. Treatment of iron deficiency anemia sometimes requires more than therapy with iron. If iron deficiency is due to bleeding from hemorrhoids, surgical correction of the hemorrhoids may be essential to prevent recurrent iron deficiency anemia. If iron deficiency is caused by bleeding due to aspirin treatment, aspirin should be discontinued. If iron deficiency is due to hookworm infestations, therapy for this parasite should be given in conjunction with protection of feet by wearing shoes whenever walking in areas that are potentially infested with hookworms.

Prognosis

The prognosis for treating and curing iron deficiency anemia is excellent. One important issue, however, is failure to take iron supplements. Pregnant women may be advised to take 100-200 mg iron/day, a dose that leads to nausea, **diarrhea**, or abdominal **pain** in 10-20% of women. Such a high dosage is recommended to rapidly cure the anemia during pregnancy. Before conception, problems associated with side effects and nonadherence may be avoided by taking iron doses (100-200 mg) only once a week. This can be continued throughout a woman's fertile period. The problem of adherence is not an issue when infusions are used, although a fraction of persons treated with iron infusions experience flushing, headache, nausea, seizures, or **anaphylaxis**.

A number of studies have shown that iron deficiency anemia in infancy can result in reduced intelligence in early childhood. It is not clear whether iron supplementation given to children with reduced intelligence due to

iron-deficiency anemia in infancy has any influence in allowing a “catch-up” in intellectual development.

Health care team roles

Screening for iron deficiency anemia is commonly conducted by nurses and physicians. However, when professionally-trained personnel are not available, other people may be given specific training to administer the screening test. Laboratory technicians process blood samples collected by screening tests. Physicians and nurses administer iron injections or intravenous infusions. Surgeons or physicians trained in gastroenterology perform gastroscopic examinations. Radiologists interpret the results of x rays taken after infusion of a barium enema.

Prevention

In a healthy population, all mineral deficiencies can be prevented by ingesting inorganic nutrients at levels defined by the RDA. Iron deficiency anemia in infants and young children can be prevented by consuming fortified foods. Cow milk-based infant formulas are generally supplemented with iron (12 mg/L). The iron in liquid formulas is added as ferrous sulfate or ferrous gluconate. Commercial infant cereals are also fortified with iron. In addition, small particles of elemental iron may be added to the cereal. The levels used are about 0.5 gram iron/kg dry cereal, an amount about 10-fold greater than what is naturally present.

Iron tests

Definition

Iron tests consist of four assays performed on serum or plasma to aid in the diagnosis and treatment of iron deficiency or iron overload. These tests are serum iron, total iron binding capacity (TIBC), serum ferritin, and serum transferrin. Iron is an essential trace element needed for the production of hemoglobin as well as the function of cytochromes (compound molecules that are important in cell respiration) and certain enzymes. Iron in plasma is almost entirely bound to transport **proteins**. The total iron binding capacity (TIBC) is the maximum amount of iron that these proteins can bind. Transferrin, a beta globulin (molecular weight 75,000) is the principal

transport protein for iron in plasma. Therefore, the TIBC is determined mainly by the concentration of serum transferrin. Iron is stored in the epithelial cells of the gastrointestinal tract and in the reticuloendothelial cells of the **liver**, spleen, and bone marrow. Ferritin is the principal form of storage iron. It consists of a protein (apoferritin) and iron in the form of ferric salts.

Purpose

Serum or plasma iron tests are used for the following purposes:

- To help in the differential diagnosis of **anemias**. **Iron deficiency anemia** is the most common form of anemia worldwide and is quite common in the United States—especially in multiparous females, young children, and persons with chronic intestinal bleeding.
- To assess the severity of anemia and monitor the treatment of patients with chronic anemia.
- To diagnose conditions of iron excess, including iron ingestion, thalassemia, hemosiderosis, and hemochromatosis. Hemosiderosis and hemochromatosis are conditions produced by excessive iron stores in the tissues. Hemosiderosis, which results from repeated **blood** transfusions, is not associated with tissue damage. Hemochromatosis, which is a disorder of iron absorption, can cause painful joints, skin bronzing, diabetes, and liver damage if the iron concentration in the body is not lowered. Hemochromatosis is still underdiagnosed because of its long latency period and lack of awareness on the part of medical professionals.

A serum iron test can be used without the others to evaluate cases of iron **poisoning**.

Precautions

Collection of blood samples

Patients should not have their blood tested for iron within four days of a blood transfusion or tests and treatments that use radioactive materials. Recent high **stress** levels or sleep deprivation are additional reasons for postponing iron tests. Clinicians should ask if patients are taking oral contraceptives or multivitamins, since these may alter results.

Blood samples for iron tests should be taken early in the morning because serum iron levels vary during the day, being higher in the morning and lower at night. This precaution is especially important in evaluating the results of iron replacement therapy.

Hemolysis must be avoided during collection of blood samples to prevent interference with test results from iron in the red blood cells.

Interpretation of test results

Some acute and chronic illnesses can increase the release of ferritin from the body stores, resulting in high serum levels. These disorders include infections, late-stage cancers, lymphomas, and severe inflammations. Alcoholics often have high ferritin levels owing to liver inflammation.

Medications and substances that can cause *increased* serum iron levels include chloramphenicol, estrogen preparations, dietary iron supplements, alcoholic beverages, methyldopa, and birth control pills. Medications that can cause *decreased* iron levels include aspirin, cholestyramine, cortisone, methicillin, and testosterone.

Medications and treatments that can cause *increased* ferritin levels include dietary iron supplements, oral contraceptives, theophylline, and x-ray therapy. Decreases in ferritin levels are seen with antithyroid therapy and high doses of ascorbic acid.

Medications that can cause *increased* transferrin levels include cortisone and cortisol. Those that can cause *decreased* transferrin levels include oral contraceptives and carbamazepine.

Description

Iron tests are performed on samples of the patient's blood, withdrawn from a vein into a vacuum tube. The amount of blood taken is between 6 mL and 10 mL (1/3 of a fluid ounce). The procedure, which is called a venipuncture, takes about five minutes.

Iron level test

The iron level test measures the amount of iron in the blood serum that is being carried by a protein (transferrin) in the blood plasma. Serum iron is most often measured by colorimetric analysis. Iron is deconjugated from the transferrin by adding dilute acid or guanidinium. The iron is reduced to Fe^{2+} by ascorbic acid. The reduced iron forms coordinate bonds with the nitrogen groups (a chromophore) forming a colored complex. The most common chromophore is FerroZine which reacts with Fe^{2+} to form a magenta-colored complex that is measured at 570 nm. Thiourea is added to prevent a reaction between FerroZine and **copper**.

Total iron-binding capacity (TIBC) test

The TIBC test measures the amount of iron that the blood would carry if the transferrin were fully saturated. Since transferrin is produced by the liver, the TIBC can be used to monitor liver function and **nutrition**.

Transferrin test

The transferrin test is a direct measurement of transferrin—which is also called siderophilin—levels in the blood. Transferrin is most often measured by rate immunophelometry. Some laboratories prefer this measurement to the TIBC. The saturation level of the transferrin can be calculated by dividing the serum iron level by the TIBC.

Ferritin test

The ferritin test measures the level of a protein in the blood that stores iron for later use by the body. Ferritin is most often measured by double antibody sandwich immunoassay. It is the most sensitive indicator of iron deficiency because a low serum level reflects depleted body stores. The body stores must be fully depleted before the serum iron becomes low or iron deficiency anemia develops. In persons with acute and chronic illness, however, ferritin levels may not reflect the status of the iron stores since more ferritin escapes into the circulation in these conditions.

Preparation

Iron absorption and **metabolism** are influenced by several factors. These should be identified prior to testing via a medical history that includes the following:

- prescription medications and multivitamins that affect iron levels, absorption, or storage
- blood transfusion within the last four days
- recent extreme stress or sleep deprivation
- recent eating habits

Blood collected for iron level or TIBC tests should be collected following a 12-hour fast. Fasting is not required for serum or plasma ferritin.

Aftercare

Aftercare consists of routine care of the area around the venipuncture.

Complications

The primary complication is the possibility of a bruise or swelling in the area of the venipuncture. The patient can apply moist warm compresses if there is any discomfort.

Results

Iron level test

Normal serum iron values are as follows:

- Adult males: 65-175 micrograms/dL.
- Adult females: 50-170 micrograms/dL.
- Children: 50-120 micrograms/dL.
- Infant: 40-100 micrograms/dL.
- Newborns: 100-250 micrograms/dL.

TIBC test

Normal TIBC values are as follows:

- Adult males: 300-400 micrograms/dL.
- Adult females: 300-450 micrograms/dL.

Transferrin test

Normal transferrin values are as follows:

- Adults: 200-400 mg/dL.
- Children: 203-360 mg/dL.
- Newborns: 130-275 mg/dL.

Normal transferrin saturation values are between 30% and 40%.

Ferritin test

Normal ferritin values are as follows:

- Adult males: 20-300 ng/mL.
- Adult females: 20-120 ng/mL.
- Children (one month): 200-600 ng/mL.
- Children (two to five months): 50-200 ng/mL.
- Children (six months to 15 years): 7-140 ng/mL.
- Newborns: 25-200 ng/mL.

Abnormal test results

Serum iron level is *increased* in thalassemia, hemochromatosis, severe hepatitis, liver disease, lead poisoning, acute leukemia, and kidney disease. It is also increased by multiple blood transfusions and intramuscular iron injections.

KEY TERMS

Anemia—A disorder marked by low hemoglobin levels in red blood cells, which leads to a decrease in the oxygen carrying capacity of the blood.

Chromophore—Any chemical group that produces color in a compound.

Cytochrome—A compound molecule consisting of a protein and a porphyrin ring. Cytochromes participate in cell respiration by electron transfer.

Ferritin—A protein found in the liver, spleen, and bone marrow that stores iron. Ferritin consists of a protein called apoferritin and iron in the form of ferric salts.

Hemochromatosis—A disorder of iron absorption characterized by increased iron absorption and excess deposition of iron in the tissues. It can cause painful joints, pancreatic, heart and liver damage if the iron concentration is not lowered.

Hemolysis—The breakdown of red blood cells with liberation of hemoglobin.

Hemosiderosis—An overload of iron in the body resulting from repeated blood transfusions. Hemosiderosis occurs most often in patients with thalassemia.

Iron poisoning—A potentially fatal condition caused by swallowing large amounts of iron dietary supplements. Most cases occur in children who have taken adult-strength iron formulas. The symptoms of iron poisoning include vomiting, bloody diarrhea, convulsions, low blood pressure, and turning blue.

Plasma—The liquid part of blood.

Siderophilin—Another name for transferrin.

Thalassemia—A hereditary form of anemia that occurs most frequently in people of Mediterranean origin.

Transferrin—A protein in the plasma that carries iron derived from food intake to the liver, spleen, and bone marrow.

Iron levels above 350-500 micrograms/dL are considered toxic; levels over 1000 micrograms/dL indicate severe iron poisoning.

Serum iron level is *decreased* in iron deficiency anemia, chronic blood loss, chronic diseases (lupus, rheumatoid arthritis), late **pregnancy**, chronically heavy menstrual periods, and thyroid deficiency.

Abnormal TIBC test

The TIBC is *increased* in iron deficiency anemia, polycythemia vera, pregnancy, blood loss, severe hepatitis, and the use of birth control pills.

The TIBC is *decreased* in malnutrition, severe **burns**, hemochromatosis, anemia caused by infections and chronic diseases, cirrhosis of the liver, and kidney disease.

Abnormal transferrin test

Transferrin is *increased* in iron deficiency anemia, pregnancy, hormone replacement therapy (HRT), and the use of birth control pills.

Transferrin is *decreased* in protein deficiency, liver damage, malnutrition, severe burns, kidney disease, chronic infections, and certain genetic disorders.

Abnormal ferritin test

Ferritin is *increased* in liver disease, iron overload from hemochromatosis, certain types of anemia, acute leukemia, Hodgkin's disease, **breast cancer**, thalassemia, infections, inflammatory diseases, and hemosiderosis. Ferritin levels may be normal or slightly above normal in patients with kidney disease.

Ferritin is *decreased* in chronic iron deficiency and severe protein depletion.

Health care team roles

Iron tests may be ordered by physicians or by nurse practitioners. Blood samples are usually drawn by nurses or phlebotomists. The samples are analyzed in the laboratory by medical laboratory technicians, with the results returned to the physician.

Patient education

Patients should be informed of any abnormal test results. Health care professionals may refer patients with iron deficiency to a dietitian to discuss nutrition therapy. With regard to excessive iron storage, all health care professionals should monitor patients for signs of hemochromatosis, which is easily treated but fatal if untreated.

Jaundice

Definition

Jaundice is a condition in which the patient has a yellow hue because of high **blood** levels of bilirubin, a breakdown product of hemoglobin that is potentially toxic. The yellow discoloration is most noticeable in the skin, the sclera (whites of the eyes), and the inner surface of the eyelids.

Description

Jaundice is a physical sign or finding, not a disease. Many different diseases or conditions may cause a person's bilirubin level to be elevated. Most important to the understanding of causes of this sign is a good explanation of normal **liver** function with regard to the production and excretion of bile. Bile is a fluid excreted by the liver that aids in digestion and absorption of **fats**.

The liver is a large, solid organ in the right upper quadrant of the abdomen. It is the premier "chemical processing plant" in the body; most incoming and outgoing chemicals pass through it. It is the first stop for all nutrients, toxins, and drugs absorbed by the digestive tract. The liver also collects waste products from the blood for disposal. Many of these outward-bound chemicals (including bilirubin) are excreted into the bile.

Bile is made up of water; chemicals that act as detergents; and substances such as glycogen, bilirubin, cholesterol, and other byproducts of hepatic **metabolism**. It is formed by cellular metabolism and passes into the network of hepatic bile ducts, which join to form the common duct. A branch of this tube carries bile to the **gallbladder**, where it is stored and concentrated. When fats enter the **stomach**, the gallbladder secretes bile into the common bile duct. Before the common bile duct reaches the duodenum, it is joined by another duct from the **pancreas**. The bile and the pancreatic juice are triggered to enter the intestine through a valve called the ampulla of

Vater by the presence of partially digested fats in the duodenum. After entering the intestine, the bile and pancreatic secretions together help to complete the process of digestion.

The liver removes toxins from the bloodstream, including bilirubin. Bilirubin is a potentially toxic waste product from the breakdown of hemoglobin, the oxygen-carrying molecule of red blood cells (RBCs). When bilirubin is first released from old RBCs or other sources, it cannot be dissolved in water. The liver changes it so that it is soluble in water. These two forms are called unconjugated (insoluble) and conjugated (soluble) bilirubin. Because of the type of laboratory test performed on the different forms of this molecule, unconjugated bilirubin is also called indirect bilirubin, and conjugated bilirubin is called direct bilirubin. Bilirubin is a bright yellow pigment and gives bile its characteristic color. If bilirubin cannot be cleared from the body in a timely fashion, it leaks into body tissues and stains them yellow temporarily, resulting in jaundice. The normal level of bilirubin in blood serum is between 0.2 mg/dL and 1.2 mg/dL. When it rises to 3 mg/dL or higher, jaundice becomes evident. "Icteric" is an adjective (based on the Greek word for jaundice) used to describe a jaundiced patient.

Causes and symptoms

There are many different causes of jaundice, but they can be divided into three categories: before, during, or after the liver has performed its task of making bilirubin soluble. These categories can also be called prehepatic, hepatic, and posthepatic causes of jaundice.

Prehepatic causes of jaundice

There are many different prehepatic causes of jaundice. When old RBCs die, hemoglobin is released into the bloodstream. When the rate of formation of new RBCs and the rate of loss of old RBCs are well balanced, the normal liver can keep pace with disposal of used hemoglobin. If the body is having difficulty making

RBCs (due to mineral or vitamin deficiencies), hemoglobin may leak into circulation and overwhelm the liver. Conversely, if RBCs are destroyed rapidly, the liver may also be overwhelmed. Disorders that cause RBCs to disintegrate prematurely are called hemolytic disorders.

One cause of hemolysis (or prematurely destroyed RBCs) to be aware of starts at the neonatal point, in babies born of Rh-negative mothers. Other causes include a long list of drugs, among them rifampin, methyldopa, certain **antibiotics**, quinine, and levodopa. Trauma can also destroy RBCs. Some common causes of trauma include surgery for mechanical **heart** valves, implants, and roughened surfaces of **blood vessels** such as occur in microangiopathic hemolytic anemia. The parasite that causes **malaria** develops inside red blood cells and ruptures the RBCs when it is mature. A number of hereditary defects affect red blood cells, including glucose-6-phosphate dehydrogenase (G6PD) deficiency (in which RBCs disintegrate under certain stresses, particularly when exposed to certain drugs), sickle-cell disease (in which the structure of hemoglobin is abnormal), and spherocytosis (in which a protein in the outer membrane of the RBC causes weakness in the membrane).

An enlarged spleen can also cause hemolysis. The spleen is the reservoir organ, located near the upper end of the stomach, that filters the blood. It is supposed to filter out and destroy only worn-out RBCs. If it becomes enlarged, it filters out normal cells as well. A wide variety of conditions, including many causes of hemolysis listed above, can enlarge the spleen to the point where it removes too many red blood cells. Also, in several types of **cancer** (such as chronic leukemia) and immune-system diseases, antibodies are produced that react with RBCs and destroy them. In addition, if a patient is given an incompatible blood type, it sets off an immune reaction, and hemolysis results.

In all causes of prehepatic jaundice, the predominant bilirubin is insoluble—that is, unconjugated. Hemolysis alone will rarely cause the total bilirubin level to rise above 7 mg/dL.

Hepatic causes of jaundice

Liver diseases of all kinds, whether temporary or life-long, threaten the organ's ability to keep up with bilirubin processing. Some of the more common causes of jaundice include infectious hepatitis (types A, B, C, D, and E, and various other **viruses**), alcoholic hepatitis, and cirrhosis (scarring of the liver, due to various diseases, to the degree that it can no longer function). Starvation, circulating infections, and certain medications (acetaminophen **overdose**, isoniazid, and others) can cause inefficiency in bilirubin disposal. Certain hereditary defects

also affect how the liver processes bilirubin (such as Gilbert's syndrome and Crigler-Najjar syndrome), causing elevated levels of unconjugated bilirubin. Also, there are several inherited conditions in which the liver cannot excrete bilirubin after it is made soluble (such as Dubin-Johnson syndrome and Rotor syndrome), resulting in direct (or conjugated) bilirubin being the predominant form of the molecule. Unlike hemolytic causes of jaundice, which always involve unconjugated bilirubin, the hepatic sources of jaundice often represent mixed results.

Posthepatic causes of jaundice

Posthepatic forms of jaundice include those caused when soluble bilirubin does not reach the intestines after it has left the liver, resulting in elevated direct bilirubin levels. These disorders are called obstructive jaundices. The most common cause of obstructive jaundice is the presence of gallstones in the ducts of the biliary system. Other causes include diseases where the bile ducts have been destroyed, such as the autoimmune disease primary biliary sclerosis, lesions (whether benign or malignant), and trauma. Some drugs (such as anabolic and contraceptive steroids), and occasionally pressures caused by a normal **pregnancy**, cause the bile in the ducts to stop flowing. This process is called cholestasis.

Neonatal jaundice

Several conditions can cause jaundice in a newborn baby. Erythroblastosis fetalis is a disease of newborns marked by the presence of too many immature red blood cells (erythroblasts) in the baby's blood. When a baby and mother have different Rh factors (positive-RH baby and negative-Rh mother), antibodies from the mother may leak into the baby's circulation through the placental exchange and destroy blood cells. This reaction may produce severe hemolysis and jaundice in the newborn. Rh-factor incompatibility is the most common cause. These births are usually induced a week or two early to keep third-trimester hemolysis to a minimum.

Even in the absence of Rh-factor incompatibility, the newborn's bilirubin level may reach threatening levels. Normal newborn jaundice is the result of two conditions occurring at the same time: a prehepatic and a hepatic source of excess bilirubin. During development, the fetal-type hemoglobin is important to extract oxygen from the mother's blood. At birth, the infant extracts oxygen directly from the **lungs** and no longer needs the fetal hemoglobin. So, fetal hemoglobin is removed from the system and replaced with mature hemoglobin. The resulting hemoglobin overload overwhelms the immature system, and bilirubin levels may rise until the third day of

life, and then decline by day five to day 10. During that time, the baby is jaundiced.

These forms of jaundice in the newborn may result in high levels of unconjugated bilirubin. If conjugated bilirubin is found, it is usually due to serious causes, such as obstruction of the biliary system or overwhelming **infection**.

Symptoms

Certain chemicals in bile may cause itching in jaundiced patients. Fatigue is a very common symptom in people with liver disease. In more severe illness, nausea may occur. Poor appetite and weight loss can be a problem for some patients, usually those with acute infection or advanced scarring of the liver (cirrhosis). Depending on the cause of jaundice, patients may or may not have **pain** over the liver (upper right quadrant). Liver pain is common if there are gallstones, and may also occur in acute hepatitis. Patients whose bile does not drain into the **small intestine** adequately will have clay-colored stools. The conjugated form of bilirubin may be excreted by the **kidneys** and result in dark urine. Long-standing jaundice may upset the balance of chemicals in the bile and cause stones to form in the gallbladder or in the ducts.

In newborns, the concern about jaundice is that insoluble or unconjugated bilirubin may get into the **brain** and do permanent damage to the **central nervous system**. This serious condition is called kernicterus. It becomes a concern as bilirubin levels approach 20 mg/dL. Newborns are more likely to have problems with jaundice if they are premature, Asian or Native American, or bruised significantly during the birth process. Jaundice is also more common if a newborn was born after an induced labor, has lost too much weight during the first few days of life, was born at high altitude, or was born to a diabetic mother.

Diagnosis

In most cases, the sign of jaundice is identified based on the appearance of the patient's sclera and complexion. The liver and spleen are palpated to check for enlargement and to evaluate any abdominal pain. The location and severity of abdominal pain and the presence of masses in the abdomen, together with the presence of **fever**, help to distinguish among the causes for jaundice. The differential diagnosis of the cause of jaundice is primarily based on blood-test results.

Laboratory testing reveals the total bilirubin and its components. The capability to evaluate total bilirubin levels and the fractionation into direct (conjugated) and

indirect (unconjugated) components is available in most laboratories. The jaundice may be determined to be of indirect (prehepatic sources, Gilbert's syndrome, or Crigler-Najjar syndrome) or direct (primarily obstructive posthepatic sources, and some hepatic diseases) origin. Liver enzymes, such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT), should be evaluated; elevations would be signs of inflammation or destruction of liver cells. If the AST is at least twice the level of the ALT, this finding strongly supports the suggestion of alcohol abuse as a source of liver disease. If alkaline phosphatase is elevated, this suggests an obstructive (posthepatic) component in the cause of jaundice. Albumin levels and prothrombin times will be abnormal (elevated) if the liver is severely damaged. Microscopic analysis of blood smears for signs of hemolysis is performed.

Liver disease is usually assessed from blood studies and physical-examination findings, but a biopsy may be necessary to clarify less obvious disease. A **liver biopsy** may be performed at the bedside. A thin, cannulated needle is inserted to draw a core of tissue from the liver. The tissue sample is sent for pathologic examination.

Diseases of the biliary system may be identified by imaging techniques, especially with the use of contrast dye. The most common and cost-effective method for beginning to assess the liver and bile ducts is ultrasound. Dilated bile ducts are very suggestive of obstruction, and abnormal amounts of fat or scar tissue may be noticed. Much more detailed information about the structure of the liver and biliary tree is gained with computed tomography (CT) or **magnetic resonance imaging** (MRI). Very detailed investigation of the bile ducts is achieved with endoscopic retrograde cholangiopancreatography (ERCP), for which a fiber-optic scope is put down the gastrointestinal tract via the mouth, all the way to the ampulla of Vater. Dye is injected to map the bile ducts and identify obstruction. A tiny brush-tipped device at the end of the scope light is used to scrape tissue from the duct lining for analysis. Treatment can also be achieved at the same time, as stones can be removed or stents placed to aid in passage of a stone or maintaining bile flow in spite of a tumor.

Treatment

Newborns are the one group of patients in whom the jaundice itself requires attention. Because the insoluble bilirubin can get into the brain, the amount in the blood must not go over certain levels. If there is reason to suspect increased hemolysis in the newborn, the bilirubin level must be measured repeatedly during the first few days of life. If the level of bilirubin shortly after birth

KEY TERMS

Ampulla of Vater—A valve at the distal end of the widened portion of the common bile duct, through which the bile and pancreatic juices enter the duodenum.

Anemia—A condition in which the blood does not contain enough hemoglobin. There are many causes of anemia, including hemolysis, bleeding, and problems producing red blood cells (RBCs).

Biliary system/bile ducts—The gallbladder and the system of tubes that carries bile from the liver into the intestines.

Bilirubin—A breakdown product of hemoglobin that is potentially toxic. The liver collects bilirubin from the bloodstream, alters it, and secretes it into bile.

Hemoglobin—The red pigment in red blood cells that carries oxygen.

Hemolysis—The premature destruction of red blood cells.

Hepatic jaundice—A cause of jaundice; jaundice that occurs while the liver is performing its task of making bilirubin soluble.

Icteric—An adjective, based on the Greek word for jaundice, used to describe a jaundiced patient.

Liver—A large, solid organ in the right upper quadrant of the abdomen that is the body's premier "chemical processing plant" of drugs, nutrients, and toxins.

Neonatal jaundice—Jaundice in a newborn baby, resulting from various conditions.

Pancreas—The organ adjacent to the stomach that produces digestive juices, insulin, and other hormones.

Posthepatic jaundice—A cause of jaundice; jaundice that occurs after the liver has performed its task of making bilirubin soluble.

Prehepatic jaundice—A cause of jaundice; jaundice that occurs before the liver has performed its task of making bilirubin soluble.

Rh incompatibility—When a baby and mother have different Rh factors; a common cause of jaundice in newborns.

Splenectomy—Surgical removal of the spleen, sometimes necessary to control certain types of hemolytic anemia.

threatens to go too high, treatment must begin immediately. Exchanging most of the baby's blood (an exchange transfusion) was the only way to reduce the amount of bilirubin until the late 1960s. Then it was discovered that bright blue light renders the bilirubin harmless. Now jaundiced babies are fitted with eye protection and placed under special lights, wearing only a diaper so that more skin surface can be exposed. The **phototherapy** alters the bilirubin in the blood as it passes through and close to the baby's skin. Under certain conditions, exchange transfusions are still done to rapidly gain control over bilirubin levels.

Most adult patients are treated based on the underlying cause of the jaundice. Surgical removal of the spleen (splenectomy) may arrest hemolytic anemia. Drugs that cause hemolysis or arrest the flow of bile are discontinued or replaced with alternate therapy. The abuse of alcohol or street drugs must stop if the liver is to begin to heal and the jaundice given a chance to subside. Obstructive jaundice frequently requires surgical repair. The gallbladder may need to be removed, or small stones removed from lower in the biliary tract. If there is neoplasm of the liver or biliary tree, partial or total removal is necessary. If the original biliary passageways cannot be restored, new ones are created in surgery.

Prognosis

Prognosis is based on the underlying cause of jaundice. The liver is a very resilient organ, and many patients do well after supportive therapy or surgical intervention for acute causes of jaundice. High bilirubin levels themselves are not dangerous to patients other than neonates, so all symptoms of high bilirubin levels are reversible if the underlying condition is treatable.

Health care team roles

Good supportive care of the jaundiced patient, regardless of the underlying disorder, is important. If alcohol abuse has been an acute or long-standing problem, nursing staff can contribute much in educating the patient about the importance of avoiding alcohol.

Prevention

Many of the numerous causes of jaundice cannot be anticipated or avoided. Alcohol abuse in patients should be identified and support provided to aid in recovery. Erythroblastosis fetalis can be prevented by giving an Rh-negative mother a gamma globulin solution called RhoGAM as a routine part of **prenatal care**. This will decrease the chances her antibody titer will rise against her baby's blood. Liver problems due to medications can

be minimized with appropriate screening blood tests and cessation of the drug if necessary. One cause of liver failure not mentioned previously is anorexia nervosa, in which patients intentionally starve themselves, disabling the body's immune-defense system and overwhelming the liver's ability to detoxify the blood. Patients with this condition need specific psychiatric therapy in addition to adequate nutritional supplementation therapy to prevent liver failure. If it occurs, transplantation may be the only recourse. Malaria may be prevented by taking certain precautions when traveling in tropical or subtropical countries and climates.

Jejunostomy see **Enterostomy**

Joint aspiration see **Joint fluid analysis**

Joint endoscopy see **Arthroscopy**

related abnormalities, such as occur in the knee or elbow. Synovial or joint fluid is an ultrafiltrate of plasma formed in the synovial membrane of movable joints. The fluid lubricates the bone and cartilage tissues of the joint.

Purpose

The purpose of joint fluid analysis is to diagnose arthritis, an inflammation of the joint, and identify its cause. In addition, removal of the fluid can decrease **pain** in the joint. Diseases which may cause joint swelling include rheumatoid arthritis, systemic lupus erythematosus, **gout**, gonococcal arthritis (caused by the **bacteria** that causes gonorrhea), other types of bacterial arthritis, and viral inflammation of the synovial lining.

Precautions

Universal precautions for the prevention of transmission of bloodborne pathogens should be observed when collecting synovial fluid. Arthrocentesis should not be performed on a patient who is uncooperative, especially if the patient cannot or will not keep the joint immobile throughout the procedure. Sampling of a joint may be contraindicated when there is evidence of **infection** in overlying skin or tissue. The joint space should be accessible. Therefore, a poorly accessible joint space, such as in hip aspiration in an obese patient, should not be subjected to this procedure.

Description

Arthrocentesis

The removal of synovial fluid, arthrocentesis, is also called a joint tap, or closed joint aspiration. The procedure is done by passing a needle into a joint space and aspirating synovial fluid using **aseptic technique**. The joint must be cleaned thoroughly with iodine before inserting the needle to prevent any infection. The size of the needle and volume of fluid withdrawn depends on the size of the joint. The patient is asked to lie on their back and remain relaxed. A local anesthetic, typically a **subcutaneous injection** of lidocaine, xylocaine, or ethyl chloride, is then administered. As the needle enters the joint, a "pop" may be felt or heard; this is normal. Correct placement of the needle in the joint space is normally painless. At this point, the clinician slowly drains some of the fluid into the syringe. The syringe may contain a small amount of sodium heparin. The needle is then withdrawn and an adhesive bandage is placed over the puncture site. The sample is transferred to one or more tubes containing liquid heparin or liquid EDTA anticoagulant.

Joint fluid analysis

Definition

Joint fluid analysis, also called synovial fluid analysis, or arthrocentesis, is a procedure used to assess joint-

The procedure takes about 10 minutes. The physician may need to prioritize the tests that he or she orders since fluid yields from this procedure may be very small. Only a drop of fluid is needed for culture and microscopic examination and these two procedures are given top priority because of their diagnostic importance. Some tests, such as glucose and total hemolytic complement must be evaluated with respect to **blood** levels. Therefore, a blood sample should be collected at the same time.

Causes of arthritis

Arthritis can be classified by cause into five categories. Noninflammatory or **osteoarthritis** is the most common form and results from loss of cartilage covering the bone. Inflammatory arthritis results from damage to the joint caused by immune complexes that deposit in the joint or autoantibodies that attach to and destroy the synovial membrane. The most common cause of inflammatory arthritis is rheumatoid arthritis. Septic arthritis is caused by bacterial infection of the joint. The most commonly implicated organism in sexually active persons is *Neisseria gonorrhoeae*. Gout is joint inflammation caused by deposition of uric acid crystals. When other crystals such as **calcium** pyrophosphate are the cause, the condition is called pseudogout. Hemorrhagic arthritis, bleeding into the joint, is caused by trauma, **hemophilia**, or other bleeding disorder such as thrombocytopenia (low platelet count).

Laboratory tests

Laboratory analysis of joint fluid should include determination of color, transparency, volume, and viscosity; red and white blood cell counts with a differential; examination of wet mounts for synovial crystals; microbiological culture; and tests for glucose, total protein, complement, rheumatoid factor, and mucin clot.

Physical characteristics

Normal joint fluid has a volume between 0.15-3.5 mL. An increased volume is common in all five classes of arthritis. The fluid should be clear and pale yellow. Observation of the color of the supernatant after centrifugation helps to discriminate between a hemorrhagic fluid (bleeding from injury to the joint) and a traumatic tap (puncture of a blood vessel during arthrocentesis). Deep yellow or pink fluid points to a hemorrhagic process whereas a normal color points to a traumatic tap. A clot in the fluid also points to a traumatic tap because large protein molecules such as fibrinogen are not found in the fluid. The specific gravity is normally the same as plasma, but the viscosity is much greater. The viscosity is

measured by inserting a wooden applicator stick into the fluid and removing it. The fluid should form a thread of at least 1.6 in (4 cm) at the end of the applicator stick. Failure to do so indicates a low level of mucoprotein which is most common in inflammatory arthritis.

Microscopic analysis

The white blood cell (WBC) count is performed manually using a hemacytometer. The fluid is diluted in saline rather than a WBC counting fluid because the acetic acid will cause the formation of a mucin plug. The normal WBC count is very low, less than 200 per microliter. High counts are seen in septic arthritis, rheumatoid arthritis, and gout. Persons with osteoarthritis or hemorrhagic arthritis may or may not have a high WBC count. The highest counts with neutrophils predominating are associated with septic arthritis.

The normal differential shows 50-65% monocytes with neutrophils and lymphocytes each accounting for less than 25% of the WBCs. Neutrophils above 80% signal septic arthritis. A higher percentage of lymphocytes favors a diagnosis of rheumatoid arthritis. Neutrophils with dark staining cytoplasmic inclusions (ingested immunoglobulins) point to a diagnosis of rheumatoid arthritis. The red blood cell (RBC) count of synovial fluid is also performed manually. The count is normally less than 2000 per microliter. Higher counts especially in the presence of xanthochromia (abnormal color) indicate a synovial hemorrhage.

Microscopic examination of the fluid for crystals requires a polarizing **microscope** with a red compensating filter. This type of microscope transmits light in a single plane through the specimen. An analyzer filter is placed above the specimen before the ocular is aligned, so that it is out of phase with the polarizing filter. The analyzer filter blocks the light transmitted through the specimen, causing a dark background unless the light is rotated by the object on the slide. Uric acid and calcium pyrophosphate are the two most common crystals seen in joint fluid. They both rotate plane polarized light which causes them to be illuminated by the polarizing microscope. However, they can be differentiated using the red compensating filter. Uric acid crystals are seen as yellow needles when the long axis of the crystal is parallel to the slow vibrating light from the filter. Calcium pyrophosphate crystals are blue when the long axis of the crystal is parallel to the slow vibrating light.

Biochemical and immunological tests

Glucose in synovial fluid is normally within 10 mg/dL of the plasma level. Low glucose is seen in septic and rheumatoid arthritis. Very low levels (less than half

of the plasma level) are seen in rheumatoid arthritis. The total protein of synovial fluid is normally below 2.0 g/dL. Increased total protein is seen in rheumatoid and hemorrhagic arthritis. In rheumatoid arthritis, complement will be low owing to chronic consumption and local immunoglobulin production will cause the ratio of synovial to serum IgG to be greater than 0.5. Rheumatoid factor in joint fluid is positive in about 60% of persons with rheumatoid arthritis and in a lesser number of persons with other autoimmune diseases.

The mucin clot test is used to measure the amount of mucin in the fluid. This substance consists of repeating subunits of hyaluronic acid that will cross link forming a mucin clot when acetic acid is added to the fluid. In infection bacterial hyaluronidase may destroy the mucoprotein causing no clot. In rheumatoid arthritis, damage to the synovial cells results in deficient production of mucoprotein and the mucin clot is either absent or easily broken apart.

Microbiological analysis

All samples of synovial fluid should be cultured and Gram-stained. The **Gram stain** results can be definitive for septic arthritis if neutrophils and bacteria are found, but is not always positive. The fluid should be inoculated on blood agar plates; on chocolate (heated blood) agar plates for gonococcus and *Haemophilus*; and in broth such as thioglycolate for the isolation of anaerobic bacteria. *N. gonorrhoeae* is responsible for about 75% of septic arthritis in young and middle aged adults. *Staphylococcus spp.* account for about 75% of septic arthritis in the elderly. *Staphylococcus*, *Streptococcus*, and *Haemophilus* are the most common genera isolated from children.

Preparation

Prior to the procedure, any risks that are involved should be explained to the patient. The patient will be given a local anesthetic but no pain medications or sedatives are required. If the clinician requests a glucose test, the patient will be asked to fast for six to 12 hours before the procedure. If not, there is no special preparation required for a joint fluid analysis.

Aftercare

Some post-procedural pain may be experienced. For this reason, the patient should arrange to be driven home by someone else. Aftercare of the joints will depend on the results of the analysis.

KEY TERMS

Aspirate—The removal by suction of a fluid from a body cavity using a needle.

Bursae—A closed sac lined with a synovial membrane and filled with fluid, usually found in areas subject to friction, such as where a tendon passes over a bone.

Gout—A painful joint disease characterized by the deposition of uric acid crystals in the joint. These crystals cause swelling and redness.

Hematoma—A localized mass of blood that is confined within an organ or tissue.

Hyaluronic acid—A high molecular weight made of carbohydrate and glucuronic acid that is found in high concentrations in the synovial fluid. This provides thickness to the fluid so it can cushion the joint.

Joint—A moveable portion of bone found between two bones.

Lupus erythematosus—A multisystem disease with an autoimmune etiology. Lupus causes problems with the skin, kidneys, joints and the serosal membranes.

Rheumatoid arthritis—A chronic and progressive inflammation of the joints whose cause is unknown.

Synovial fluid—A transparent lubricating fluid secreted in a sac to protect an area where a tendon passes over a bone.

Complications

While joint fluid analysis is generally a safe procedure, especially when performed on a large, easily accessible joint, such as the knee, some risks are possible. Some of the complications to the procedure, although rare, include infection at the site of the needle stick, an accumulation of blood (hematoma) formation, local pain, injury to cartilage, tendon rupture, and nerve damage.

Results

Normal values typical for synovial fluid are shown below:

- Volume: 0.15-3.5 mL.
- Transparency: clear.
- Color: straw or pale yellow.

- Viscosity: 1.6 in (4 cm) thread or greater.
- Mucin clot: firm.
- Glucose: different from plasma by 10 mg/dL or less.
- Total protein: less than or equal to 2.0 g/dL.
- White blood cell count: less than 200 per microliter.
- Differential: less than 25% granulocytes.
- Crystals: negative.

Health care team roles

The removal of synovial fluid from a joint should be done by a physician. Laboratory tests are performed by clinical laboratory scientists/medical technologists. Physicians interpret the results of laboratory tests.

Joint integrity and function

Definition

Joints serve as links between structures; in this case, bones in the human body. There are numerous joints in the body that act to stabilize and control bony segments. One example is the knee joint, which joins the femur and tibia. This joint allows the lower leg to swing freely, but also to be stable during the stance phase of gait. Some joints provide the body with stability, while others provide it with mobility. However, most joints provide both stability and mobility.

Description

There are two major types of joints: synarthroses and diarthroses. Synarthroses are joints connected by fibrous tissue. Diarthroses are synovial joints, where two bones

are bound together by a joint capsule, forming a joint cavity. In synovial joints, there is a nourishing lubricating fluid called synovial fluid.

Function

Synarthroses

There are two types of synarthroses: fibrous joints and cartilaginous joints.

FIBROUS JOINTS. In fibrous joints, bones are united by fibrous tissue. There are three types of fibrous joints: gomphosis, suture, and syndesmosis. A gomphosis joint occurs where one bone fits into another bone. The articulating edges are bound together by connective tissue, and the bony surfaces in the articulation are close together. An example of a gomphosis joint is a tooth in the jawbone. An example of a suture is the fibrous joints between the bones of the **skull** of an infant. Before birth fibrous tissue forms soft spots on the skull, called fontanelles. As growth and development occurs the sutures ossify. A syndesmosis joint connects two bones through connective tissue and is found throughout the human body. An example is the tibio-fibular syndesmosis, the connective tissue that binds the distal ends of the fibula and tibia. A syndesmosis allows the fibula and tibia to work in unison as part of the lower leg. The limited motion available at this joint allows the tibia and fibula to move about each other, yet still function as a unit.

CARTILAGINOUS JOINTS. In cartilaginous joints, bones are connected by either fibrocartilage or hyaline cartilage. There are two types of cartilaginous joints: symphyses and synchondroses. A symphysis is a cartilaginous joint where the connecting entity is fibrocartilage. The symphysis is stable but it allows limited motion. An example of a symphysis joint is the attachment of one vertebra to another by an intervertebral disk, a fibrocartilage ring, in the **vertebral column**. In this symphysis joint only minimal motion occurs between vertebrae, thus maintaining stability. The combination of small movements between each successive vertebral attachment is what allows the vertebral column to flex and extend. A synchondrosis is a joint where the articulating surfaces are close together, yet are bound by hyaline cartilage. An example of a synchondrosis is the two distinct portions of long bone separated by a hyaline cartilaginous plate. This typically occurs at the ends of long bones, where a cartilaginous plate separates the diaphysis from the epiphysis. This plate allows the end of bones to grow throughout early human development. As growth and development continues, the hyaline cartilage ossifies and by adulthood the joint is gone. Another example of a synchondrosis in the human body is the articulation

between the first rib and the manubrium, the upper portion of the sternum.

Diarthroses

A diarthroses has a synovial component. The bones are connected to a joint capsule that surrounds the bones and creates a joint cavity. Ligaments also attach bone-to-bone stabilizing the joint and making the diarthrotic joint stable, yet mobile. Again, the knee joint is a good example of a diarthroses; two bones (tibia and femur) that are attached by ligaments called the anterior and posterior cruciate ligaments. An extensive joint capsule also surrounds the knee joint. In synarthroses there are also disks or menisci that aid in maintaining congruency between bones, i.e., the medial and lateral menisci of the knee joint. Making the diarthroses even more unique from the synarthroses is the addition of synovial fluid. The synovial fluid provides lubrication within the joint. In summary, the diarthroses is complex, with ligaments and capsule providing stability, disks or menisci aiding in congruency, and synovial fluid providing lubrication.

Synovial-type joints can be further classified into three categories: uniaxial, biaxial, and triaxial.

UNIAXIAL JOINTS. Uniaxial joints can be further categorized into hinge and pivot joints. Examples of hinge joints are the joints of the fingers, i.e. interphalangeal joints. An example of a pivot-type joint is the articulation between the axis and atlas in the cervical region, allowing true rotation of the head. In a uniaxial joint the motion is in one plane or is said to have one degree of freedom.

BIAXIAL JOINTS. In a biaxial joint, motion occurs in two planes; thus, there are two degrees of freedom. There are two types of biaxial joints: saddle and condyloid. An example of a saddle joint is the carpometocarpal joint of the thumb, where bones fit together like an individual riding a horse while sitting on a saddle. One bone is concave, the other is convex. Examples of condyloid joints are the metacarpophalangeal joints of the fingers.

TRIAXIAL JOINTS. Triaxial joints have three degrees of motion and can move in three planes. There are two types of triaxial joints: ball and socket, and plane joints. An example of a **ball and socket joint** is the hip. The attachment of the carpal bones in the hand are considered plane joints where gliding is permitted between bones.

Role in human health

Synarthrotic joints allow little or no movement. Their main function is to provide stability, and they also join bones to form a larger unit. Diarthrotic joints provide stability and mobility. Joints can be affected by injury,

increased demand, immobilization, or long-term bed rest, and diseases, such as **osteoarthritis**. Injury can occur if a large stress or load is placed on a joint. Constant excessive loading over time can also cause joint structure to break down. Immobilization or long-term bed rest causes muscles around joints to weaken. Furthermore, joints and articular surfaces need some load, such as gravity, to maintain proper integrity. Over time, if load is not present, articular surfaces will weaken and degenerate due to lack of stimulus. Disease processes such as osteoarthritis can also disrupt the integrity of the joint. All of the above problems can affect joint structure and eventually disrupt functions such as walking. Severe joint degradation can lead to disability.

Common diseases and disorders

Increased demand or trauma placed on a joint can cause tearing or even rupture of the ligaments, joint capsule, or hyaline cartilage. Furthermore, immobilization and disease can degrade the joint surfaces. Any one of these complications can disrupt the integrity of the joint. If the integrity of a joint is compromised, there could be decreased motion at the joint and possibly **pain**. Thus, pain and decreased joint mobility can lead to decreased function and eventual disability.

Other pathologies such as osteoarthritis, rheumatoid arthritis, trauma, and **gout** can all negatively affect joint integrity and function. In the acute phases of gout, joint effusion secondary to injury, and rheumatoid arthritis the joint capsule of diarthroidal joints becomes distended due to over production of synovial fluid. Because of this distention, joint receptors are impaired and may provide inaccurate information on position and movement. Furthermore, there is pain associated with these conditions. If treatment is not effective in reducing pain and inflammation, joint integrity and eventual function will be compromised. In situations where injury has occurred to a joint, such as ligament tear or rupture, the joint is unstable. This instability leads to further stresses placed on other structures within the joint. Eventually, if the ligament is not healed or repaired, further damage to the joint will occur because of the increased demand on other structures. An example is tearing of a ligament in the knee or ankle.

Osteoarthritis is a disease process that negatively affects the integrity and function of a joint. In this degenerative disease the articular surfaces of the joint are degrading. As time passes, the degradation of the joint continues. The most common joints affected by osteoarthritis are the knee and the hip. Conservative treatments such as medications and rehabilitation may be used to decrease pain and restore mobility. However,

KEY TERMS

Diathroses—Synovial joints.

Femur—The large upper bone, also known as the thigh bone.

Gait—Refers to walking, i.e. ambulation.

Gomphosis—A joint where a bony structure is implanted deep into another bony structure. An example would be the joint between a tooth and the mandible (jaw bone).

Immobilization—Keeping a joint from moving, i.e. when an individual breaks the lower leg; a cast may be used that covers the knee, thus preventing motion.

Knee joint—A lower limb joint connecting the tibia to the femur. It allows for straightening and bending of the knee.

Stance phase—The point where, when walking, one foot is in contact with the ground.

Suture—A joint where two bony structures are united by dense fibrous tissue. An example is the sutures of the skull.

Symphyses—Joints where bones are connected by a fibrocartilage disk. An example is the symphysis pubis.

Synchondroses—Joints that connect two bony structures by hyaline cartilage. Examples are the ends of long bones, where the bone growth is not yet complete. As the skeleton matures, the hyaline cartilage eventually ossifies.

Syndesmosis—A joint where two bones are joined by a ligament or membrane. An example is the membrane that joins the shaft of the tibia to the shaft of the fibula in the lower leg.

Tibia—The large lower leg bone between the knee and ankle.

there are instances where conservative treatments fail and joint replacement is a viable option, i.e. total knee arthroplasty.

Joint structures need optimum motion and stress to maintain proper function. Moreover, proper cartilage and joint **nutrition** are required for proper joint function. Therefore, it is important to have synovial fluid maintaining nourishment to the joint surfaces and cartilage in an effort to maintain the integrity of the joint. Since joints are not well supplied by **blood** flow it is important that

movement and weight-bearing are encouraged to promote fluid flow between joint surfaces and disks, i.e., menisci.

Joint mobilization and manipulation

Definition

Joint mobilization is a treatment technique used to manage musculoskeletal dysfunction. Most manipulative and mobilization techniques are performed by physical therapists, and fall under the category of manual therapy.

In most cases, at the end of a long bone there is a joint or articulation. The long bone is attached or joined to another bone by a joint. For example, the femur is attached to the tibia at the knee joint. The knee joint is made up of the surface of the tibia, femur, ligaments, and capsule. Thus, the knee joint is stable and yet mobile. When an individual is sitting in a chair and freely kicks his leg out (knee extension), the tibia moves, while the femur is stationary. However, at the surface of the articulating bones (tibia and femur), there is other movement. This movement is known as slide or glide; some have termed it “joint play.” When an individual kicks his leg out, the lower leg or tibia is not only moving forward, but also gliding across the end of the femur. Mobilization is the treatment technique that involves the clinician applying a force to mimic the gliding that occurs between bones. It is a passive movement, the goal of which is to

produce a slide or glide. Mobilizations are usually completed at slow speed, sometimes with oscillations, and even with a “hold” or stretch. Manipulations are more aggressive, high velocity techniques, or thrusts. They occur very fast, and at the end of available joint play.

Purpose

Mobilizations are used to restore joint play that has been lost due to injury or disease. In order for an individual to kick his leg out, there must be sufficient joint play, or freedom for the tibia to move on the femur. Thus, mobilizations are used when range of motion or mobility is lacking. Furthermore, gentle oscillations within the available joint play range is a technique used to decrease **pain**. Manipulations are quick movements that occur beyond the available joint play range. The purpose of manipulations, or joint thrusts, is to increase the available range if it is not full. Secondly, manipulations are done to break adhesions that disrupt joint movement.

Precautions

Mobilizations and manipulations should not be done in the following circumstances:

- to the spine if there is severe **osteoarthritis** or osteoporosis
- if there is any tumor or malignancy in the area
- to the cervical region if there is dysfunction with the flow of **blood** within the vertebral artery
- if there is bleeding in a joint
- if there is a loose body in the joint
- to total joint replacements
- to joints near a growth plate
- if the joint is degenerative
- until a full diagnosis is reached

Description

Peripheral joint mobilization means mobilizing the joints of the periphery or limbs. There is a grading system for completing mobilizations. The grading system is based on how much joint play is available. Thus, the clinician must know what the total range is by examination through passive movement. Furthermore, there are stretching mobilizations used for **pain management** and stretching. The first common mobilization techniques are sustained joint play movements that have three grades. These mobilizations aid in decreasing pain and increasing mobility.

Grade 1

The clinician applies passive movement in a very small range, approximately 15-25% of the available joint play range.

Grade 2

Bone is passively moved in a moderate range to 50% or half of the available joint play range.

Grade 3

Passive force by the clinician causes one bone to move on the other to the end of the available joint play range.

Within these three grades the stretch or “hold” is approximately five to seven seconds.

The other common mobilization technique is termed oscillatory mobilization. These mobilizations have five grades associated with them. Grades one to two are used to help decrease pain within a joint. Grades three to five are used to increase mobility of joint play. Interestingly, a grade five mobilization is really a manipulation. The following are grades for oscillatory mobilizations:

Grade 1

Slow oscillations within the first 20-25% of the available joint play range.

Grade 2

Slow oscillations within 45-55% of the available joint play range, or from the beginning to the middle of available joint play range.

Grade 3

Slow oscillations from the middle of the available joint play range to the end of available joint play range.

Grade 4

Slow oscillations at the end of the available joint play range.

Grade 5

Bone is passively moved to the end-range, and a fast thrust is performed. This is manipulation.

Preparation

The clinician should be aware of the following prior to performing manipulations:

KEY TERMS

Cryotherapy—Usually an ice or cold treatment after physical therapy treatment.

Femur—The long bone of the thigh which articulates with the hip bone and the tibia.

Knee extension—The act of straightening the knee or kicking the leg out, as in kicking a ball.

Ligaments—Fibrous structures that provide an attachment on bone to bone, and provide stability to joint structures.

Musculoskeletal—Pertains to the muscular and skeletal systems, and the relationship between the two.

Passive movement—Movement that occurs under the power of an outside source such as a clinician. There is no voluntary muscular contraction by the individual who is being passively moved.

Tibia—The larger, longer bone of the lower leg which articulates or joins with the ankle and knee.

- The clinician must use good body mechanics and be comfortable with the patient and the technique.
- The clinician must understand the patient's pain and not proceed if the patient has pain.
- The patient must be comfortable with the clinician, and the procedure must be explained fully to the patient.
- The patient must be relaxed.

Aftercare

Individuals with a chronic joint problem may have Grade 1 and Grade 2 techniques used at the beginning of treatment to decrease pain. Then, after treatment, the patient progresses to more aggressive rehabilitation such as **therapeutic exercise**. At the end of a rehabilitation session, Grades 3 and 4 can be used in conjunction with stretching to increase mobility. In an acute joint pathology, only Grades 1 and 2 should be used. Grades 1 and 2 mobilizations can be used at the beginning of therapy to reduce pain in an effort to increase performance during therapeutic **exercise**. Grades 1 and 2 mobilizations can be used again at the end of the treatment before cryotherapy to help alleviate pain.

Complications

Some complications associated with mobilizations, but more so with manipulations are:

- fracture
- dislocation
- joint capsule tearing
- ligamentous tearing
- muscle or tendon injury
- nerve damage

Results

If done appropriately, mobilizations can help reduce pain and restore joint play, which is critical for normal mobility. Manipulations are beneficial for releasing adhesions and are usually done under anesthesia by a medical physician. Chiropractic manipulations are not discussed here.

Health care team roles

It is important that nurses and other members of the allied health care team be aware of patients who undergo mobilization and monitor pain and any possible inflammation after treatment. Moreover, pain and inflammation may need to be more closely monitored in individuals having manipulation to restore joint mobility. An example of a patient requiring closer monitoring is an individual having manipulation after total knee replacement secondary to increased adhesions and limited range of motion. Today, most manual therapy is done by physical therapists. However, the education for physical therapists to conduct forceful or thrust manipulations continues to grow and is becoming more a part of **physical therapy** education and post education.

Journal therapy

Definition

Journal therapy is the purposeful and intentional use of a written record of one's own thoughts or feelings to further psychological healing and personal growth. It is often used as an adjunct to many **psychotherapy** and recovery programs. Healthcare practitioners maintain that written expression fills a very important role in the therapeutic process by providing a mechanism of emotional expression in circumstances in which interpersonal expression is not possible or viable.

Origins

People have kept journals and diaries to record dreams, memories, and thoughts since ancient times. Emotional expression has also long held a central role in the study and practice of psychology. Throughout history, psychologists have advocated the expression of emotions as essential for good mental and physical health. Since the early 1980s, interest in this topic has resulted in numerous research studies investigating the health benefits of expressive writing.

Benefits

Journal writing produces a number of benefits in healthy people—among other things, it enhances creativity, helps cope with **stress**, and provides a written record of memorable life experiences. Likewise, some researchers have found that journal writing has a number of psychological and physical health benefits for people who are ill.

Aside from a reduction in physical symptoms of disease, the psychological benefits include reconciling emotional conflicts, fostering self-awareness, managing behavior, solving problems, reducing **anxiety**, aiding reality orientation, and increasing self-esteem. Writing therapy has been used as an effective treatment for the developmentally, medically, educationally, socially, or psychologically impaired and is practiced in mental health, rehabilitation, medical, educational, and forensic institutions. Populations of all ages, races, and ethnic backgrounds are served by writing therapy in individual, couple, family, and group therapy formats.

The therapeutic use of expressive writing allows individuals to confront upsetting topics, thus alleviating the constraints or inhibitions associated with not talking about the event. The psychological drain of the inhibition is believed to cause and/or exacerbate stress-related disease processes. Researchers have found that emotional expression facilitates cognitive processing of the traumatic **memory**, which leads to emotional and physiological change. Specifically, written emotional expression promotes integration and understanding of the event while reducing negative emotions associated with it.

Description

Journal writing and other forms of writing therapy are based on the premise that the mind and the body are inseparably joined in the healing process. Although there are many methods of conducting journal writing therapy depending on the therapeutic technique of the psychologist or psychiatrist, the therapist often instructs the participant to write about a distressing or traumatic event or thought in one or more sessions.

Although researchers are uncertain about exactly how writing about traumas produces improvements in psychological well-being, traumatic stress researchers have pointed out that ordinary memories are qualitatively different from traumatic memories. Traumatic memories are more emotional and perceptual in nature. The memory is stored as a sensory perception, obsessional thought, or behavioral reenactment. It is associated with persistent, intrusive, and distressing symptoms, avoidance, and intense anxiety that results in observed psychological and biological dysfunction. Thus, one goal in treating traumatic memories is to find a means of processing them.

A narrative that becomes more focused and coherent over a number of writing sessions is often associated with increased improvement, according to several research studies. The memories become deconditioned and restructured into a personal, integrated narrative. Changes in psychological well-being after writing therapy may result from cognitive shifts about the trauma either during or after the writing process.

Preparations

In a health care setting, the participant often prepares for journal writing by receiving (from the therapist) a set of instructions regarding the length and focus of the writing session or sessions. Other instructions may include writing in a stream-of-consciousness fashion, without censorship or concern about grammar or style.

KEY TERMS

Art therapy—The use of art media to assess and treat an individual's development, abilities, personality, interests, concerns, or conflicts.

Psychodynamic—The scientific study of mental or conditional forces developing especially in early childhood and their effect on behavior and mental states.

Precautions

It is advisable that journal therapy be conducted only by a licensed health professional, such as a certified **art therapy** practitioner or trained psychologist or psychiatrist. While journal writing classes available to the general public may perform a variety of useful functions, these classes are not intended to provide medical therapy. In journal therapy, the participant may, for example, uncover potentially traumatic, repressed, or painful memories. Therefore, a trained health professional may be necessary to supervise the process and treat these symptoms as they arise.

Side effects

There are no known side effects of journal or writing therapy.

Research and general acceptance

Therapeutic writing became an increasingly popular topic in the final decades of the twentieth century, not only among trained health care professionals, but also among self-improvement speakers without medical training. Seminars, workshops, and Internet sites purportedly offering therapy through expressive writing sprang up around the nation and gained popular acceptance. Despite the large body of research indicating that writing confers benefits on healthy people, the topic of writing therapy's effects on diseased individuals has not received a great deal of research attention. Although increasingly used by health care professionals as an adjunct to various therapeutic approaches, the practice has been criticized by some members of the health care community. Some researchers are distrustful of the findings that so much measurable improvement in health status can occur in just a few brief writing sessions.

In the United Kingdom, the focus of journal therapy has been on descriptive accounts and psychodynamic

explanations for subjective improvements in the health status of participants. In the United States, on the other hand, the focus is on formal scientific research aimed at validating the impact of brief, highly standardized writing exercises on physical measures of illness. The research demonstrates that although physical measures of illness may change, the reasons for the change are not always clear.

In the United States, one study on the effects of writing about stressful experiences on symptom reduction in patients with **asthma** or rheumatoid arthritis found that after four months of writing therapy—in conjunction with standard pharmacotherapy—nearly half the patients enrolled in the study experienced clinically relevant improvement. A growing number of studies have documented symptom improvement in patients with psychiatric disorders as well, suggesting that addressing patients' psychological needs produces both psychological and physical health benefits.

Training and certification

Although journal therapy is often provided by certified instructors who receive variable amounts of training in a number of programs around the country, journal therapy is best administered by a licensed psychologist (who may also be an art therapist) or psychiatrist.

Educational, professional, and ethical standards for art therapists who conduct writing therapy are regulated by The American Art Therapy Association, Inc. The American Art Therapy Credentials Board, Inc., an independent organization, grants postgraduate supervised experience. A registered art therapist who successfully completes the written examination administered by the Art Therapy Credentials Board qualifies as Board Certified (ATR-BC), a credential requiring maintenance through continuing education credits.

Kidney function tests

Definition

Kidney function tests are a cadre of tests that are used to screen for and manage renal disease. Tests commonly used for this purpose are plasma creatinine, **blood urea nitrogen (BUN)**, electrolytes, and routine **urinalysis**. Additional laboratory tests are performed to evaluate abnormal renal function and help differentiate between causes. The most commonly used follow-up tests are creatinine clearance, plasma and urine osmolality, and urine sodium.

Purpose

Renal function tests are used to screen for renal disease, to differentiate the cause of renal disease, and to determine the extent of renal dysfunction. These tests attempt to define the clinical state of renal dysfunction and not the process of injury. The latter is determined primarily by a combination of clinical data and biopsy to determine the histological pattern of injury.

Precautions

A complete history should be taken prior to kidney function tests to assess the patient's symptoms and food and drug intake. A wide variety of prescription and over-

the-counter medications can affect blood and urine kidney function test results, as can some food and beverages. Renal function tests are performed on both blood and urine. Blood samples are collected by venipuncture from a vein in the crease of the arm. The nurse or phlebotomist performing the procedure should observe **universal precautions** for the prevention of transmission of blood-borne pathogens. The creatinine clearance test requires a timed urine sample. Explicit written instruction must accompany the explanation of how to collect this sample. It is imperative that the patient empty his or her bladder at the start of the test and not include this urine in the collection. It is equally important that all urine produced during the time of the test be saved and refrigerated, and that the bladder be emptied completely and this urine added to the collection at the end of the test.

Description

The **kidneys** are a pair of organs located in the back of the abdominal cavity on either side of the **vertebral column**. Their purpose is to filter the blood and remove wastes and excess water. They also selectively reabsorb compounds that have been filtered, thus conserving essential nutrients, electrolytes, amino acids and other biomolecules. Approximately one-quarter of the cardiac output, 1200 mL of blood per minute are received by the kidneys. Each kidney is made up of functional microscopic units called nephrons. Each nephron contains a capillary tuft, the glomerulus and a tubule. Blood flows into the kidneys, and engorges the capillary tufts. Water and small solutes pass through the vessel walls forming a filtrate of the plasma which enters the underlying space, Bowman's capsule. The walls of the capsule form a tubule that traverses the kidney. Blood leaves the glomerular capillaries through an efferent arteriole which forms a capillary network, the vasa recta, that follows the path of the tubules. The cells of the renal tubule modify the filtrate along its length ultimately forming urine that passes out of the body. The tubule is responsible for two processes, reabsorption and secretion. Reabsorption is

the process of moving solutes from the tubular lumen into the interstitium that bathes the tubules, so that they can be absorbed by the vasa recta. Some substances such as glucose and sodium are one-hundred percent reabsorbed until the plasma level exceeds a certain concentration called the renal threshold. Secretion is the process of transporting solutes from the interstitium into the tubular lumen, so that they can be excreted in the urine. Secretion allows substances such as hydrogen ions to be eliminated at a rate that exceeds glomerular filtration. These processes are controlled by the selective permeability of different segments of the tubule to water, salt and urea, and the response of the distal collecting tubules to hormones such as aldosterone, antidiuretic hormone, and parathyroid hormone.

When kidney function becomes compromised by disease, the processes of glomerular filtration and tubular reabsorption and secretion become affected to different extents. This can result in retention of waste products that are incompletely filtered, loss of essential solutes that are not reabsorbed, and failure of the tubules to respond to hormonal control of electrolyte and water balance. Blood and urine biochemistry tests reflect the extent of this dysfunction and are used to characterize the clinical state of the patient. Fortunately, the kidneys have a large reserve capacity, and a significant amount of damage must be incurred before kidney function tests become significantly abnormal.

There are several renal states that can be categorized by renal function test results, but the two major ones are acute and chronic renal failure. Renal failure is a term used to describe a loss of renal function characterized by uremia, the retention of nitrogenous wastes in the blood. The acute form is rapid in onset and often reversible. It can occur as three different states, termed prerenal, renal (intrarenal), and postrenal failure. Prerenal failure results from decreased blood flow to the kidneys, and its most common cause is congestive **heart failure**. Renal failure results from injury to the glomerulus and the tubules. The most common causes are glomerulonephritis which is mediated by autoantibodies that damage the glomerulus and obstruct the tubules; pyelonephritis which is caused by a bacterial **infection** of the interstitium; and tubular damage caused by drugs, heavy metals, and viral infections. Post renal failure is caused by obstruction below the kidneys. This can result from urinary tract stones, tumors, or anatomic obstruction as in benign prostatic hypertrophy. The chronic form is characterized by slow onset without accompanying symptoms in its early stage. Chronic renal failure often follows episodes of acute renal failure, and it is not reversible. Chronic renal failure is most commonly a sequela to acute glomerulonephritis or pyelonephritis which together account for

more than half the cases. Other causes of chronic renal failure are chronic diseases such as **diabetes mellitus**, renal vascular disease (e.g., atherosclerosis of the renal vessels), **hypertension**, polycystic kidney disease, drug damage, and **kidney stones**. Kidneys from patients with chronic renal failure will appear smaller than average and a biopsy of the kidney will demonstrate scarring of the tubules.

Laboratory tests

Regardless of the cause, most persons with acute renal failure are characterized by three common laboratory findings: reduced creatinine clearance, azotemia (excessive nitrogen compounds in the blood), and hyperkalemia (excessive potassium in the blood). Creatinine is a waste product of muscle **metabolism**. It is produced at a constant rate and filtered freely by the glomeruli without reabsorption. Therefore, creatinine levels in the blood are increased when there is reduced glomerular filtration. Although specific for glomerular disease, plasma creatinine is not a sensitive test, and about 60% of the renal capacity is usually lost before levels become abnormal. A more sensitive indicator of glomerular dysfunction is the creatinine clearance test. This test measures the ratio of urine to plasma creatinine. As plasma levels rise, urine levels fall causing the ratio to decrease before plasma creatinine becomes definitively abnormal.

CREATININE CLEARANCE TEST. The creatinine clearance is defined as the volume of plasma that contains the same amount of creatinine as is excreted in the urine in one minute. Because the tubules do not reabsorb creatinine, all of the creatinine filtered by the glomeruli in a given amount of time is excreted in the urine. This test is an estimate of the glomerular filtration rate. The test is performed by measuring creatinine in a timed urine specimen—a cumulative sample collected over a four, 12, or 24-hour period. Determination of the plasma creatinine is also required to calculate the urine clearance. The clearance formula is $U/P \times V \times 1.73/A$. “U” is the urine creatinine in gm/dL; “P” is the plasma creatinine in mg/dL; and “V” is the volume of urine produced per minute. This is usually calculated by dividing the volume of urine produced per day by 1440 minutes per day. “A” is the person’s body surface area expressed in square meters, and 1.73 is the average body surface area in square meters. During the test, the patient must be well hydrated because under conditions of slow filtrate flow the tubules will secrete some creatinine causing an overestimate of clearance. Creatinine can be measured by a colorimetric method called the Jaffe reaction or by a coupled enzymatic reaction. The Jaffe reaction is performed by mixing a plasma or diluted urine sample with a solution of sodium hydroxide and saturated picric acid. At an

alkaline pH, the creatinine combines with picric acid to form creatinine picrate and the rate of absorbance change is measured over a precisely defined timed interval to eliminate interference from **proteins** and other reducing agents

Azotemia is the accumulation of nitrogenous (azo)waste products in the blood as a consequence of renal failure. The azo compounds routinely measured are creatinine, urea, and uric acid. While an increase of plasma urea or uric acid is not specific for renal disease, both compounds are retained whenever there is a reduction in the glomerular filtration rate. Of the two compounds, urea is the more sensitive, and urea levels can be used with creatinine to help differentiate prerenal and renal failure.

BLOOD UREA NITROGEN (BUN) TEST. Historically, urea concentration has been expressed as the concentration of nitrogen derived from urea, called the BUN. This test is performed by an enzymatic-ultraviolet photometric method using the enzyme urease. The enzyme catalyzes the hydrolysis of urea by water forming ammonia and carbon dioxide. A coupling enzyme, glutamate dehydrogenase, catalyzes the formation of glutamate from alpha-ketoglutarate and ammonia. In this reaction NADPH is converted to NADP⁺ which causes a decrease in the absorbance of 340 nm light. The rate of absorbance decrease is proportional to the urea nitrogen concentration of the sample. Urea is freely filtered by the glomerulus but is reabsorbed by the tubules to a variable extent depending upon the movement of filtrate through the tubule. When filtrate flow is slow, 40% or more of the filtered urea can be reabsorbed. For this reason, BUN levels increase much more than creatinine in prerenal failure. In prerenal failure, the kidney is not damaged, but glomerular filtration is reduced because of insufficient blood flow to the glomeruli. This results in increased retention of all three azo compounds. However, poor renal blood flow is a stimulus for ADH secretion that promotes water and urea reabsorption. Since the tubules are undamaged, they reabsorb a maximal amount of urea. This causes the ratio of plasma BUN to creatinine to increase dramatically. The reabsorption of BUN is impaired in renal failure caused by renal damage because the tubules are impaired. Ratios in prerenal failure are approximately 20:1, twice that seen in renal failure caused by damaged kidneys.

Electrolyte disturbances are common to all forms of renal failure. Potassium is filtered by the glomerulus and partly reabsorbed in the proximal tubule. A significant amount of potassium is secreted by the collecting tubule in response to aldosterone. Therefore, when the kidneys receive insufficient blood flow potassium is incompletely filtered. When the tubules are damaged, potassium lev-

els rise further because the exchange of potassium for sodium is impaired.

Plasma potassium levels must be maintained within a very narrow range to avoid cardiac arrhythmia. Elevated plasma potassium is the single most important (life-threatening) consequence of renal failure. Plasma potassium is the criterion used to determine the need for dialysis and the frequency and duration of treatment. Urine sodium is very useful in helping to differentiate prerenal from renal failure. In prerenal failure, the daily excretion of sodium is lower than normal because the kidneys attempt to reabsorb sodium in order to restore blood flow. However, in renal failure, daily urine sodium loss is increased owing to tubular failure. Urinary sodium is about twofold higher in intrarenal failure than in prerenal failure.

Urinalysis

There are a variety of urine tests that assess kidney function. A simple, inexpensive screening test, routine urinalysis, is often the first test administered when kidney problems are suspected. A first-morning or randomly voided urine sample is examined visually for color and clarity, and a series of up to ten dry reagent strip biochemical tests are performed. Protein, blood, leukocytes, and specific gravity are four tests that are often abnormal in persons with renal failure. Glomerular damage causes albumin and red blood cells to pass through the basement membrane and enter the filtrate in Bowman's space. Leukocytes migrate to the site of injury and enter the filtrate through glomerular lesions and by passing between the tubular cells. Tubular failure disables the concentrating and diluting capacity of the kidneys and the urine produced is consistently of the same specific gravity as the plasma (1.010). Glucose and pH are also useful because a high percentage of diabetics develop renovascular disease, and renal failure results in acidosis (hydrogen ion retention) with concomitant failure to acidify the urine. While these findings can occur in severe lower urinary tract disease, the renal origin of the cells can often be confirmed by microscopic analysis of urinary sediment. In renal injury, stasis, protein, and obstruction of the tubules by cells cause the precipitation of mucoproteins in the tubules. When these are washed out by urine flow, they can be seen using the **microscope**, and are called casts. The finding of cellular casts in the urinary sediment, identifies the kidney as the source of the cells. Experienced technologists can often distinguish glomerular bleeding from bleeding below the kidney because the former causes characteristic abnormalities in red blood cell structure (dysmorphic cells). Furthermore, the presence of cells and casts signifies renal damage and

KEY TERMS

Blood urea nitrogen (BUN)—The nitrogen portion of urea in the bloodstream. Urea is a waste product of protein metabolism in the body.

Creatinine—The metabolized by-product of creatine, an organic compound that assists the body in producing muscle contractions. Creatinine is found in the bloodstream and in muscle tissue. It is removed from the blood by the kidneys and excreted in the urine.

Creatinine clearance rate—The clearance of creatinine from the plasma compared to its appearance in the urine. Since there is no reabsorption of creatinine, this measurement can estimate glomerular filtration rate.

Diuretic—A drug that increases the excretion of salt and water, increasing the output of urine.

Glomerular filtration rate—The rate in milliliters per minute at which plasma is filtered through the glomerular membrane.

Hematuria—The presence of blood in the urine.

Nephrologist—A doctor specializing in kidney disease.

Nephron—The functional unit of the kidney.

Oliguria—The formation of very small amounts of urine.

Osmolality—A measurement of urine concentration that depends on the number of particles dissolved in it. Values are expressed as milliosmols per kilogram (mOsm/kg) of water.

Polyuria—The formation of very large amounts of urine.

Proteinuria—The presence of protein in the urine often caused by damage to the glomerular membrane.

Renal—Pertaining to the kidney

Specific gravity—The ratio of the weight of a body fluid when compared to water.

Urea—A by-product of protein metabolism that is formed in the liver. Because urea contains ammonia, which is toxic to the body, it must be quickly filtered from the blood by the kidneys and excreted in the urine.

Uric acid—A product of purine breakdown that is excreted by the kidney. High levels of uric acid, caused by various diseases, can cause the formation of kidney stones.

Urine—A fluid containing water and dissolved substances excreted by the kidney.

rules out prerenal failure as the cause of abnormal biochemistry results.

Glomerulonephritis is the most common cause of intrarenal failure. Urinary sediment in this condition displays large numbers of both red and white blood cells, and usually a predominance of red blood cell casts. Pyleonephritis, the second most common renal disease is characterized by a predominance of white blood cells and white blood cell casts. **Bacteria** are usually abundant in the sediment signaling the causative infection.

Postrenal failure may also result in abnormal sediment. The presence of large numbers of crystals in association with biochemical evidence of worsening renal function and hematuria may alert the clinician to the presence of a urinary tract stone. The presence of large numbers of abnormal (cancerous) transitional epithelial cells may be shed into the urine by a bladder tumor and seen in the urine microscopic exam. In such cases, an imaging test, the intravenous pyelogram, is often per-

formed in order to identify the size, location, and possible cause of the obstruction.

OSMOLALITY. Urine osmolality is a measure of the number of dissolved particles in urine. It is a more precise measurement than specific gravity for evaluating the ability of the kidneys to concentrate or dilute the urine. Kidneys that are functioning normally will excrete water in relation to the amount consumed. Those with failing kidneys may not be able to concentrate urine. Solutes will equilibrate by passive diffusion in the tubule and the osmolality will be the same as plasma, approximately 290 mOsm/Kg water. The test may be done on a urine sample collected first thing in the morning as water deprivation overnight should concentrate the urine; multiple timed samples, or on a cumulative sample collected over a 24-hour period. In addition, the ratio of urine to plasma osmolality is another useful way to differentiate prerenal and intrarenal failure. In prerenal failure the kidneys attempt to restore blood volume by reabsorbing sodium. This raises the plasma osmolality causing release of

antidiuretic hormone (ADH) from the posterior pituitary. Under the influence of ADH, the tubules reabsorb more water concentrating the urine. As mentioned, the plasma and urine osmolality are the same in intrarenal disease. The urine to plasma osmolality ratio in prerenal failure is usually twofold higher than in renal disease, in which the ratio is one.

The acute and chronic forms of renal failure display some distinguishing characteristics. In chronic renal failure, the tubules become scarred causing water loss. This results in polyuria (increased urine volume) as opposed to oliguria (low urine volume) seen in acute renal failure. Scarring also results in salt wasting causing the serum potassium to be lower than seen in acute renal failure. The urinary sediment shows heavy proteinuria, hematuria (red blood cells) and abundant casts. The casts are usually broad and waxy, which are unique characteristics of end-stage renal failure.

OTHER BLOOD TESTS. Measurement of the blood levels of other analytes regulated or affected in part by the kidneys can be useful in evaluating kidney function and in managing conditions such as osteomalacia and renal acidosis that are secondary to renal disease. These include bicarbonate, **calcium**, magnesium, **phosphorus**, **plasma renin activity**, and parathyroid hormone.

Preparation

Patients will be given specific instructions for collection of urine samples, depending on the test to be performed. During routine urinalysis, the patient will be given a sealed cup to urinate into. Nurses stress that the patient obtain a “clean catch” by initiating urination and placing the sample cup in the urine stream after a few seconds. This prevents the collection of the initial urine which may contain bacteria that are present in the lower urethra or on the skin. Some timed urine tests require an extended collection period of up to 24 hours, during which time the patient collects all urine voided and transfers it to a specimen container. Refrigeration and/or preservatives are typically required to maintain the integrity of such urine specimens. Certain dietary and/or medication restrictions may be imposed for some of the blood and urine tests. The patient may also be instructed to avoid **exercise** for a period of time before a test to prevent changes in creatinine.

Aftercare

If medication was discontinued prior to a kidney function test, it may be resumed once the test is completed.

Complications

Complications for these tests are minimal, but may include slight bleeding from a venipuncture site, hematoma (accumulation of blood under a puncture site), or fainting or feeling light-headed after venipuncture. In addition, suspension of medication or dietary changes imposed in preparation for some blood or urine tests may trigger side-effects in some individuals.

Results

Normal values for many tests are determined by the patient’s age and sex. Reference values can also vary by laboratory, but are generally within the ranges that follow.

Urine tests

- **Creatinine clearance.** For a 24-hour urine collection, normal results are 90-139 mL/min for adult males less than 40 years old, and 80-125 mL/min for adult females less than 40 years old. For people over 40, values decrease by 6.5 mL/min for each decade of life.
- **Urine osmolality.** With restricted fluid intake (concentration testing), osmolality should be greater than 800 mOsm/kg of water. With increased fluid intake (dilution testing), osmolality should be less than 100 mOsm/kg in at least one of the specimens collected. A 24-hour urine osmolality should average 300-900 mOsm/Kg. A random urine osmolality should average 500-800 mOsm/Kg.
- **Urine protein.** A 24-hour urine collection should contain no more than 150 mg of protein.
- **Urine sodium.** A 24-hour urine sodium should be within 75-200 mmol/day.

Blood tests

- **Blood urea nitrogen (BUN)** should average 8-20 mg/dL.
- **Creatinine** should be 0.8-1.2 mg/dL for males, and 0.6-0.9 mg/dL for females.
- **Uric acid levels** for males should be 3.5-7.2 mg/dL and for females 2.6-6.0 mg/dL.

Low clearance values for creatinine indicate diminished ability of the kidneys to filter waste products from the blood and excrete them in the urine. As clearance levels decrease, blood levels of creatinine, urea, and uric acid increase. Since it can be affected by other factors, an elevated BUN, by itself, is suggestive, but not diagnostic, for kidney dysfunction. An abnormally elevated plasma creatinine is a more specific indicator of kidney disease than is BUN.

Inability of the kidneys to concentrate the urine in response to restricted fluid intake, or to dilute the urine in response to increased fluid intake during osmolality testing indicates decreased tubular function. Because the kidneys normally excrete almost no protein in the urine, its persistent presence, in amounts that exceed the normal 24-hour urine value, usually indicates glomerular or tubular injury. These can be distinguished by urine protein electrophoresis. This procedure separates proteins in an electric field based upon their charge. Albuminuria is characteristic of glomerular disease, while urinary excretion of alpha-1 and beta-2 microglobulins is characteristic of tubular damage. Proteinuria of tubular origin is caused by drugs, heavy metals, or viral infection of the kidneys. Urine protein electrophoresis also detects monoclonal immunoglobulin light chains (multiple myeloma and related conditions) and immunoglobulin fragments (systemic autoimmune diseases), which are nonrenal causes of proteinuria.

Health care team roles

Kidney function tests are ordered and interpreted by a physician. Blood samples are collected by a nurse or phlebotomist. Nurses should educate the patient on why the tests are being done and how to collect timed urine samples. In addition, patients with kidney disease may be advised to change their diets. A dietitian may be consulted.

Patient education

Some kidney problems are the result of another disease process such as diabetes or high **blood pressure**. Clinicians should take the time to inform patients about how their disease or its treatment will alter kidney function and the different measures they can take to help prevent these changes.

Jane E. Phillips, PhD

Kidney radionuclide scan

Definition

A kidney radionuclide scan, also called a kidney scan or renal scan, is a diagnostic imaging test that involves administering a small amount of radionuclide, also called a radioactive tracer, into the body and then imaging the **kidneys** with a gamma camera. The images obtained can help in the diagnosis and treatment of various kidney diseases and conditions.

Purpose

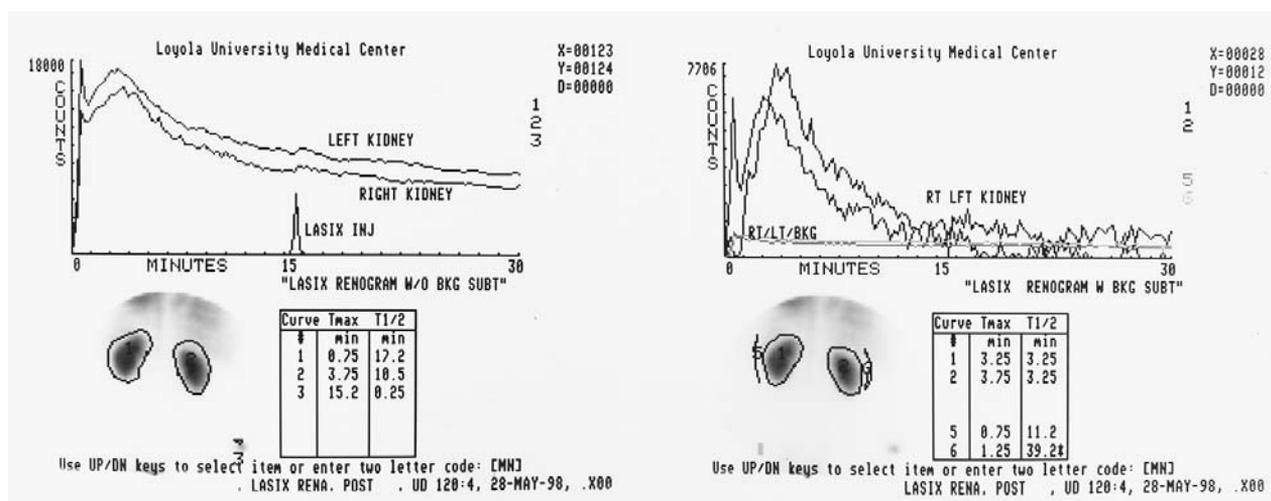

While many tests—such as x rays, ultrasounds, or computed tomography (CT scans)—can reveal the structure of the kidneys, the kidney radionuclide scan is unique in that it also reveals how the kidneys are functioning. Candidates for a kidney scan may include patients who have acute or chronic renal failure, obstruction in their **urinary system**, renal artery stenosis, kidney transplant, trauma to the kidney, reflux nephropathy, renal vascular disorders and/or **hypertension**, or congenital abnormalities.

Precautions

A kidney scan requires the use of a radioactive material; therefore, patients who are pregnant or suspect they may be pregnant are cautioned not to have the test unless the benefits outweigh the risks. Women should inform their doctor if they are breast feeding. The doctor will recommend the woman stop breast feeding for a specified period of time, depending on the particular tracer and dose used.

Description

Kidney scans are performed either in a hospital nuclear medicine department or in an outpatient radiology or nuclear medicine facility. The patient is positioned in front of, or under, a gamma camera—a special piece of equipment that detects the radiation emitted from the body and produces an image. An intravenous injection of the radionuclide is administered. Immediately after the injection imaging begins, and, in most studies, the flow of **blood** to each kidney is evaluated. Serial images of the kidneys are obtained over a specified period of time, depending upon the particular radiopharmaceutical used. Kidney scans may be performed to determine the rate at which the kidneys are filtering a patient's blood. These studies use a radiopharmaceutical called technetium DTPA (Tc99m DTPA). This radiopharmaceutical also can identify obstruction in the renal collecting system. To

A computer-generated time activity curve generated from a renal scan. This time activity curve looks at the radiation count over a period of time. (Photograph by Collette Placek. Reproduced by permission.)

establish the function of the renal tubules, the radiopharmaceutical Technetium DMSA (Tc99m DMSA) is used.

A kidney scan ranges from 45 minutes to three hours in length, depending upon the goals of the test, but the test typically takes about an hour to an hour and a half. It is important to understand that kidney scans can reveal an abnormality, but they do not always identify the specific problem. They are very useful in providing information about how the various parts of the kidneys function, which, in turn, can assist in making a diagnosis.

Typically, posterior images are obtained but images are also obtained at oblique angles. If indicated, the patient may be positioned so that mobility of the kidney is demonstrated by sitting up or lying down for the images. If obstruction or renal function is being evaluated, a diuretic (drug to induce urination), such as Lasix, may be injected. If hypertension or renal artery stenosis is being evaluated, Captopril or Enalapril (ACE inhibitors) may be injected.

Preparation

No special preparation is necessary for a kidney scan. In some instances the patient may be required to drink additional liquids and to empty their bladder before the exam. If another nuclear medicine study was recently performed, the patient may have to wait for a specified period to avoid any interference from residual radioactivity in the body. The patient is instructed to remove metal items from the area to be scanned.

Aftercare

Patients can resume their normal daily activities immediately after the test. Most radioactive tracers are

excreted through the urinary system, so drinking fluids after a kidney scan can help flush the tracer out of the body more quickly.

Complications

Nuclear medicine procedures are very safe. Unlike some of the dyes that may be used in x-ray studies, radioactive tracers rarely cause side effects. There are no long-lasting effects of the tracers themselves, because they have no functional effects on the body's tissues. If pharmaceuticals are injected these can temporarily raise or lower **blood pressure**, or cause one to urinate.

Results

The scan should reveal normal kidney function for the patient's age and medical status, as well as show normal relative position, size, configuration, and location of the kidneys. Initial blood flow images should reflect that blood circulation to both kidneys is equal. Patients whose images suggest a space-occupying lesion or obstruction may require other imaging procedures, such as CT or ultrasound, to provide more information. Also, if the kidneys appear to be abnormal in size, have an unusual contour, or are unusually positioned, other imaging procedures may be required.

Health care team roles

Kidney scans are performed by a nuclear medicine technologist trained in handling radioactive materials, operating the equipment, and processing data obtained during the procedure. The technologist is responsible for explaining the test to the patient, obtaining pertinent

KEY TERMS

medical history, and administering injecting the radionuclide. All data collected is submitted either to a doctor who is a nuclear medicine specialist or a radiologist for interpretation. Patients obtain the results of the study from their primary care physician or the physician who ordered the study.

Kidney stone analysis *see* **Stone analysis**

Kidney stones

Definition

Kidney stones are solid accumulations of material that form in the tubal system of the kidney. Kidney stones cause problems when they block the flow of urine through or out of the kidney. When the stones move along the ureter (the tube that connects the kidney and the urinary bladder), they cause severe **pain**.

Description

Urine is formed by the **kidneys**. **Blood** flows into the kidneys, and specialized tubes (nephrons) within the kidneys allow a certain amount of fluid from the blood, and certain substances dissolved in that fluid, to flow out of the body as urine. However, sometimes tiny crystals may form in the urine, meet, and cling together to create a larger solid mass called a kidney stone. A kidney stone is also called a nephrolith or urolith (nephro refers to the kidney, uro refers to urine, and lith means stone).

Many people do not ever find out that they have stones in their kidneys. These stones are small enough to allow the kidney to continue functioning normally, never causing any pain. These are called silent stones. Kidney stones cause problems when they interfere with the normal flow of urine. They can block (obstruct) the flow down the tube (the ureter) that carries urine from the kidney to the bladder. When pressure in the kidney builds from backed-up urine, the kidney may swell (hydronephrosis). If the kidney is subjected to this pressure for some time, it may cause damage to the delicate kidney structures. When the kidney stone is lodged further down the ureter, the backed-up urine may also cause the ureter to swell (hydroureter). Because the ureters are muscular tubes, the presence of a stone will make these muscular tubes spasm, causing severe pain.

About 10% of all people will have a kidney stone in their lifetime. Kidney stones are most common among:

- Caucasians
- males
- people over the age of 30
- people who previously have had kidney stones
- relatives of persons with kidney stones

Causes and symptoms

Kidney stones can be composed of a variety of substances. The most common types of kidney stones include:

- **Calcium** stones. About 80% of all kidney stones fall into this category. These stones are composed of either calcium and phosphate, or calcium and oxalate. People with calcium stones may have other diseases that cause them to have increased blood levels of calcium. These diseases include primary parathyroidism, sarcoidosis, hyperthyroidism, renal tubular acidosis, multiple myeloma, hyperoxaluria, and some types of **cancer**. A diet heavy in meat, fish, and poultry can cause calcium oxalate stones.

- **Struvite stones.** About 10% of all kidney stones fall into this category. This type of stone is composed of magnesium ammonium phosphate. These stones occur most often when persons have had repeated urinary tract infections with certain types of **bacteria**. These bacteria produce a substance called urease, which increases the pH of urine, making urine more alkaline and less acidic. This chemical environment allows struvite to precipitate in the urine, forming stones.
- **Uric acid stones.** About 5% of all kidney stones fall into this category. Uric acid stones occur when increased amounts of uric acid circulate in the bloodstream. When the uric acid content becomes very high, it can no longer remain dissolved. Molecules of uric acid precipitate out of the urine. A kidney stone is formed when these bits of uric acid begin to cling to each other within the kidney, slowly growing into a solid mass. About half of all persons with this type of stone also have deposits of uric acid elsewhere in their body, commonly in the joint of the big toe. This painful disorder is called **gout**. Other causes of uric acid stones include **chemotherapy** for cancer, certain bone marrow disorders where blood cells are over-produced, and an inherited disorder called Lesch-Nyhan syndrome.
- **Cystine stones.** About 2% of all kidney stones fall into this category. Cystine is a type of amino acid. People with this type of kidney stone have an abnormality in the way their bodies process amino acids in the diet.

People who have kidney stones usually do not have symptoms until the stones pass into the ureter. Prior to this, some individuals may notice blood in their urine. Once the stone is in the ureter, however, most people will experience bouts of very severe pain. The pain is crampy and spasmodic, and is referred to as colic. The pain usually begins in the flank region, the area between the lower ribs and the pelvis. As the stone moves closer to the bladder, a person will often feel the pain radiating along the inner thigh. In women, the pain may be felt in the vulva. In men, the pain may be felt in the testicles. Nausea, vomiting, extremely frequent and painful urination, and obvious blood in the urine are common. **Fever** and chills usually mean that the ureter has become obstructed, allowing bacteria to become trapped in the kidney causing a kidney **infection** (pyelonephritis).

Diagnosis

Diagnosing kidney stones is based on a person's history of the very severe, distinctive pain associated with the stones. Diagnosis includes laboratory examination of a urine sample and an x-ray examination. During the passage of a stone, examination of the urine almost always reveals blood. A number of x-ray tests are used to diag-

X ray of kidney stone. (Custom Medical Stock Photo. Reproduced by permission.)

nose kidney stones. A plain x ray of the kidneys, ureters, and bladder may or may not reveal the stone. A series of x rays taken after injecting iodine dye into a vein is usually a more reliable way of seeing a stone. This procedure is called an intravenous pyelogram (IVP). The dye highlights the **urinary system** as it travels through it. In the case of an obstruction, the dye will be stopped by the stone or will only be able to get past the stone at a slow trickle.

When a person is passing a kidney stone, it is important that all of the urine is strained through a special sieve. This is to ensure that the stone is caught. The stone can then be sent to a special laboratory for analysis so that the chemical composition of the stone can be determined. After the kidney stone has been passed, other tests will be required to understand the underlying condition that may have caused the stone to form. Collecting urine for 24 hours, followed by careful analysis of its chemical makeup, can often determine a number of reasons for stone formation.

Treatment

A person with a kidney stone will say that the most important aspect of treatment is adequate pain relief. Because the pain of passing a kidney stone is so severe, narcotic pain medications such as meperidine or morphine are often required. It is believed that stones may pass more quickly if a person is encouraged to drink large amounts of water (2–3 quarts, or 1.8–2.8 liters, per day). If an individual is vomiting or unable to drink because of the pain, it may be necessary to provide fluids through a vein. If symptoms and urine tests indicate the presence of infection, **antibiotics** will be required.

Although most kidney stones will pass on their own, some will not. Surgical removal of a stone may become necessary when a stone appears too large to pass. Surgery

KEY TERMS

Hydronephrosis—Swelling of a kidney due to elevated pressure from excess fluid accumulation.

Hydroureter—Swelling of a ureter due to elevated pressure from excess fluid accumulation.

Lithotripsy—Technique that uses focused sound waves to pulverize kidney stones, thus avoiding surgery.

Nephron—Tube within the kidney that processes filtrate from the blood, reclaiming some substances and creating urine.

Pyelonephritis—Infection of the kidney.

Ureter—Tube that connects the kidney and urinary bladder, whose function is to transport urine.

may also be required if the stone is causing serious obstructions, pain that cannot be treated, heavy bleeding, or infection. Several alternatives exist for removing stones. One method involves inserting a tube into the bladder and up into the ureter. A tiny basket is then passed through the tube, and an attempt is made to snare the stone and pull it out. Open surgery to remove an obstructing kidney stone was relatively common in the past, but current methods allow the stone to be crushed with shock waves (called **lithotripsy**). These shock waves may be aimed at the stone from outside of the body by passing the necessary equipment through the bladder and into the ureter. The shock waves may be aimed at the stone from inside the body by placing the instrument through a tiny incision located near the stone. The stone fragments may then pass naturally or may be removed through the incision. All of these methods reduce an individual's recovery time considerably when compared to the traditional open operation.

Alternative treatment

Alternative treatments for kidney stones include the use of herbal medicine, **homeopathy**, acupuncture, **acupressure**, hypnosis, or guided imagery to relieve pain. Starfruit (*Averrhoa carambola*) is recommended to increase the amount of urine a person passes and to relieve pain. Dietary changes can be made to reduce the risk of future stone formation and to facilitate the resorption of existing stones. Supplementation with magnesium, a smooth muscle relaxant, can help reduce pain and facilitate stone passing. Homeopathy and herbal medicine, both western and Chinese, recommend a number of remedies that may help prevent kidney stones.

Prognosis

A person's prognosis depends on the underlying disorder causing the development of kidney stones. In most cases, people with uncomplicated calcium stones will recover very well. About 60% of these individuals, however, will have other kidney stones. Struvite stones are particularly dangerous because they may grow extremely large, filling the tubes within the kidney. These are called staghorn stones and will not pass out in the urine. They will require surgical removal. Uric acid stones may also become staghorn stones.

Health care team roles

A physician makes an initial diagnosis of kidney stones. A radiologist confirms the diagnosis. A surgeon is needed to operatively remove a kidney stone. A technician performs a lithotripsy under the supervision of a physician.

Prevention

Prevention of kidney stones depends on the type of stone and the presence of an underlying disease. In almost all cases, increasing fluid intake so that a person consistently drinks several quarts of water a day is an important preventive measure. Persons with calcium stones may benefit from taking a medication called a diuretic, which has the effect of decreasing the amount of calcium passed in the urine. Eating less meat, fish, and chicken may be helpful for individuals with calcium oxalate stones. Other items in the diet that may encourage calcium oxalate stone formation include beer, black pepper, berries, broccoli, chocolate, spinach, and tea. Uric acid stones may require treatment with a medication called allopurinol. Struvite stones will require removal and an affected person should receive an antibiotic. When a disease is identified as the cause of stone formation, treatment specific to that disease may lessen the likelihood of repeated stones.

L. Fleming Fallon, Jr., M.D., Dr.P.H.

Kidney, ureter, and bladder x-ray study

Definition

A kidney, ureter, and bladder (KUB) x ray is an AP (anteroposterior) abdominal x ray. Despite its name, KUB does not show the ureters and only sometimes shows the **kidneys** and bladder and, even then, with uncertainty.

Purpose

The KUB is used to detect **kidney stones**, **foreign bodies** in children, and to diagnose some gastrointestinal disorders. It is also used as a preliminary film for an intravenous pyelogram and **barium enema**, or as a follow-up x ray after the placement of devices such as ureteral stents and nasogastric or nasointestinal tubes (feeding tubes). It may also be requested in the operating room to detect sponges or clamps before the patient's incision is closed and would be done with the portable x-ray machine.

Precautions

Because of the risks of radiation exposure to the fetus, pregnant women are advised to avoid this x-ray procedure.

A KUB study is a preliminary screening test for kidney stones, and should be followed by a more sophisticated series of diagnostic tests [such as an **abdominal ultrasound**, **intravenous urography**, or computed tomography scan (CT scan)], if kidney stones are suspected.

Description

A KUB is typically a single x-ray procedure. The patient lies supine (face-up) on the x-ray table and may flex the knees if it is more comfortable. The x-ray technologist centers on the iliac crest, making sure the pubic

KEY TERMS

Pubic symphysis—The line of fusion between the pubic bones.

Ureteral stent—A surgical device implanted in patients with damaged ureters that holds the ureter open so that urine can flow freely from the kidneys to the bladder.

symphysis will be visualized. The collimation may be reduced to the ASIS (anterior superior iliac spine) for better detail of the kidney outline, ureter and bladder, especially during an intravenous pyelogram. The radiographic technique of the film should demonstrate peritoneal fat lines, psoas muscles, and both renal (kidney) outlines. The patient is asked to hold his or her breath on expiration. Sometimes a second film is obtained with the patient standing.

Preparation

A KUB study requires no special diet, fluid restrictions, medications, or other preparation. The patient is typically required to wear a hospital gown or similar attire. A lead apron can not be used since it will obstruct necessary structures of the abdomen.

Aftercare

No special aftercare treatment or regimen is required for a KUB study.

Complications

The KUB study is an x-ray procedure, so it does involve minor exposure to radiation.

Results

Normal KUB x-ray films show two kidneys of a similar size and shape, no renal calculi (stones), and a normal bowel gas pattern.

Abnormal KUB films may show calculi (kidney stones). If both kidneys are visible, it may be possible to diagnose renal size discrepancies. The film may also demonstrate an increase in bowel gas, indicating a possible bowel obstruction. In this case an additional film of the abdomen should be done either upright or in a lateral decubitus position. Soft tissue masses may also be visualized on a KUB.

Health care team roles

The x-ray technologist must confirm with the emergency physician that just a KUB is necessary to complete a diagnosis instead of a complete abdominal series. When a KUB is done with the mobile x-ray machine all staff remaining in the room must receive lead shielding. All radiographical technologists must be certified and registered with the A.S.R.T. and continue to upgrade and maintain their certification with ongoing education credits.

Patient education

The x-ray technologist must advise the patient to remain still and follow breathing instructions so that a detailed image of the abdomen may be taken.

Kidneys

Definition

The kidneys maintain body fluid volumes and **blood pressure**, filter **blood**, and contribute to waste removal by producing urine.

Description

The kidneys are two bean-shaped organs that sit just below the rib cage on either side of the **spinal cord**. Each is about the size of a bar of soap. At any one time 20–25% of the body's blood flows through them, even though they comprise only 0.5% of the body's total weight. At this rate, the kidneys filter the entire blood supply 60 times per day.

Blood flows into the kidney through the renal artery and exits through the renal vein. Within the kidney are many small capillaries that perfuse it with blood, giving the organ its reddish-brown color.

The gross anatomy of the kidney can be divided into four parts:

- **Capsule:** A thin but tough outer membrane that protects the kidney against **infection** and trauma.
- **Cortex:** The outer layer of the kidney's interior, about 1 cm (0.4 inch) thick.
- **Medulla:** The inner layer of the kidney's interior, which contains triangular structures called renal pyramids. Between pyramids are sections of cortex called renal columns.
- **Renal pelvis:** A large funnel for collecting urine from all parts of the kidney, connected to the bladder by the ureter.

Each cortex and medulla together contain about a million nephrons, microscopic filtering systems that are the basic unit of each kidney. Each nephron has two main components. The first is a vascular system that includes 1) the glomerulus, 2) afferent and efferent arterioles, and 3) peritubular capillaries. The second, tubular component contains five main parts: Bowman's capsule, proximal tubule, loop of Henle, distal tubule, and the collecting duct.

Bowman's capsule forms one end of each nephron. It contains a bundle of tiny capillaries called the glomerulus, which receives its bloodflow from the afferent arteriole. The glomerulus filters **minerals**, nutrients, wastes, and water from the blood that flows through it, and passes them down into the proximal tubule. The glomerulus also returns large plasma **proteins** and red blood cells to the blood supply through the efferent arteriole. The efferent arteriole is connected to a second capillary bed called the peritubular capillaries. These two successive capillary beds create a pressure difference that forces fluid through the nephron.

Once filtrate enters the proximal tubule, specialized cells reabsorb sodium and other ions, water, glucose, and amino acids back into the blood. The fluid then goes into the loop of Henle, which helps concentrate the waste products to be excreted in urine. After the loop of Henle, fluid then flows into the highly coiled distal tubule, where potassium is secreted and more water and sodium are reabsorbed back into the blood. The fluid then flows into the last part of the nephron, the collecting duct, where final adjustments are made to the urine concentration. The collecting ducts respond to the antidiuretic hormone (ADH), which regulates the amount of water reabsorbed by the blood. The urine then flows through the renal pelvis to the ureter, which delivers urine to the bladder for excretion.

Function

By filtering the blood, the kidneys play a very important role in the body. They adjust the water volume,

remove wastes such as urea, ammonia, and drugs, establish **acid-base balance**, determine the composition of blood, help maintain blood pressure, stimulate the production of red blood cells, and determine **calcium** levels.

The maintenance of water volume is a particularly important function. When the body sweats on a hot day or during **exercise**, it needs a way to sense water loss to avoid **dehydration**. Water volume is monitored by specialized osmoreceptors in the hypothalamus that measure sodium concentration in the blood. A high sodium concentration means there is insufficient water; this signals the hypothalamus to increase ADH secretion, which in turn prevents the kidneys from reabsorbing water from the blood in the collecting ducts. If the sodium concentration is low, there is too much water in the blood, so the hypothalamus reduces ADH secretion, which tells the kidneys to increase the water concentration of the urine.

The kidneys are also crucial in removing waste products such as urea, ammonia, and any chemical compounds such as medications from the blood. For this reason patients with damaged kidneys must be monitored closely when they take medications that are excreted in the urine. If the kidneys are not working properly, drug concentrations in the blood could rise to fatal levels.

In addition, the kidneys play a pivotal role in the body's acid-base balance. The blood's pH is maintained by a fixed ratio of hydrogen-to-bicarbonate ions in the blood. If the number of hydrogen ions increase, then the blood becomes acidic, a condition known as acidosis. Likewise, if the number of sodium bicarbonate ions rise, the blood becomes basic, a condition known as alkalosis. The kidneys help sustain this hydrogen-to-bicarbonate ratio by adjusting the amount of bicarbonate in the blood. If the blood is too basic the proximal and distal tubules of the kidney will decrease bicarbonate reabsorption and more bicarbonate will be excreted into the urine. If the blood is acidic, then the proximal tubule will allow reabsorption of bicarbonate back into the blood and excrete more hydrogen into the urine.

Another major task the kidneys perform is to help maintain blood pressure. Kidney cells can recognize when a drop in blood pressure occurs, because when this happens, blood flow to the kidney decreases. This means less sodium is present in the kidney cells, a condition that causes the kidney cells to release an enzyme called renin. Renin converts angiotensin I into angiotensin II, which in turn constricts **blood vessels** and causes sodium retention by the kidneys, thereby raising blood pressure. This is known as the renin-angiotensin system. Angiotensin II also causes the **adrenal glands** to release the hormone aldosterone, which tells the kidneys to allow more sodium and water to be reabsorbed back into the blood. This

KEY TERMS

Adrenal gland—Small gland on top of each kidney that produces and releases several different hormones that are involved in maintaining internal fluid and salt levels and also mediates stress responses.

Angiotensin I—Inactive form of angiotensin that circulates in the blood; it is a precursor of angiotensin II.

Angiotensin II—Active form of angiotensin that constricts blood vessels, thus raising blood pressure.

Capillary—Small blood vessel that is the point of connection for blood and veins and where exchanges occur between the blood and tissue.

Hydronephrosis—Distention of the renal pelvis that occurs when urine is trapped in the kidney and blocked from flowing into the bladder.

Ureter—Carries urine from the kidney to the bladder.

increase in water volume in the blood increases blood pressure. Many medications for high blood pressure act by working on the kidneys to decrease blood volume and therefore blood pressure. These blood pressure medications are collectively known as diuretics.

Role in human health

The kidneys play a crucial role in human health because they perform many vital functions. The kidneys work constantly, simultaneously, and influence each other. Individuals are born with two kidneys but can function with one. However, a person with kidney function at 10–15% of capacity will require dialysis or a kidney transplant to sustain life. Individuals with high blood pressure and diabetes have a significant risk of kidney disease.

Common diseases and disorders

Diabetic nephropathy

Diabetic patients cannot process blood glucose properly, and if their disease is untreated or poorly controlled, it can lead to high blood sugar levels. This can damage the nephrons, leading to diabetic neuropathy. This usually means that soft kidney tissue hardens and thickens, a process called sclerosis; this is especially true for the glomerulus. The American Diabetes Association esti-

mates that 35–45% of type 1 diabetics and 20–30% of type 2 diabetics have damaged kidneys. Because the symptoms of nephropathy may not appear until 80% of kidney function is gone, periodic tests of kidney function and strict compliance with diet and treatment regimens are important for patients with diabetes.

High blood pressure

The kidneys use small blood vessels called capillaries to filter blood and to help create a pressure gradient to move fluid through the nephron. Continuous high blood pressure can damage the fragile walls of these vessels. When this happens, blood may not filter properly, allowing waste products and/or drug levels to build up, sometimes to dangerous or fatal levels.

Kidney stones

Kidney stones occur when crystals form in the lumen of the tubules or in the ureters. The stones are most commonly made of calcium and oxalate or phosphate. The basis of stone formation is not clear but certain foods in certain people can cause them to accrete. **Kidney stones** can be extremely painful, and can also cause hydronephrosis. Patients with kidney stones are encouraged to drink plenty of water in effort to have the stone excreted in the urine. In some cases, kidney stones must be surgically removed.

Polycystic kidney disease

Polycystic kidney disease (PKD) is an inherited disease in which cysts form in the kidney. These fluid-filled cysts can take over a significant amount of space in the kidney, eventually reducing kidney function and causing kidney failure. Most cases of PKD show no symptoms until the patient is well into adulthood. PKD that appears in children is often more virulent, frequently leading to kidney failure and death. **Nutrition** and dietary modification play a major role in controlling the progression of PKD.

Wilms' tumor

Wilms' tumor, or nephroblastoma, is a **cancer** of the kidney that appears during childhood. Both sporadic cases and a few rare inherited cases have been linked to mutations in the Wilm's tumor gene (WT1) on chromosome 11. Many cases of Wilms' tumor are curable if caught early enough.

KOH test

Definition

The KOH (potassium hydroxide) test is the microscopic examination of a skin, nail, or hair sample for the presence of a fungus that infects these structures. The test takes its name from the chemical formula for potassium hydroxide (KOH), the substance used in the test to clear skin cells, protein, and cellular debris, making the **fungi** easier to observe. A sample from the infected area is analyzed under a **microscope** following the addition of a few drops of potassium hydroxide. A stain may be added to make the fungi more easily visible.

Purpose

The KOH test is used for the rapid, differential diagnosis of infections produced by dermatophytes from skin disorders such as eczema and psoriasis which may appear similar. Dermatophytes are a type of fungus that invade the skin, hair, or nails, and produce an **infection** commonly called ringworm (tinea). There are three genera of fungi commonly implicated in human skin, nail, and hair infections. These are *Trichophyton spp.* (found in skin, nail, and hair infections), *Epidermophyton spp.* (skin and nail infections), and *Microsporum spp.* (skin and hair infections). The KOH test may also be used on scrapings from the mouth or vagina for the rapid identification of *Candida spp.*, the cause of yeast infections of the mouth (thrush) and the vagina (vaginitis). If a dermatophyte or yeast infection is found, antibiotic treat-

ment can be started immediately, and further testing is not usually required. The KOH prep cannot identify the specific causative organism. When fungus is found, the specimen can be submitted for **fungal culture** to identify the causative agent(s).

Precautions

There are no specific precautions for patients who require this test. Health care professionals who perform this test should be properly trained in skin scraping, nail, and hair follicle removal procedures, the identification of fungi and yeasts by microscopy, and the safe handling of specimens.

Description

Ringworm of the skin produces red or gray, scaly patches of itchy skin. Hair infection results in brittle hair shafts that fall out easily. Deeper infections may be ulcerative, discolored, and purulent. The health care provider selects an infected area from which to collect the sample. A scalpel or edge of a glass slide is used to gently scrape skin scales from the infected area. For hair samples, a forceps is used to remove hair shafts and follicles from the infected site. If the test is to be performed immediately, the scrapings are placed directly onto a microscope slide and are covered with 10% or 20% potassium hydroxide. If the test will be sent to a laboratory, the scrapings are placed in a sterile covered container for later testing.

After adding KOH, the slide should be allowed to stand for five minutes in order to dissolve skin cells, hair, and debris. If the sample remains unclear after five minutes, it may be left for an additional five to 10 minutes. Dimethyl sulfoxide can be added to the KOH to enhance clearing, and lactophenol cotton blue stain can be added to make the fungi easier to see. The slide may be gently heated to enhance the digestive action of the KOH. If a fluorescent microscope is available, calcofluor white stain may be added to the KOH preparation. This will cause the fungi to become fluorescent, making them easier to identify.

Dermatophytes are easily recognized under the microscope by their long branch-like tubular structures called hyphae. Fungi causing ringworm infections produce septate (segmented) hyphae. Some show the presence of spores formed directly from the hyphae (arthroconidia). Yeast infections of the skin can also be identified by the KOH test. Yeast cells appear round or oval and budding forms may be seen.

Fungal infections of the skin are described by the site of infection. Tinea cruris is a fungal infection occur-

KEY TERMS

Tinea—A superficial infection of the skin, hair, or nails, caused by a fungus and commonly known as ringworm.

ring in the groin or inner thigh, tinea pedis on the feet, tinea capitis on the scalp and hair, and tinea unguium on the nails. Tinea versicolor refers to a fungal infection of the skin caused by *Malassezia furfur*. This organism cannot be cultured, and is recognized by characteristic yellowish skin patches and the microscopic appearance of the organism. The fungus produces curved hyphae and round yeast forms that give it a spaghetti-and-meatball appearance under the microscope.

Preparation

There is no special preparation for the patient prior to sample collection.

Aftercare

The patient will experience slight discomfort from sample collection. The skin site or area exposed when the nail is removed may need to be covered by a gauze bandage.

Complications

There are usually no complications for the patient associated with this test.

Results

A normal, or negative, KOH test shows no fungi (no dermatophytes or yeast). Dermatophytes or yeast seen on a KOH test indicate the patient's symptoms are caused by a fungal infection. Follow-up tests are usually unnecessary.

Health care team roles

Physicians, nurses, or physician assistants usually collect the skin, nail, or hair samples from the patient. The KOH test procedure may be performed by the physician or by a clinical laboratory scientist/medical technologist. If fungal cultures are required, they are performed by a clinical laboratory scientist/medical technologist who specializes in microbiology.

Patient education

The health care professional who collects the sample also explains the testing procedure to the patient, and explains why the test is required. The physician or nurse will also explain the treatment regimen, as well as the importance of adhering to the treatment as required, if a fungal infection is diagnosed.

Lactation

Definition

Lactation is the medical term used for breastfeeding. It also specifically refers to the synthesis and secretion of milk.

Purpose

Breastfeeding provides a baby with **nutrition** in the form of breast milk. Not only does breast milk contain all the nutrients needed by a rapidly developing newborn, but it also contains antibodies that provide the baby with additional protection from common early childhood diseases.

Precautions

Most common illnesses can not be transmitted via breast milk. However, some **viruses**, including HIV (the virus that causes **AIDS**) can be passed in breast milk; for this reason, women who are HIV-positive should not breastfeed.

Many medications have not been tested in nursing women, so it is not known if these drugs can affect a breast-fed child. A nursing woman should always check with her doctor before taking any medications, including over-the-counter drugs.

These drugs are not safe to take while nursing:

- radioactive drugs for some diagnostic tests

- chemotherapy drugs for **cancer**
- bromocriptine
- ergotamine
- lithium
- methotrexate
- street drugs (including **marijuana**, heroin, amphetamines)
- tobacco

Description

Early in a woman's **pregnancy** her milk-producing glands, called mammary glands, begin to prepare for the baby's arrival and by the sixteenth week of pregnancy the breasts are ready to produce milk. Shortly after the baby is born, the expulsion of the placenta triggers hormone shifts in the woman's body to activate lactation. The levels of the hormones estrogen and progesterone fall abruptly while the level of the hormone prolactin—the main hormone involved in the biosynthesis of milk—increases. The anterior **pituitary gland** secretes prolactin during lactation in very large quantities so that by 36 to 96 hours postpartum the woman's milk volume has dramatically increased. Subsequently, the volume of milk the mother produces levels off and the removal of milk becomes the predominant factor in regulating milk production.

Another hormone called oxytocin controls the release of milk from the breasts. The baby's sucking stimulates nerve endings in the nipple, which signal the mother's pituitary gland to release the oxytocin. This is called the "let-down reflex." While the baby's sucking is the primary stimulus for the reflex, a baby's cry, thoughts of the baby, or the sound of running water also may trigger the response.

Breast milk cannot be duplicated by artificial milk, although both contain protein, fat, and **carbohydrates**. Breast milk changes to meet the specific needs of a baby.

Breastfeeding is healthy for both mother and baby. (Photograph by J.M. Trois. Science Source/Photo Researchers. Reproduced by permission.)

In particular, the mother produces milk called colostrum at the end of pregnancy and in the initial postpartum period. Colostrum is called “first milk” and is thicker than mature milk. It is yellowish in color and is rich in **proteins**, many of which are immunoglobulins that can protect the child against illness and **allergies**. Immunoglobulins are part of the body’s natural defense system against infections and other agents that can cause disease. Breast milk also helps a baby’s own **immune system** mature faster. As a result, breast-fed babies have fewer ear infections, bouts of **diarrhea**, rashes, allergies, and other medical problems than bottle-fed babies do.

There are many other benefits to breast milk. Because it is easily digested, babies do not get constipated. Breast-fed babies have fewer speech impediments due to good cheekbone development and jaw alignment.

Breastfeeding is also good for the mother. It releases hormones that stimulate the uterus to contract, helping the uterus to return to normal size after delivery and reducing the risk of bleeding. The act of producing milk burns calories, which helps the mother to lose excess

weight gained during pregnancy. Breastfeeding also may be related to a lower risk of **breast cancer**, ovarian cancer, and cervical cancer.

Breast milk is free, and saves money by eliminating the need to buy artificial milk (formula), bottles, and nipples. Because breast-fed babies overall have fewer illnesses, their health care costs may be lower.

Breastfeeding should begin as soon as possible after birth and should continue every two to three hours. However, all babies are different; some need to nurse very frequently at first, while others can go much longer between feedings. A baby should be fed at least eight to 12 times in 24 hours. Because breast milk is easily digested, a baby may be hungry again as soon as one and one-half hours after the last meal. Frequent nursing will also help in increasing milk production.

Some babies have no trouble breastfeeding, while others may need some assistance. Once the baby begins to suck, the mother should make sure that most of the areola is in the baby’s mouth. Proper latching-on will help stimulate milk flow and will prevent nipple soreness.

Breastfeeding mothers should offer the baby both breasts at each feeding. Breastfeeding takes about 15-20

minutes on each side. After stopping the feeding on one side, the mother should burp the baby before beginning the feeding on the other breast. The next feeding should begin with the breast that the baby nursed on last.

Mothers can tell if the baby is getting enough milk by checking diapers; a baby who is wetting between four to six disposable diapers (six to eight cloth) and who has three or four bowel movements in 24 hours is getting enough milk.

Preparation

Loose, front-opening clothes and a good nursing bra are recommended. Mothers should find a comfortable chair with lots of pillows, supporting the arm and back, to nurse in. Feet should rest on a low footstool with knees raised slightly. The baby should be level with the breast. The new mother may have to experiment with different ways of holding the baby before finding one that is comfortable for both the mother and baby.

Complications

Breastfeeding problems

New mothers may experience breastfeeding problems, including:

- **Engorged breasts.** Breasts that are too full can prevent the baby from sucking. Expressing milk manually or with a breast pump can help, as can warm showers and compresses.
- **Sore nipples.** In the early weeks nipples may become sore and even cracked. Treatments include changing the position that the baby nurses in, ensuring that the baby has latched on to most of the areola, and using lanolin-based lotion on the nipples. Nipple shields are sometimes effective as a short-term remedy but their use may reduce milk supply, further irritate the breast, and change the baby's sucking pattern.
- **Inverted nipples:** A mother with inverted nipples may still breastfeed in most instances. The baby should be enticed to open the mouth widely before latching on. The mother can use various techniques to evert the nipple such as wearing a breast shell between feedings, rolling the nipple, pulling the nipple out, and applying a breast pump on the breast for a few seconds before starting the breastfeeding session.
- **Infection.** Soreness and inflammation on the breast surface or a **fever** in the mother, may be an indication of a breast infection called **mastitis**. **Antibiotics** and

Suggestions for breastfeeding women who work outside the home

Stay at home as long as possible, and work part-time, if possible.
 Try taking a few hours away from the baby to anticipate problems.
 Have an extra set of towels, an extra bra, and a change of clothes at the work site.
 Take a quart of liquid to work and remember to drink it frequently.
 When choosing a pump, consider portability as well as cost and comfort.
 Practice with a pump ahead of time to get used to it and so that the milk will let-down quickly.
 If working full-time and manual expression or a manual pump is objectionable or does not work well, rent a dual hook-up electric pump to keep at work.
 Find a place at work to feel comfortable and have some privacy while pumping, and have a backup place in mind as well.
 If the baby will be in day care, be certain the day care provider is supportive of breastfeeding.
 Arrange to nurse the baby during the day if possible.
 Arrive early at the day care provider's site to nurse the baby right before going to work to help the baby settle down and allow time for talking with the provider.

SOURCE: Wheeler, L. *Nurse-Midwifery Handbook: A Practical Guide to Prenatal and Postpartum Care*. Philadelphia: Lippincott-Raven Pub., 1997.

continued nursing on the affected side may solve the problem.

Results

There are no rules about when to stop breastfeeding. A baby needs breast milk or artificial milk for at least the first year of life. As long as a baby eats age-appropriate solid food, the mother may nurse for several years.

Health care team roles

Several members of the health care team, including obstetricians, nurses, midwives, and lactation consultants, are equipped to provide guidance and support to mothers who wish to breastfeed their babies. By meeting specific eligibility requirements and passing an independent examination, lactation consultants may be certified by the International Board of Lactation Consultants. Such certification demonstrates that these consultants possess the necessary skills, knowledge, and attitudes to provide quality breastfeeding assistance. It is important for new mothers to understand that breastfeeding is something that mothers and babies must learn to do together. The development of a satisfying breastfeeding relationship requires patience on the mother's part and the mother may benefit from the support and guidance of a lactation consultant or other qualified member of her health care team.

KEY TERMS

Areola—The pigmented, circular area surrounding the nipple of each breast.

Bromocriptine—A drug used to treat Parkinson's disease that can decrease a woman's milk supply.

Ergotamine—A drug used to prevent or treat migraine headaches. This can cause vomiting, diarrhea, and convulsions in infants.

Immunoglobulin—A protein produced by plasma cells; a component of the immune system. Transferred in utero and through breast milk providing passive immunity to the baby.

Lactation—Secretion of milk from the breasts; the act of breastfeeding.

Latch-on—The process whereby the baby opens the mouth widely and first exerts negative pressure on the mother's nipple and then positive pressure. Good latch-on will result in adequate transfer of milk into the baby's mouth and prevent sore nipples from occurring.

Lithium—A drug used to treat manic depression (bipolar disorder) that can be transmitted in breast milk.

Methotrexate—An anticancer drug also used to treat arthritis that can suppress an infant's immune system when taken by a nursing mother.

Postpartum—Refers to the six-week period after childbirth.

Lactation consulting

Definition

Lactation consultants assist lactating mothers in self-care and management techniques related to breastfeeding.

Description

Lactation consulting has emerged as a new field over the past twenty years. Because scientific inquiry has consistently shown breastfeeding to be the recommended source of **nutrition** for infants through the first year of life, more mothers are opting to nurse their infants. Lactation consultants try to meet the educational needs of these mothers and sometimes of other health care providers who have an interest in their patients' breastfeeding needs.

Lactation consulting is the only specialty within health care that places the advocacy of the woman who wishes to breastfeed her baby as its primary responsibility. The mother and her baby are described as a nursing couple or a nursing dyad—two separate people forming one unit. If other members of the health care team choose a plan of care that could be detrimental to the nursing dyad relationship, then the lactation consultant may need to suggest an alternate course if one is available.

Caring for the mother and baby

The primary function of the lactation consultant is to gently guide the mother's breastfeeding in a manner that involves the least intrusion and generates a minimal amount of complications. The consultant's skills are based on scientific information and familiarity with breastfeeding.

A useful approach for the consultant is to make suggestions to the mother while explaining the rationale behind these recommendations. The mother can then determine how to adapt these recommendations to best promote her needs and the needs of her baby. Potential problems that a lactation consultant would assist a client with are nipple soreness, breast engorgement, and milk production. A lactation consultant should be knowledgeable in the various components of science of lactation: milk production, normal breastfeeding behaviors, and factors that may impact the breastfeeding relationship.

Work settings

Lactation consulting can occur in a variety of settings—within the hospital, in the home, in a clinic or

physician's office, in prenatal classes, as part of routine **postpartum care**, by operating a telephone help line, or through referrals to peer support groups. The location of practice is frequently determined by what other credentials the individual had prior to becoming a lactation consultant. In the hospital setting, the lactation consultant often is a **registered nurse** on the maternity unit. In a clinic such as the Special Supplemental Food Program for Women, Infants and Children (WIC), the consultant may be a registered dietician.

Hospital setting

Every postpartum mother who is breastfeeding should ideally be observed feeding her newborn at least one time prior to being discharged home. In the hospital setting, the role of the lactation consultant is to observe every mother breastfeeding and to ensure that maternity staff receive training in basic breastfeeding management and common problems and are capable of making such observations. The maternity staff can then refer complicated problems to the lactation consultant.

Lactation consultants in the hospital setting also act as an advisor in the development of breastfeeding policies and procedures for the facility. The consultant may compile handouts and other reading resource materials for breastfeeding mothers, as well as design forms for documentation of breastfeeding activities. If the nursing mother needs to use a breast pump or other breastfeeding device, the consultant may be the one responsible for assisting the mother in obtaining the equipment and training the client in its use.

Outpatient settings

There are several outpatient facilities that the lactation consultant might practice in. Some of these are **public health** clinics, health care provider offices, home health care, or as a consultant in private practice.

PUBLIC HEALTH CLINIC. Working in a public health clinic, such as Women, Infants, and Children (WIC), the lactation consultant will be an active advocate for breastfeeding because WIC, through the U.S. Department of Agriculture (USDA) has undertaken a breastfeeding promotion program. WIC participants represent a significant proportion of the low income and at-risk population of women and infants. The WIC program is having an impact on meeting the Healthy People 2010 breastfeeding goals for the United States. Women who are breastfeeding in the WIC program receive priority treatment and additional services. The breastfeeding mother will receive an enhanced food package including additional fruit juice, dairy products, legumes, carrots, and canned tuna fish.

In the WIC program, the lactation consultant may be responsible for the training of peer counselors. Peer counselors are individuals of a similar background as other WIC clients who have breastfed or are breastfeeding a child and have an interest in supporting other mothers to do the same. WIC clients come from ethnically diverse backgrounds, and peer counselors are particularly useful in expressing sensitivity to the different cultures, socioeconomic backgrounds, and value systems. WIC uses peer counselors to promote breastfeeding and lactation consultants to manage breastfeeding problems.

HEALTH CARE PROVIDER OFFICES. In the clinic/office setting the consultant will conduct prenatal education in breastfeeding, will make rounds in the hospital on patients who have delivered and will provide follow-up after discharge through home visits and a telephone help line sometimes referred to as a "warm line." The lactation consultant in a health care provider's office will serve as a resource person for doctors and nurses by providing updates on breastfeeding research and information on medications that are contraindicated for the mother to take while breastfeeding.

HOME HEALTH CARE. If a mother is discharged prior to 48 hours after delivery, the home health visit is particularly important for assessing proper initiation of breastfeeding. The lactation consultant making such a visit may also be a registered nurse and will be checking the mother and baby for recovery and transition, in addition to breastfeeding. As part of such an assessment conducted by a registered nurse, certain phenomena should be observed. The infant should be having at least six wet diapers and four stools a day after the milk is "in." The mother's bleeding should be decreasing, she should not have a temperature—be afebrile—and any incisional discomfort should be under control with proper medications. The home assessment may involve taking **vital signs** on the mother and the infant.

Relatives and siblings may make for a hectic environment as compared with another setting, but the home environment allows for a more realistic environment in which to observe breastfeeding, and the consultant also gets a view of the client's support system. Involving family members in breastfeeding education will help relatives to understand the benefit of breastfeeding and may prompt a more supportive environment for the mother. The lactation consultant may wish to encourage the mother to make use of a telephone help line if she has any problems and concerns that were not addressed during the home visit.

PRIVATE PRACTICE. A private practice affords the lactation consultant the greatest flexibility but simultaneously constrains the consultant with more administrative

KEY TERMS

Consulting—Providing advice or an opinion.

Lactation—Secretion of milk from the breasts; the act of breastfeeding.

responsibilities. The independent lactation consultant may operate out of a home office or maintain a regular office, possibly sharing it with other consultants or health care providers. The source of referrals for the independent lactation consultant is from clients themselves, from other lactation consultants, from other health care providers, and from hospitals.

Education and training

The field of lactation consulting attracts people from a varied background. Some hold advanced degrees in medicine, nursing and nutrition and have been working in maternal child health. Others are lay counselors who obtained the necessary education to become lactation consultants after having had a positive breastfeeding experience of their own.

Professional education for lactation consultants was first offered in the early 1980s. The International Board of Lactation Consultant Examiners (IBLCE) started to offer a certification exam for lactation consulting in 1985. Shortly thereafter, the International Lactation Consultant Association (ILCA) became the professional association for lactation consultants.

Language acquisition

Definition

Language acquisition is defined as a natural progression or development in the use of language, typified by infants and young children learning to talk. It is an unconscious process that occurs when language is used in ordinary conversation. Language acquisition is distinguished from intentional study of a language by its informality.

Description

Theories of language acquisition

Developmental psychologists are not agreed as to how humans acquire the ability to speak their first language. It was only in the 1950s that the availability of portable tape recorders made it possible for researchers to record children's speech patterns for later analysis in the laboratory. One early theory of language acquisition was based on imitation, which is the notion that children learn to speak by imitating adults and older children. The difficulty with the imitation theory is that it fails to account for the ability of even small children to form new sentences from words they know. A second theory, associated with the behavioral school of psychology, maintains that language acquisition is explained by reinforcement. Children learn to speak because their parents give them positive reinforcement when they speak correctly and negative reinforcement (correction or criticism) when they speak ungrammatically. This theory does not hold up under the findings of recent research that parents reinforce the *meaning* of what children say rather than its grammatical correctness. In addition, children often chatter to themselves or to no one in particular for the sheer pleasure of talking. This activity is hard to explain in terms of the reinforcement theory.

A third theory of language acquisition is called nativism. This theory holds that humans are neurologically "programmed" from birth with the capacity to acquire language as soon as their nervous system reaches a certain point of maturation. Noam Chomsky maintained that the human **brain** has a built-in language acquisition device, or LAD, that analyzes the parts of speech in the language that a child hears. The phases of language acquisition and the age at which children begin to acquire language are similar enough across different cultures and different languages to give some support to the nativist view.

Biological and neuroanatomical features of language acquisition

EVOLUTION AND DEVELOPMENT OF THE HUMAN VOCAL TRACT AND NERVOUS SYSTEM. Language is, as far as we know, unique to humans. Chimpanzees are able to learn a rudimentary sign language, but they cannot combine vocalized sounds into meaningful structured combinations as humans do. The human mouth and throat appear to have been modified over the course of evolutionary history for speech. The human larynx is situated low in the throat, and the sharp right-angle bend at the back of the mouth divides the human vocal tract into two resonant cavities (the mouth and the throat) that allow for the production of a large range of vowel sounds.

The maturation of certain neural circuits in a child's brain may explain why language development proceeds most rapidly in young children after the first year of life. Although babies are born with most of their nerve cells already formed, their head size, brain weight, and junctions between nerve cells (synapses) continue to increase in the first year after birth. The long-distance connections in the child's nervous system are not complete until nine months of age, and the rate of **metabolism** in the child's brain reaches adult levels by ten months. There appears to be a neurologically determined critical period for language acquisition. Children acquire language easily until age four, or six at the latest. After **puberty**, it is rare for humans to learn to speak if they have not done so earlier.

AREAS OF THE BRAIN ASSOCIATED WITH LANGUAGE. The areas of the brain that govern the interpretation and production of language were discovered in the nineteenth century by physicians studying patients with **speech disorders**. In 1861, Pierre Paul Broca, a French physician, was able to demonstrate from post-mortems of patients who had lost the ability to speak, that the loss of this ability is associated with damage to an area of the brain toward the front of the left hemisphere. In 1876, a German physician named Karl Wernicke found that damage to an area in the posterior part of the left temporal lobe of the brain is also associated with **language disorders**. This area, now called Wernicke's area, is connected to Broca's area by a group of nerve fibers called the arcuate fasciculus.

When a person reads aloud, information from the eyes travels along the optic nerve to the primary visual cortex of the brain. From the primary visual cortex, the information is transmitted to Wernicke's area, where it is interpreted. From Wernicke's area, it is carried by the arcuate fasciculus to Broca's area, then to the primary motor cortex. When a person repeats a word that is spoken, the information is carried from the nerves in the ear

to the primary auditory cortex in the brain. It is then transmitted from the primary auditory cortex to Wernicke's area, then to Broca's area via the arcuate fasciculus, then to the primary motor cortex.

Stages of language acquisition

A young human's acquisition of language takes place in a series of six stages:

- Prelinguistic stage (birth to six months): The baby cries, coos, laughs, and makes other sounds.
- Babbling (six to 12 months): The baby makes nonspecific sounds from all human languages.
- One-word (holophrastic) stage (1–2 years): The child speaks single words in isolation, in his or her first language.
- Two-word stage (24–30 months): The child forms two-word phrases or strings that reflect the language being acquired. The vocabulary increases; the child begins to learn words at the rate of one word every two waking hours.
- Telegraphic speech (30–36 months): Children begin to utter short phrases like telegraph messages, without formal grammatical structure.
- Fluent speech (three years +): The child learns grammar and syntax (patterns of sentence formation) with surprising rapidity and accuracy; sentences increase in length and complexity.

Function

Human language functions as a means of interpersonal communication, to convey thoughts, feelings, and many other forms of information. It is necessary to human social life as well as to intellectual development. Language also stimulates the expression of human creativity: poetry, drama, novels, short stories, vocal music, and similar forms of art are based on language.

Role in human health

The fact that language is unique to humans implies that language acquisition is necessary to full psychosocial as well as intellectual development. People who lose the ability to speak normally in later life because of a stroke or a condition known as primary progressive **aphasia** often become depressed because they feel cut off from others. Children and adolescents with dyslexia (a learning disability that affects reading and is sometimes related to problems understanding spoken language) often have additional difficulties learning to inter-

KEY TERMS

Aphasia—The loss of previously held ability to speak or to understand written or spoken language, caused by disease or injury to the brain.

Arcuate fasciculus—A group of nerve fibers in the brain that connects Wernicke’s area with Broca’s area.

Broca’s area—An area in the left hemisphere of the brain associated with the motor impulses necessary for speech. It is named for Pierre Paul Broca (1824-1880), a French physician.

Dyslexia—A reading disorder associated with impairment of the ability to integrate auditory and visual information, or to process sounds accurately.

Holophrastic—An early stage in language acquisition in which a single word serves the function of a phrase or sentence.

Nativism—The theory that humans have neural circuits that are genetically programmed to acquire language.

Specific language impairment (SLI)—A developmental disorder of childhood characterized by significant delays in language development in the absence of deafness, autism, mental retardation, or similar handicaps.

Wernicke’s area—An area in the left hemisphere of the brain that is important in the reception and interpretation of speech. Wernicke’s area is connected to Broca’s area by the arcuate fasciculus.

Williams syndrome—A rare congenital disorder caused by a deletion of the elastin gene on chromosome 7. Children with Williams syndrome have normal language skills even though they are usually mildly retarded.

act with others and feeling comfortable in social situations.

Studies of “wild” children and children reared by emotionally disturbed parents who did not talk to them indicate that children who do not learn to speak by age eight never achieve normal fluency. This feature of language acquisition implies that language is an important component of the social dimension of human nature. Humans who have never acquired the ability to communicate with others cannot be completely socialized.

Common diseases and disorders

Aphasia

Aphasia refers to the loss of a previously held ability to speak or to understand written or spoken language. Aphasia is most often the result of a stroke or head trauma, but it can occur in relation to other neurological disorders. Primary progressive aphasia is a disorder of the nervous system in which the person’s ability to speak gradually deteriorates. In Broca’s aphasia, caused by damage to Broca’s area, the person can understand what words mean, but has trouble with speech output. Broca’s aphasia is sometimes called motor or expressive aphasia. In Wernicke’s aphasia, caused by damage to Wernicke’s area, the person cannot understand spoken language. They can speak, but their speech is ungrammatical and incoherent. Wernicke’s aphasia is sometimes called fluent or receptive aphasia.

Dyslexia

Dyslexia is a disorder that affects the ability to read. Its symptoms may include problems with spelling, difficulty recognizing the sounds in words, problems processing visual information, and difficulty saying words quickly when asked to do so. Present dyslexia research is focused on studying the parts of the brain that process speech sounds and relate them to **vision** and other language areas in the brain.

Williams syndrome

Williams syndrome is a rare congenital disorder that occurs once in every 20,000 births. It results from a deletion of the genetic material on human chromosome 7 that makes a protein called elastin. Although children with Williams are usually mildly retarded, they often have normal language abilities. The dissociation of language acquisition from general intelligence in Williams syndrome suggests that human speech is not simply a byproduct of intelligence as such.

Specific language impairment (SLI)

Specific language impairment, or SLI, refers to a group of inherited syndromes in which children with normal intelligence and **hearing** are slow to acquire and use language. SLI is thought to affect 5–7% of children starting school. A cross-cultural study done in 1999 suggests that SLI may differ from other language disorders in that the number and specific types of problems the children had were related to their specific first language. The study showed that children learning Italian or Hebrew had fewer difficulties with verbs, for example, than children learning English.

Language development see **Language acquisition**

Language disorders

Definition

A language disorder is a communication disorder characterized by an impaired ability to understand and/or use words in their proper context, whether verbal or nonverbal.

Description

Language disorders belong to a broad category of disorders called *communication disorders* that also include speech and **hearing** disorders. As of 1998, communication disorders were affecting one person out of every 10 in the United States. Language disorders are characterized by one or more of the following features: sound substitutions in words, difficulty in processing sounds into syllables and words, improper use of words, confusion about their meaning, difficulty in expressing ideas and thoughts, inappropriate use of grammatical forms, limited vocabulary development and inability to follow directions, remember questions or numbers and letters in sequence. Language disorders can be classified as either developmental or acquired.

Developmental language disorders

Developmental language disorders occur in children who do not develop functional language skills. Clinically, they are diagnosed as language-delayed or language-disordered. Language-delayed children can have receptive language impairments, expressive language impairments or both.

Receptive language impairments refer to a difficulty understanding language at the level of meaning. The vocabulary range is usually very limited. The purpose of simple grammatical constructions is also not properly understood. For example, that adding an “-s” to a noun makes it plural, or that “’s” is a possessive form, or that a verb with an “-ed” ending means that the action occurred in the past. There is also difficulty in understanding nonverbal signals, such as body language, or difficulty understanding sarcasm and irony, or indirect requests and sentences.

Expressive language impairments refer to the use of defective language patterns, for example using too few words in sentences. Or the sentences may be truncated, or contain words that lack proper endings, or miss the verbs “is” and “are.” Limited or ambiguous vocabulary is also a feature. Affected individuals have difficulty using language properly, and as a result, they often seem rude or

blunt. There is also a distinct pattern of changing topics very abruptly.

Acquired language disorders

Acquired language disorders, also called *aphasias*, are language impairments caused by damage to the areas of the **brain** responsible for language function. Various aspects of language may be affected depending on the location and extent of the brain damage. Language function is believed to be associated with the left hemisphere of the brain and some aphasias are accordingly classified with respect to the affected brain area:

- **Broca's aphasia.** This type of aphasia is an expressive aphasia and it is associated with damage to Broca's area, a region located in the frontal lobe of the left hemisphere of the brain. It is characterized by an impaired ability to produce language.
- **Wernicke's aphasia.** This type of aphasia is a receptive aphasia and it is associated with damage to Wernicke's area, a region located in the left temporal lobe of the brain. It is characterized by an impaired ability to understand language.
- **Dyslexia.** Dyslexia is a neurological learning difficulty that also affects the learning of language skills. It is characterized by an impaired ability to manage verbal codes in **memory** and difficulties with writing, spelling, and reading. Other symbolic functions, such as mathematics and musical notation, can also be affected.

Causes and symptoms

Developmental language disorders have been associated with a wide variety of causes, such as hearing impairment, cognitive impairment, autism, or a physical handicap that prevents the child from interacting normally with his environment, such as mental retardation, or a cleft lip or palate. Emotional/psychological problems may also be a cause, and lack of intellectual stimulation as well. Often, there is no identifiable cause for a developmental language disorder.

Acquired language disorders or aphasias resulting from brain damage can be caused by **cerebral palsy**, stroke, tumor or **head injury** affecting the left hemisphere of the brain. It should be noted that individual differences do exist in brain function and when coupled with differences in the extent of the brain damage, the degree of impairment caused by aphasia is then unique to the affected individual.

Although the symptoms of language disorders vary from one individual to the next, and also depend on whether they are developmental or acquired, they do

present a range of characteristic symptoms. Generally speaking, in the case of developmental disorders, a child's language skills are considered delayed when the child is noticeably behind his or her peers in the acquisition of basic language skills. Sometimes a child will have a greater receptive (understanding) impairment than an expressive (speaking) impairment, but the overall result is the same as both functions are required for the full development of language skills.

Some general symptoms are typical of an aphasic language disorder. Most affected individuals experience *anomia*, or difficulty finding words and some aphasic people try to cope with this difficulty by providing descriptions or definitions for the missing words. This is called circumlocution. Another symptom is paraphasia, meaning the use of an incorrect or unrecognizable word in place of the desired word. There are three types of paraphasias. Phonemic or literal paraphasias are faulty words that sound very close to the intended word (for example, using "bait" instead of "bake"). Verbal or semantic paraphasias are faulty words that are close in meaning to the target word (for example, using "apple" instead of "orange"). The third type of paraphasias are neologisms, or invented words that do not exist in the speaker's language. Another symptom is perseveration, meaning the repetition of a word or sentence when it is not required. The aphasic person gets stuck in a pattern of repetitive sentences without being able to break out of it.

Diagnosis

The early diagnosis of language disorders is important because they are first and foremost a communication disorder that always leads to social and educational isolation. Evaluation procedures, usually performed by a speech-language pathologist, are used to diagnose the disorders and any child whose language is not similar to that of other children of the same age should be evaluated. While faulty language patterns are considered normal "baby talk" during early childhood, they become indicative of a language disorder if they are not outgrown as expected. Because of brain development patterns, it is easier to learn language and communication skills before the age of five, thus the importance of timely diagnosis. One or a combination of typical features usually occur in a child affected by a language disorder or developmental language delay. The child may hear or see a word but be incapable of understanding its meaning. He may have trouble getting others to understand what he wants to communicate or display a high level of inattention or lack of organizational skills. These are all pointers that are used to establish diagnosis.

Treatment

The treatment of language disorders belongs to speech pathology, the specialty concerned with disorders of speech and language. Language therapy with preschoolers is centered on working with parents and other family members to create an optimal environment for learning language. For example, when speaking with a child who has aphasia, it helps to minimize distractions, and to speak slowly and clearly. If the child has difficulty understanding, the use of short and simple sentences is beneficial. Pairing gestures with speech to help comprehension also helps. So does allowing the child ample time to respond and the formulation of questions that can be answered easily with a yes or no or other single word. Speech pathologists can recommend strategies to help families of children with language disorders. School-age children with developmental language disorders can benefit from special education programs, usually monitored by a speech pathologist.

Prognosis

Prognosis is dependent on the cause of the language disorder. If the cause is brain damage, the acquired disorder usually remains. In the case of developmental language disorders, many affected children are able to catch up with their peers, but many also continue to have difficulty with the gap between their skill level and that of their peers, which may increase over time. Since many factors influence outcome, it is not possible to predict which individuals are most likely to recover or how significant the progress will be. Developmental language disorders also have different stages that follow the overall development of children. At different ages, different demands are made on the language system. For example, language-disordered children in the preschool years may appear to catch up to peers by age five or six years, but in later years, as language demands evolve, (e.g., the stage of learning how to read), new impairments usually become apparent.

Health care team roles

Language disorders are usually treated by a speech pathologist working with a collaborative team consisting of the family, physicians, educational professionals as well as special educators. The team usually includes:

- Speech-language pathologists. These specialists have several responsibilities, including: providing individual therapy to the language-impaired; informing teachers and health care professionals on how to identify children who are at risk; performing the evaluation of spoken and written language skills; interviewing family

members and teachers; observing the child in the classroom setting so as to evaluate language skills; assessing reading, spelling and writing levels for older children and adolescents.

- Audiologists. Audiologists are specialists of hearing disorders and their expertise may be required in cases where the language disorder is associated with a hearing deficiency.
- Reading specialists. These specialists are special educators who design remedial reading and language skill acquisition therapies.
- Teachers of the language handicapped. These specialized teachers are trained to teach language-delayed children.

Prevention

There are no specific preventive measures for language disorders, but their early detection will often improve the chances of a successful special education therapy. Thus, identifying children that are at risk of developing a language disorder is important. The following conditions are considered to represent high-risk factors and children exposed to them should be tested early and regularly:

- diagnosed medical conditions, such as chronic ear infections
- biological factors, such as fetal alcohol syndrome
- genetic defects, such as Down syndrome
- neurological defects, such as cerebral palsy
- family history, such as family incidence of literacy difficulties

KEY TERMS

Anomia—Difficulty finding words.

Aphasia—Acquired language disorder caused by damage to the areas of the brain responsible for language function.

Broca's aphasia—Language disorder associated with damage to Broca's area, a region in the frontal lobe of the left hemisphere of the brain. It is characterized by an impaired ability to produce language.

Communication disorder—Disorder characterized by an impaired ability to communicate. Communication disorders include language, speech and hearing disorders. They are associated with a wide variety of physical and psychological causes.

Dyslexia—Dyslexia is a specific learning difficulty that hinders the learning of literacy skills. This problem with managing verbal codes in memory is neurological and tends to run in families. Other symbolic systems, such as mathematics and musical notation, can also be affected.

Language disorder—Communication disorder characterized by an impaired ability to understand and/or use words in their proper context, whether verbal or nonverbal. The disorder can be either developmental or acquired.

Paraphasia—Use of an incorrect or unrecognizable word.

Speech disorder—Communication disorder characterized by an impaired ability to produce speech sounds or by problems with voice quality.

Speech pathology—The field of speech pathology, formerly known as speech therapy, is concerned with disorders of speech and language. A speech pathologist is a professional trained to diagnose and treat language and speech disorders.

Wernicke's aphasia—Language disorder associated with damage to Wernicke's area, a region in the left temporal lobe of the brain. It is characterized by an impaired ability to understand language.

Laparoscope

Definition

A laparoscope is a telescope-like **endoscope** used to view the abdominal cavity for diagnosis and treatment during a minimally invasive surgical procedure called **laparoscopy**.

Purpose

A laparoscope is used to directly examine the abdominal and pelvic organs to diagnose certain conditions and—depending upon the condition—to perform therapeutic surgery. Laparoscopes are commonly used in gynecologic laparoscopy to examine the outside of the uterus, the Fallopian tubes, and the ovaries—particularly in pelvic **pain** cases where the underlying cause of pain could not be determined using diagnostic imaging (e.g., ultrasound; computed tomography). Gynecologic conditions diagnosed using laparoscopy include endometriosis, ectopic **pregnancy**, ovarian cysts or tumors, pelvic inflammatory disease, pelvic **abscess**, **infertility**, uterine fibroids, and **cancer**. Laparoscopes are used in general surgery to examine abdominal organs such as the **gallbladder**, bile ducts, **liver**, appendix, and intestines (external surface). Laparoscopy can identify **appendicitis**, cholecystitis, cirrhosis, hernias, ascites, and abdominal cancers.

During the laparoscopic procedure, certain conditions can be treated surgically using special laparoscopic instruments and devices designed to be used with laparoscopes. For example, appendectomy, cholecystectomy, biopsy of the ovary or liver, hernia repair, and removal of endometriotic tissue or cysts, can all be performed laparoscopically. Medical devices that can be used in conjunction with laparoscopy include surgical lasers and electro-surgical units. Other procedures that can be performed laparoscopically include hysterectomy, oophorectomy, tubal ligation, and lymphadenectomy. Laparoscopic surgery is now preferred over open surgery for several types of procedures due to its minimally invasive nature and associated lower complication rate.

A relatively new type of laparoscope is the microlaparoscope—a smaller laparoscope used to perform microlaparoscopy in the physician's office. Common clinical applications of microlaparoscopy in gynecology include pain mapping (e.g., endometriosis), and sterilization and fertility procedures. Common applications in general surgery include evaluation of chronic and acute abdominal pain (e.g., appendix), basic trauma evaluation, biopsies, and evaluation of abdominal masses.

Laparoscopes are most commonly used by gynecologists, urologists, and general surgeons for abdominal and pelvic applications. In addition to expanding applications in these areas, orthopedic surgeons are now using laparoscopes for spinal applications, and cardiac surgeons for minimally invasive **heart** surgery.

Description

Laparoscopes are rigid, telescope-like endoscopes used during laparoscopic procedures for either viewing or operating. Viewing laparoscopes typically range from 5 to 10 mm in diameter, and operating laparoscopes usually range from 8 to 12 mm in diameter. Operating laparoscopes have a separate instrument channel in their shaft where laparoscopic **surgical instruments** can be inserted to perform therapeutic procedures. Viewing laparoscopes do not have an instrument channel and are used primarily for diagnosis. Microlaparoscopes of approximately 2 mm in diameter are available for diagnostic procedures performed in the physician's office. Although most laparoscopes are rigid, some manufacturers supply semi-flexible or flexible laparoscopes to increase the viewing range. The size and type of laparoscope chosen depends upon the type of procedure being performed, the patient's size and age, and the patient's medical condition.

Laparoscopes have an optical system of lenses, prisms, and mirrors to provide magnification of tissue and organs, a wide field of view, and high image resolution. A bundle of illuminating fibers are located in the laparoscope's shaft surrounding the lenses and are connected to a separate fiber-optic light source that provides light during the procedure. Most laparoscopes have integral cameras or allow connection of a camera for transmitting images during the procedure. The images from the laparoscope are transmitted to one or more viewing monitors, which the surgeon uses to visualize the internal anatomy and guide any surgical procedures. Video and photographic equipment are used to document the procedure.

Operation

Laparoscopy is typically performed in the hospital under **general anesthesia**, although some laparoscopic procedures can be performed using **local anesthesia** and conscious sedation. Once the patient is under anesthesia, a urinary catheter is inserted to collect urine during the procedure. As the procedure begins, a small incision is made just below the navel and a cannula or trocar is inserted into the incision to accommodate the insertion of the laparoscope. Other incisions (one or two) may be made in other areas of the abdomen to allow for insertion of other laparoscopic instrumentation. A laparoscopic insufflation device is used to inflate the abdomen with carbon dioxide gas to create a space in which the laparoscopic surgeon can maneuver the instruments.

Once the laparoscope is inserted, the surgeon manipulates it to view the anatomical areas of interest. Depending on the surgeon's preference and the type of

A laparoscope can be used for internal examination and minor surgery through only a small incision. (Photograph by John Watney. Science Source/Photo Researchers. Reproduced by permission.)

procedure, an eyepiece can be attached to the scope for direct viewing, or television/video cameras can be attached for viewing on a monitor. Instruments such as forceps, graspers, and manipulators can be used in conjunction with operating laparoscopes. For example, a uterine manipulator would be used in gynecologic procedures involving the uterus (e.g., hysterectomy).

After laparoscopic diagnosis and treatment are completed, the laparoscope, cannula, and other instrumentation are removed, and the incision is sutured and bandaged.

Complications related to the use of a laparoscope can occur during laparoscopy. The most serious complication is laceration of a major abdominal **blood** vessel resulting from improper positioning, inadequate insufflation (inflation) of the abdomen, abnormal pelvic anatomy, or too much force during scope insertion. Thin patients with well-developed abdominal muscles are at higher risk, since the aorta may only be an inch (2-3 cm) or so below

the skin. Obese patients are also at higher risk because more forceful and deeper needle and scope penetration is required. There is also a risk of bleeding from vessels, and adhesions that may require repair by open surgery if bleeding cannot be stopped using laparoscopic instrumentation. In laparoscopic procedures that use electro-surgical devices, **burns** to the incision site are possible due to conduction of electrical current through the laparoscope due to a fault or malfunction in the equipment.

Any abdominal surgery, including laparoscopy, carries the risk of unintentional organ injury (punctures and perforations). For example, the bowel, bladder, ureters, or fallopian tubes may be injured during the procedure by the laparoscope itself. These injuries are often unavoidable due to the patient's anatomy or medical condition. Patients at higher risk for bowel injury include those with chronic bowel disease, pelvic inflammatory disease, a history of previous abdominal surgery, or severe endometriosis. Some types of laparoscopic procedures have a higher risk of organ injury. For instance, during laparoscopic removal of endometriosis adhesions or ovaries, the ureters may be injured due to its proximity to each other.

Several clinical studies have shown that the complication rate during laparoscopy is associated with surgeon experience. Surgeons experienced in laparoscopic procedures have fewer complications than surgeons performing their first 100 cases.

Maintenance

The success of the laparoscopic procedure is highly dependent upon the condition of the laparoscope and its associated accessories. Improper disinfection, sterilization, and handling of laparoscopic equipment can result in equipment damage, unnecessary wear, and ultimately surgical errors. All clinical staff using laparoscopes and related equipment should be well-trained and familiar with disassembling and assembling scopes and accessory parts (e.g., couplers; adapters; instrumentation) so that defects in equipment can be recognized before a complication occurs or equipment malfunctions. Manufacturers of laparoscopic equipment usually provide maintenance guidelines, including cleaning techniques, for their scopes and accessories. The hospital **biomedical engineering** department and/or the scope manufacturer will implement actual repairs to equipment. The introduction of disposable accessories (e.g., trocars; couplers) has simplified preparation for procedures and minimized maintenance needs.

Health care team roles

Laparoscopy may be performed by a gynecologist, general surgeon, gastroenterologist, or other physician,

depending upon the patient's condition. An anesthesiologist is required during the procedure to administer general and/or local anesthesia and to perform patient monitoring. Nurses and surgical technicians/assistants aid with scope positioning, video system adjustments and image recording, and laparoscopic instrumentation. Clinical staff trained in the daily maintenance, disinfection, and sterilization of laparoscopes are required to sterilize equipment between procedures and make sure all scopes are in working order.

Training

Physicians and surgeons using laparoscopes should be well-trained in laparoscopic techniques. A surgeon skilled and experienced in open surgical techniques cannot necessarily transfer those skills to laparoscopic techniques because a different skill set is involved in minimally invasive surgery. Organizations focused on laparoscopy, and laparoscope manufacturers, offer clinical training in laparoscopic surgery.

KEY TERMS

Ascites—Accumulation of fluid in the abdominal cavity; Laparoscopy may be used to determine its cause.

Cannula—A small tube inserted into the incision site through which laparoscopes and instruments are inserted; used in conjunction with a trocar.

Cholecystitis—Inflammation of the gallbladder; often diagnosed using laparoscopy.

Electrosurgical device—A medical device that uses electrical current to cauterize or coagulate tissue during surgical procedures; often used in conjunction with laparoscopy.

Endometriosis—A disease involving occurrence of endometrial tissue (lining of the uterus) outside the uterus in the abdominal cavity; often diagnosed and treated using laparoscopy.

Hysterectomy—Surgical removal of the uterus; often performed laparoscopically.

Insufflation—Inflation of the abdominal cavity using carbon dioxide; performed prior to laparoscopy to give the surgeon space to maneuver surgical equipment.

Oophorectomy—Surgical removal of the ovaries; often performed laparoscopically.

Trocar—A small sharp instrument used to puncture the abdomen at the beginning of the laparoscopic procedure.

Laparoscopy

Definition

Laparoscopy is a minimally invasive surgical procedure performed to examine the abdominal and pelvic organs.

A laparoscopy procedure. (Delmar Publishers, Inc. Reproduced by permission.)

Purpose

Laparoscopy is performed to directly examine the abdominal and pelvic organs to diagnose certain conditions and—depending upon the condition—to perform surgery. Laparoscopy is commonly used in gynecology to examine the outside of the uterus, the Fallopian tubes, and the ovaries—particularly in pelvic **pain** cases where the underlying cause of pain cannot be determined using diagnostic imaging (e.g., ultrasound; computed tomography). Gynecologic conditions diagnosed using laparoscopy include endometriosis, ectopic **pregnancy**, ovarian cysts or tumors, pelvic inflammatory disease, pelvic **abscess**, **infertility**, uterine fibroids, and **cancer**. Laparoscopy is used in general surgery to examine abdominal organs such as the **gallbladder**, bile ducts, **liver**, appendix, and intestines (external surface). Laparoscopy can identify **appendicitis**, cholecystitis, cirrhosis, hernias, ascites, and abdominal cancers.

During the laparoscopic procedure, certain conditions can be treated surgically using special laparoscopic instruments and devices designed to be used with laparoscopes. For example, appendectomy, cholecystectomy, biopsy of the ovary or liver, hernia repair, and removal of endometriotic tissue or cysts can all be performed laparoscopically. Medical devices that can be used in conjunction with laparoscopy include surgical lasers and electro-surgical units. Other procedures that can be performed laparoscopically include hysterectomy, oophorectomy, tubal ligation, and lymphadenectomy. Laparoscopic surgery is now preferred over open surgery for several types of procedures due to its minimally invasive nature and associated lower complication rate.

A relatively new development is microlaparoscopy performed in the physician's office using smaller laparoscopes. Common clinical applications in gynecology include pain mapping (e.g., endometriosis), and sterilization and fertility procedures. Common applications in general surgery include evaluation of chronic and acute abdominal pain (e.g., appendix), basic trauma evaluation, biopsies, and evaluation of abdominal masses.

Laparoscopy has been most commonly used by gynecologists, urologists, and general surgeons for abdominal and pelvic applications. In addition to expanding applications in these areas, laparoscopy is now being used by orthopedic surgeons for spinal applications and by cardiac surgeons for minimally invasive **heart** surgery.

Precautions

Patients should be carefully screened for **allergies** to anesthetic agents used for laparoscopy. Obese patients, very thin patients, and patients with abnormal anatomy have a higher risk of complications, and laparoscopy should be performed with caution in these patients. Preoperative imaging examinations may be helpful to visualize any anatomical abnormalities. Some daily medications, such as **blood** thinners or arthritis medications, may need to be stopped for a certain time period prior to the procedure. Any medications taken on a regular basis, including over-the-counter medicines, should be discussed with the physician and anesthesiologist. Patients who have had prior abdominal surgical procedures may have resulting scar tissue that would interfere with laparoscopy; thus, these patients are usually not considered good candidates for laparoscopic procedures.

Description

Laparoscopy is typically performed in the hospital under **general anesthesia**, although some laparoscopic procedures can be performed using **local anesthesia**. Once the patient is under anesthesia, a urinary catheter is inserted to collect urine during the procedure. To begin the procedure, a small incision is made just below the navel and a cannula or trocar is inserted into the incision to accommodate the insertion of the **laparoscope**. Other incisions (one or two) may be made in other areas of the abdomen to allow for insertion of other laparoscopic instrumentation. A laparoscopic insufflation device is used to inflate the abdomen with carbon dioxide gas to create a space in which the laparoscopic surgeon can maneuver the instruments.

Laparoscopes, which have integral cameras for transmitting images during the procedure, are available in various sizes depending upon the type of procedure

being performed. The images from the laparoscope are transmitted to a viewing monitor, which the surgeon uses to visualize the internal anatomy and guide any surgical procedure. Video and photographic equipment are used to document the procedure.

After laparoscopic diagnosis and treatment are completed, the laparoscope, cannula, and other instrumentation are removed, and the incision is sutured and bandaged.

Robotic systems are available to assist with laparoscopy. A robotic arm attached to the operating table may be used to hold and position the laparoscope in order to reduce unintentional camera movement that is common when a surgical assistant holds the laparoscope. The surgeon controls the robotic arm movement by foot pedal, voice-activated command, or handheld control panel.

Microlaparoscopy has become more common over the past few years. This procedure involves the use of smaller laparoscopes (e.g., 2 mm compared to 5 to 10 mm for hospital laparoscopy) with the patient undergoing local anesthesia with conscious sedation in a physician's office. Video and photographic equipment used are similar to that used for general laparoscopy.

Preparation

Because laparoscopy requires general anesthesia in most cases, the patient is required to fast for several hours before the procedure. Sometimes bowel cleansing is also required. The patient is screened by anesthesiology staff regarding allergies to medication and previous experiences (e.g., allergic reaction) with anesthesia.

Aftercare

Following laparoscopy, patients are required to remain in a recovery area until the immediate effects of anesthesia wear off and until normal voiding is accomplished after urinary catheter removal. **Vital signs** are monitored to ensure that no reactions to anesthesia have occurred and no internal injuries are present. For healthy patients undergoing elective procedures such as tubal ligation, diagnostic laparoscopy, or hernia repair, laparoscopy is usually an outpatient procedure and patients are discharged from the recovery area within a few hours after the laparoscopy. Due to the aftereffects of anesthesia, patients should not drive themselves home. Patients with more serious medical conditions, or patients undergoing emergency laparoscopy, may be kept in the hospital overnight or for a few days.

Discharged patients receive instructions regarding activity level, medications, and side effects of the proce-

This surgeon is performing a laparoscopic procedure on a patient. (Photo Researchers, Inc. Reproduced by permission.)

cedure. Depending upon the nature of the laparoscopic procedure and the patient's medical condition, daily activity may be restricted for a few days and strenuous activity restricted for several days to weeks. Pain-relieving medications are usually prescribed for several days following the procedure. In addition, **antibiotics** to prevent **infection** may also be prescribed. Patients are instructed to watch for signs of a urinary tract infection or unusual pain, which may indicate organ injury.

Complications

The most serious complication that can occur during laparoscopy is laceration of a major abdominal blood vessel resulting from improper positioning, inadequate insufflation (inflation) of the abdomen, abnormal pelvic anatomy, and too much force exerted during scope insertion. Thin patients with well-developed abdominal muscles are at higher risk, since the aorta may only be an inch or so below the skin. Obese patients are also at higher risk because more forceful and deeper needle and scope penetration is required. During laparoscopy, there is also a risk of bleeding from vessels, and adhesions that may require repair by open surgery if bleeding cannot be stopped using laparoscopic instrumentation. In laparoscopic procedures that use electrosurgical devices, **burns** to the incision site are possible due to conduction of electrical current through the laparoscope caused by a fault or malfunction in the equipment.

KEY TERMS

Ascites—Accumulation of fluid in the abdominal cavity; Laparoscopy may be used to determine its cause.

Cholecystitis—Inflammation of the gallbladder, often diagnosed using laparoscopy.

Electrosurgical device—A medical device that uses electrical current to cauterize or coagulate tissue during surgical procedures; often used in conjunction with laparoscopy.

Embolism—Blockage of an artery by a clot, air or gas, or foreign material. Gas embolism may occur as a result of insufflation of the abdominal cavity during laparoscopy.

Endometriosis—A disease involving occurrence of endometrial tissue (lining of the uterus) outside the uterus in the abdominal cavity; often diagnosed and treated using laparoscopy.

Hysterectomy—Surgical removal of the uterus; often performed laparoscopically.

Insufflation—Inflation of the abdominal cavity using carbon dioxide; performed prior to laparoscopy to give the surgeon space to maneuver surgical equipment.

Oophorectomy—Surgical removal of the ovaries; often performed laparoscopically.

Pneumothorax—Air or gas in the pleural space (lung area) that may occur as a complication of laparoscopy and insufflation.

Subcutaneous emphysema—A pathologic accumulation of air underneath the skin resulting from improper insufflation technique.

Trocar—A small sharp instrument used to puncture the abdomen at the beginning of the laparoscopic procedure.

Complications related to insufflation of the abdominal cavity include gas inadvertently entering a blood vessel and causing an embolism, pneumothorax, and subcutaneous **emphysema**. One common, but not serious, side effect of insufflation is pain in the shoulder and upper chest area for a day or two following the procedure.

Any abdominal surgery, including laparoscopy, carries the risk of unintentional organ injury (punctures and perforations). For example, the bowel, bladder, ureters, or fallopian tubes may be injured during the laparoscop-

ic procedure. Many times these injuries are unavoidable due to the patient's anatomy or medical condition. Patients at higher risk for bowel injury include those with chronic bowel disease, pelvic inflammatory disease, a history of previous abdominal surgery, or severe endometriosis. Some types of laparoscopic procedures have a higher risk of organ injury. For instance, during laparoscopic removal of endometriosis adhesions or ovaries, the ureters may be injured due to their proximity to each other.

During the recovery period following laparoscopy, complications may also occur. An organ injury may be overlooked, so patients should be monitored for any unusual pain, particularly in association with the bowel, as bowel injuries may not be apparent during the procedure. Other complications include urinary tract infection (resulting from catheterization) and minor infection of the incision site.

Several clinical studies have shown that the complication rate during laparoscopy is associated with surgeon experience. Surgeons experienced in laparoscopic procedures have fewer complications than surgeons performing their first 100 cases.

Results

In diagnostic laparoscopy, the surgeon will be able to see signs of a disease or condition (e.g., endometriosis adhesions; ovarian cysts; diseased gallbladder) immediately, and can either treat the condition surgically or proceed with appropriate medical management. In diagnostic laparoscopy, biopsies may be taken of questionable areas, and laboratory results will govern medical treatment. In therapeutic laparoscopy, the surgeon performs a procedure that rectifies a known medical problem, such as hernia repair or appendix removal. Because laparoscopy is minimally invasive in comparison to open surgery, patients experience less trauma and postoperative discomfort, have fewer procedural complications, can return to daily activities sooner, and have a shorter hospital stay.

Health care team roles

Laparoscopy may be performed by a gynecologist, general surgeon, gastroenterologist, or other physician—depending upon the patient's condition. An anesthesiologist is required during the procedure to administer general and/or local anesthesia and to perform patient monitoring. Nurses and surgical technicians/assistants are needed during the procedure to assist with scope positioning, video system adjustments and image recording, and laparoscopic instrumentation.

Laryngoscopy

Definition

Laryngoscopy is a procedure used to view the inside of the larynx (the voice box).

Purpose

The purpose of seeing inside the larynx is to assess the vocal cords and to detect tumors, **foreign bodies**, nerve or structural injury, or other abnormalities.

Precautions

A patient undergoing a laryngoscopy should be assessed for **allergies** to local anesthetics or other pharmacologic agents in order to prevent possible allergic reactions.

Patients may have fears concerning this procedure. Prior to laryngoscopy, the physician should explain the procedure in detail and assure the patient that he or she will be closely monitored for respiratory or other problems.

Description

Two methods of laryngoscopy allow the examiner to view the structures of the larynx and the surrounding areas. A light and lens affixed to a surgical viewing instrument called an **endoscope** are used in both methods.

Indirect laryngoscopy

Indirect laryngoscopy, the simplest form of laryngeal examination, involves the placement of a small, angled mirror at the back of the throat, allowing the examiner to reflect light onto the larynx and view its major structures. However, since the mirror must remain in the back of the throat, examination of the larynx during normal speech is hindered. Also, a strong gag reflex in some patients may limit the usefulness of this procedure.

A rigid endoscope may also be used to perform an indirect laryngoscopy. An examination using a rigid scope involves placement of the tip of the instrument through the mouth and into the back of the throat. A prism at the tip allows the examiner to view the larynx. This type of exam provides clear and highly magnified images of the vocal cords and allows better examination of the larynx during phonation (the production of vocal sounds). Another advantage to these instruments is that photographic or video recordings can be made through the endoscope for future review, also allowing more than one person to observe the laryngeal area.

Direct laryngoscopy

In direct laryngoscopy, a flexible, fiber-optic endoscope is threaded through the nasal passage and down into the throat. This procedure is used to detect or remove

KEY TERMS

Aspirate—To draw by suction.

Biopsy—The removal of a sample of tissue for study under the microscope.

Endoscope—An instrument used for visualizing the interior of a hollow organ such as the larynx.

Epiglottis—The lid-like appendage that covers the glottis during swallowing.

False cords—The protective valves of the larynx that prevent food from entering the trachea.

Laryngectomy—The surgical removal of the larynx.

Larynx—The organ of sound production, sometimes called the voice box. The larynx is made of cartilage and muscle.

Phonation—The production of vocal sounds. Examination of the larynx may be facilitated by asking the patient to produce a high-pitched “e-e-e” sound, since this lifts the epiglottis.

True cords—Also called vocal cords, these are two small shelves of muscular tissue within the larynx. They supplement the protective valves of the larynx that prevent food from entering the trachea. Their main function is to vibrate against each other and generate a sound tone.

lesions or foreign bodies in the larynx, or to diagnose **cancer** by removing tissue for biopsy or samples for culture. Once the instrument is inserted, flexible glass fibers illuminate the laryngeal area and transmit the image to the external part of the scope. From this position, an image of the larynx and vocal folds (including their movement and position during respiration and speech) can be clearly obtained.

Bronchoscopy is a similar, but more extensive procedure in which the tube is continued through the larynx and down into the trachea and bronchi.

Preparation

Patients should not eat for several hours before the examination.

Patients undergoing indirect laryngoscopy should sit in an upright position and breathe normally. The patient should be leaning slightly forward, with the head lifted. This facilitates the passage of the laryngeal mirror into the mouth and facilitates the procedure.

Topical anesthetics, such as lidocaine or dyclonine, may be used during laryngoscopy to suppress the gag reflex. The patient should be warned that the agent may **taste** bad and that the effects may be unpleasant. Anesthetized patients may feel as if their swallowing mechanism is impaired, and many experience an ill-defined sense of insecurity. Patients who are receiving anesthesia should be warned about these side effects and reassured throughout the procedure.

The gag reflex can also be reduced in the adult by the intravenous injection of diazepam (Valium). The typical dose is 10 mg. Diazepam may be used as an alternative for patients who are allergic to local anesthetics or who require both agents to allow adequate examination. Diazepam should be injected slowly into a large vein, and is only appropriate for healthy adults.

Complications

This procedure carries no serious risks, although the patient may experience soreness of the throat or cough up small amounts of **blood** until the irritation subsides. After the procedure, the patient should ingest nothing by mouth until the gag reflex returns. Once the reflex returns, fluid intake should be encouraged because it promotes the expectoration of secretions, and lozenges or gargles may be used to relieve a **sore throat**.

Vital signs should be assessed frequently for 24 hours to detect bleeding or complications such as difficult or labored respiration (dyspnea).

Results

A normal result would be the absence of signs of disease or damage.

An abnormal finding, such as a tumor or an object lodged in the tissue, would either be removed or examined for further medical attention.

Health care team roles

A nurse plays an important role in explaining the procedure to the patient, preparing the patient for the procedure, and assisting the physician in conducting the procedure. A nurse also assists patient recovery after the procedure, administering fluids and lozenges once the gag reflex returns, and monitoring vital signs.

Laser-assisted in-situ keratomileusis see Refractive eye surgeries

Laser surgery

Definition

Laser is an acronym that stands for Light Amplification by Stimulated Emission of Radiation. Laser surgery uses an intensely hot, precisely focused beam of light to remove or vaporize tissue and control bleeding in a wide variety of noninvasive and minimally invasive procedures.

Purpose

Laser surgery may be used to:

- cut or destroy tissue that is abnormal or diseased without harming healthy, normal tissue
- shrink or destroy tumors and lesions
- cauterize (seal) **blood vessels** to prevent excessive bleeding

Precautions

Although many laser surgeries can be performed in the physician's office rather than in a hospital, practitioners must be at least as thoroughly trained and highly skilled their counterparts in a hospital setting. The American Society for Laser Medicine and Surgery, Inc. recommends that:

- All operative areas be equipped with oxygen and other drugs and equipment required for **cardiopulmonary resuscitation** (CPR).
- Nonphysicians performing laser procedures be properly trained, licensed, and insured.
- A qualified and experienced supervising physician be able to respond to and manage unanticipated events or other emergencies within five minutes of the time they occur.
- Emergency transportation to a hospital or other acute-care facility be available whenever laser surgery is performed in a nonhospital setting.

All patients who are considering laser surgery should be fully informed about the procedure's relative risks and benefits, as well as any alternatives that may exist. Some types of laser surgery, for example, should not be performed on pregnant women or on patients with severe cardiopulmonary disease or other serious health problems. The patient should understand why laser surgery a better choice than traditional surgery (in this instance), and how much experience the physician has in performing the laser procedure the patient is considering. Generally, surgical nurses will inform patients about the planned procedure and, if hospital policy permits nurses to do so, obtain their **informed consent** to proceed; some hospitals require doctors to do this.

Description

The first working lasers were introduced in 1960. They were initially used to treat diseases and disorders of the eye, where transparent tissues gave ophthalmic surgeons a clear view of how the narrow, concentrated beam was being directed. Dermatologic surgeons helped further pioneer laser surgery, developing and improving many early techniques and refining surgical procedures.

Lasers are medically useful because they can be directed with pinpoint accuracy to cut, vaporize, or weld tissue while cauterizing **blood** vessels and nerves to reduce or eliminate surgical bleeding and postoperative **pain**. This reduces postoperative swelling and scarring as well as the length of the recovery period. A laser's heat often destroys **bacteria** and **viruses** in the surgical field, creating a more sterile environment that is less prone to

infection. Because a smaller incision is required, laser procedures often take less time than traditional surgery. Lasers can also be tailored to particular applications.

All lasers operate on the principle of selective photothermolysis, meaning that the laser's wavelength, energy density, power, and exposure time determine what types of tissue will be affected and the effects that will be produced. Lasers can be further adapted to different medical procedures with special delivery (such as fiberoptic cables) that help apply the laser beam.

Laser applications

Sometimes described as “scalpels of light,” lasers are used alone or with conventional **surgical instruments** and can be tailored with seemingly infinite precision for a vast number of surgical procedures. For these reasons laser surgery is often standard operating procedure for specialists in cardiology, dentistry, dermatology, gastroenterology, gynecology, neurosurgery, oncology, ophthalmology, orthopedics, otolaryngology, pulmonology, and urology.

Lasers are used to erase birthmarks, skin discolorations, and skin changes due to aging; to remove benign, precancerous, or cancerous tissues or tumors; to stop snoring; remove tonsils; remove or transplant hair; and relieve pain and restore function in patients too weak to undergo more invasive surgery. Lasers are also used to treat angina; cancerous or noncancerous tumors that cannot be removed or destroyed; cold and canker sores, gum disease and tooth sensitivity or decay; ectopic **pregnancy**, endometriosis, and fibroid tumors; gallstones; **glaucoma**, mild-to-moderate nearsightedness, **astigmatism**, and other conditions that impair **vision**; migraine headaches; noncancerous enlargement of the prostate gland; nosebleeds; ovarian cysts; ulcers; **varicose veins**; warts; and numerous other conditions, diseases, and disorders.

Types of lasers

CARBON DIOXIDE LASER. Carbon dioxide (CO₂) lasers were the first to find surgical applications, and they remain the most used of all **medical lasers**. CO₂ laser light is absorbed readily by water in the cells, allowing tissue to be cut precisely with minimal bleeding. The laser beams can be concentrated into a fine beam that slices like a scalpel, or diffused to shave or vaporize tissue. This versatility makes them valuable in many types of procedures from wart removal to **brain** surgery.

NEODYMIUM:YTRIUM-ALUMINUM-GARNET LASER. Neodymium:yttrium-aluminum-garnet laser (Nd:YAG) lasers can penetrate tissue more deeply than other lasers, allowing surgeons to operate on parts of the body that

could previously be reached only through invasive surgery. Nd:YAG lasers are the most frequently used laser in dental procedures, and are also well suited for respiratory surgery because they cauterize and seal the tiny vessels of the lung. They are also used to excise tumors with minimal damage to healthy tissue, and may even eliminate micrometastases before they can spread to another region.

Other types of YAG lasers are:

- The KTP laser, produced when Nd:YAG laser light is passed through a potassium-titanyl-phosphate (KTP) crystal. This green laser is used frequently for vascular lesions (such as leg veins) and to remove certain tattoo colors.
- The erbium (Er:YAG) laser, which penetrates less deeply into tissue; it is used in dental and hair removal procedures.
- The holmium (Ho:YAG) laser, used in orthopedic surgery to eliminate extraneous bone and cartilage, to destroy **kidney stones**, in endoscopic sinus procedures, and for prostate removal.

ARGON LASER. Another laser to find early medical application, the argon laser produces a blue-green light that is selectively absorbed by hemoglobin and melanin. This means that argon laser light is drawn to areas that are heavily pigmented or rich in blood vessels. Argon lasers are most often used for ophthalmic surgery and surface skin blemishes (birthmarks, enlarged blood vessels) because they vaporize and seal blood vessels on contact. In a special procedure known as photodynamic therapy (PDT), this laser is also used in conjunction with light-sensitive dyes to shrink or dissolve tumors.

Preparation

Because laser surgery is used to treat such a wide variety of conditions, patients should be given specific, detailed instructions about how to prepare for their procedure. Diet, activities, and medications may or may not have to be limited prior to surgery, so it's important that nurses offer written and/or verbal preoperative **patient education** and instructions. Many procedures require a preoperative **physical examination** to determine the patient's general health and current medical status, especially if **general anesthesia** will be used. Patients should also be given a realistic expectation of the procedure's outcome and the duration of recovery.

Aftercare

Many laser surgeries are performed on an outpatient basis, and patients are usually permitted to leave the

Cosmetic laser surgery in progress. The wavelengths of the laser's light can be matched to a specific target, enabling the physician to destroy the capillaries near the skin's surface without damaging the surrounding tissue. (Photograph by Will & Deni McIntyre, Photo Researchers, Inc. Reproduced by permission.)

hospital, medical office, or surgical center once their **vital signs** have stabilized. Patients who have been sedated should not be discharged until they have completely recovered from the anesthesia and they are oriented and alert. Most practitioners require discharged patients to be accompanied by a responsible adult. Patients should not drive themselves to or from the facility.

The physician may prescribe analgesic medication for postoperative pain, and should provide easy-to-understand written instructions that describe how the patient's recovery should progress, the actions to take in the event of complications, and how to recognize complications requiring emergency medical treatment.

Complications

The risks and complications associated with laser surgery are comparable to those for other surgical procedures. Treated areas can become infected following laser surgery; this should be suspected if burning, crusting of the skin, itching, pain, scarring, severe redness, and swelling appear at the treatment site. Other risks are associated with anesthesia and complications such as hemor-

rhage, perforation, or infection. Fortunately, errors of this sort tend to occur when a physician is poorly supervised while learning a new skill. Serious complications are rare with experienced doctors.

Some complications may be cosmetic: lighter or darker skin may appear when a laser is used to remove sun damage or age spots from an olive- or dark-skinned individual. This abnormal pigmentation may or may not disappear in time. Black, Asian, Hispanic, or dark-skinned patients should make sure that their surgeon has performed laser procedures successfully on people of color.

Laser surgery also involves unique risks: Imprecisely aimed lasers can burn or destroy healthy tissue, cause injuries that are painful and sometimes permanent, and even compound the problems they are supposed to solve. Errors or inaccuracies in laser eye surgery can damage or worsen a patient's vision, for example. Scarring or rupturing of the cornea is uncommon, but laser surgery on one or both eyes can increase sensitivity to light or glare, reduce night vision, permanently cloud vision, or cause sharpness of vision to decline throughout

KEY TERMS

Argon—A colorless, odorless gas, which, when used in a laser, emits a blue-green beam.

Astigmatism—A condition in which one or both eyes cannot filter light properly because the corneal surface is irregular. This results in blurred, indistinct images unless corrected by glasses, contact lenses, or laser surgery.

Carbon dioxide—A heavy, colorless gas that dissolves in water.

Cauterize—The use of heat or chemicals to stop bleeding, prevent the spread of infection, or destroy tissue.

Cornea—The outer, transparent lens that covers the pupil of the eye and admits light.

Endometriosis—An often painful gynecologic condition in which endometrial tissue migrates from the inside of the uterus to other organs inside and beyond the abdominal cavity.

Glaucoma—A disease of the eye in which increased pressure within the eyeball can cause gradual loss of vision. Iridectomy is the laser surgical procedure that helps relieve the pressure.

Invasive surgery—Surgery that involves making an incision in the patient's body and inserting instruments or other medical devices into it.

Nearsightedness—A condition in which one or both eyes cannot focus normally, causing objects at a distance to appear blurred and indistinct. Also called myopia.

Ovarian cyst—A benign or malignant growth on an ovary. An ovarian cyst can disappear without treatment or become extremely painful and have to be surgically removed.

Papillomavirus—A group of viruses that cause several types of warts, some of which can cause cancer.

Vaporize—To dissolve solid material or convert it into smoke or gas with a laser.

Varicose veins—Peripheral veins, usually in the legs, that have valvular insufficiency. This allows blood to pool in the vessels of the lower extremities, permanently dilating the veins.

surgery on any part of the face near the eyes or eyelids, and a United States Food and Drug Administration (FDA) mandate requires both health care personnel and patients to use special protective eyewear whenever a CO₂ laser is used.

An unexpected risk associated with laser surgery is the “plume” or smoke that is emitted when lasers vaporize tissue. Studies have shown that although the particles in the smoke are very small (0.5–5.0µm), they are small enough to pass through a surgical mask. This is a concern for both patient and health care personnel because viral DNA has been shown to survive in the smoke produced when warts are removed by a laser, and some forms of papillomavirus are infectious. To guard against any possible contagion, a vacuum system with a multistage filter is recommended to suction the smoke produced during laser procedures; it must be held very close (about 1 cm) from the target to be effective.

Results

The nature and severity of the problem addressed by the laser procedure, the skill of the surgeon performing the procedure, as well as the patient's general health and realistic expectations about the result of the procedure are among the factors that influence the outcome of laser surgery.

Patients considering any type of laser surgery should be fully apprised of the risks, benefits and potential complications of the procedure as well as any alternative treatment that might be feasible in place of laser surgery. It is especially important for patients undergoing cosmetic procedures to have realistic expectations about the outcomes of these procedures.

Health care team roles

Laser surgery may be performed by a general surgeon, cardiologist, dentist, oral surgeon, dermatologist, gynecologist, ophthalmologist, otolaryngologist, plastic surgeon, urologist or other physician specialist, assisted by specially trained surgical nurses. Preoperative blood work is performed by laboratory technologists, and when necessary, imaging studies may be performed by radiologic technicians.

Patient education

Nurses have a vital role in delivering pre- and post-operative patient education. There is considerable evidence that well-informed patients achieve better clinical outcomes and experience higher levels of satisfaction with treatment. Patients considering laser surgery should

the day. To guard against some of these risks, patients must wear protective eye shields while undergoing laser

be provided with detailed information about the anticipated outcomes of the surgery and the duration of recovery process.

Laxatives

Definition

Laxatives are products that promote bowel movements.

Purpose

Laxatives are used to treat constipation—the passage of small amounts of hard, dry stools, usually fewer than three times a week. Before recommending use of laxatives, differential diagnosis should be performed. Prolonged constipation may be evidence of a significant problem, such as localized peritonitis or diverticulitis. Complaints of constipation may be associated with obsessive-compulsive disorder. Use of laxatives should be avoided in these cases. Patients should be aware that patterns of defecation are highly variable, and may vary from two to three times daily to two to three times weekly.

Laxatives may also be used prophylactically for patients, such as those recovering from a **myocardial infarction** or those who have had recent surgery, who should not strain during defecation.

Description

Laxatives may be grouped by mechanism of action.

Saline cathartics include dibasic sodium phosphate (Phospo-Soda), magnesium citrate, magnesium hydroxide (milk of magnesia), magnesium sulfate (Epsom salts), sodium biphosphate, and others. They act by attracting and holding water in the intestinal lumen, and may produce a watery stool. Magnesium sulfate is the most potent of the laxatives in this group.

Stimulant and irritant laxatives increase the peristaltic movement of the intestine. Examples include cascara and bisacodyl (Dulcolax). Castor oil works in a similar fashion.

Bulk producing laxatives increase the volume of the stool, and will both soften the stool and stimulate intestinal motility. Psyllium (Metamucil, Konsil) and methylcellulose (Citrucel) are examples of this type. The overall effect is similar to that of eating high-fiber foods, and this class of laxative is most suitable for regular use.

Docusate (Colace) is the only representative example of the stool softener class. It holds water within the fecal mass, providing a larger, softer stool. Docusate has no effect on acute constipation, since it must be present before the fecal mass forms to have any effect, but may be useful for prevention of constipation in patients with

KEY TERMS

Carbohydrates—Compounds, such as cellulose, sugar, and starch, that contain only carbon, hydrogen, and oxygen, and are a major part of the diets of people and other animals.

Cathartic colon—A poorly functioning colon, resulting from the chronic abuse of stimulant cathartics.

Colon—The large intestine.

Diverticulitis—Inflammation of the part of the intestine known as the diverticulum.

Fiber—Carbohydrate material in food that cannot be digested.

Hyperosmotic—Hypertonic, containing a higher concentration of salts or other dissolved materials than normal tissues.

Osteomalacia—A disease of adults, characterized by softening of the bone. Similar to Rickets which is seen in children.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies, or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies, or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Steatorrhea—An excess of fat in the stool.

Stool—The solid waste that is left after food is digested. Stool forms in the intestines and passes out of the body through the anus.

recurrent problems, or those who are about to take a constipating drug, such as narcotic **analgesics**.

Mineral oil is an emollient laxative. It acts by retarding intestinal absorption of fecal water, thereby softening the stool.

The hyperosmotic laxatives are glycerin and lactulose (Chronulac, Duphalac), both of which act by holding water within the intestine. Lactulose may also increase peristaltic action of the intestine.

Precautions

Short term use of laxatives is generally safe except in **appendicitis**, fecal impaction, or intestinal obstruction. Lactulose is composed of two sugar molecules; galactose and fructose, and should not be administered to patients who require a low galactose diet.

Chronic use of laxatives may result in fluid and electrolyte imbalances, steatorrhea, osteomalacia, **diarrhea**, cathartic colon, and **liver** disease. Excessive intake of mineral oil may cause impaired absorption of oil soluble **vitamins**, particularly A and D. Excessive use of magnesium salts may cause hypermagnesemia.

Lactulose and magnesium sulfate are **pregnancy** category B. Casanthranol, cascara sagrada, danthron, docusate sodium, docusate **calcium**, docusate potassium, mineral oil and senna are category C. Casanthranol, cascara sagrada and danthron are excreted in breast milk, resulting in a potential increased incidence of diarrhea in the nursing infant.

Interactions

Mineral oil and docusate should not be used in combination. Docusate is an emulsifying agent which will increase the absorption of mineral oil.

Bisacodyl tablets are enteric coated, and so should not be used in combination with **antacids**. The antacids will cause premature rupture of the enteric coating.

Recommended dosage

See specific resources.

Learning theory

Definition

Learning is defined as a relatively permanent change in behavior as a result of experience. This definition excludes changes that might occur solely as a result of maturation, injury, or disease. To learn is to adapt. A child might stick his or her finger in a light socket, but not more than once. Sea lions in an aquarium will learn to bark and slap the water if these behaviors prompt people to toss them food. Changes that occur as a result of learning are not always positive. We may acquire bad (maladaptive) habits, as well as good ones. Three basic kinds of learning have been studied extensively by psychologists. These are: classical conditioning, operant conditioning, and observational learning.

Description

Classical conditioning

The pioneer of the study of classical conditioning was Ivan Pavlov. While studying salivation in dogs as part of his research on digestion, Pavlov discovered an interesting phenomenon. Dogs that had been repeatedly given meat in order to induce salivation began to salivate before the presentation of the meat. The sight of the pan containing the meat, or the sound of the experimenter's footsteps coming toward the laboratory was enough to initiate salivation. This was curious. Dogs do not normally salivate to the sound of footsteps, thus they must have acquired this response as a result of experience. In other words, learning had taken place.

Pavlov recognized the potential importance of the dogs' behavior, and subsequently turned his attention to the study of what we now know as conditioned **reflexes**. By carefully scrutinizing the dogs' behaviors under controlled laboratory conditions, Pavlov discovered and described the principles of classical conditioning. In order to understand its operation, there are a few key terms that need to be explained. An unconditional stimulus refers to a thing or event that triggers a response (change) reflexively or automatically. This response is referred to as an unconditional response. It is automatically produced; no learning is needed for it to occur. A neutral stimulus is a stimulus that elicits no response (or at least not the response being studied). When a neutral stimulus is repeatedly paired with an unconditional stimulus it will produce an effect similar to that of the unconditional stimulus. This mutated neutral stimulus, if you will, is referred to as a conditioned stimulus and the response it produces is called a conditioned response. The conditioned response, unlike the unconditioned

response, is learned. Each pairing of an unconditional stimulus with a conditional stimulus is referred to as reinforcement. The pairing strengthens or reinforces the conditioned response. In classical conditioning it is important to remember that the initial stimulus and its response (i.e., the unconditioned stimulus and response) occur naturally; they are instinctual, so to speak.

HOW CLASSICAL CONDITIONING WORKS. In the first stage, the unconditioned (natural) response to an unconditioned stimulus occurs automatically. It is a natural, reflexive reaction. For example, eating meat will make a dog salivate to aid in digestion. In the second stage, a neutral stimulus is paired with the natural or unconditioned stimulus. Using our example of the dog and meat, suppose we ring a bell just before the meat is given to the dog. If we do this repeatedly the bell alone will cause the dog to salivate and this represents the third stage of classical conditioning. In other words the conditioned stimulus now produces a conditioned response. This response was not present before the conditioning process (or learning) took place. Conditioning occurs most quickly and effectively when the conditioned stimulus immediately precedes the unconditioned stimulus.

Because of classical conditioning, certain events can produce unwanted distress for reasons that are largely unrelated to the event itself. Young children, for example, often become fearful during their first visit to a barber. Barbers often wear white smocks, similar to those worn by doctors. There are also numerous metallic instruments (scissors, razors) in plain sight in the barbershop. Unpleasant experiences at the doctor's office (e.g., an injection) could become associated with accompanying stimuli (the doctor's white coat, silver instruments) in such a way that similar stimuli (in other settings) could trigger an **anxiety** response. Some children's barbers make a point of wearing colored (as opposed to white) jackets, and take pains to reduce any similarities between their work areas and doctors' examining rooms.

Viewpoints

On the basis of his research, Pavlov assumed that the basic associations established through classical conditioning were universal. In other words, he believed that all animals would show conditioning, and that any natural response could be conditioned to any and all neutral stimuli. More recent research has shown that there are restrictions on the kinds of associations that are amenable to conditioning. For example when tastes, sounds, and visual stimuli were used as conditioned stimuli prior to being given a nausea-inducing drink, rats very quickly learned to associate **taste** with illness, and forever after avoided similar tasting food. This happened even if the

nausea occurred several hours after the ingestion. Moreover, neither the visual nor the auditory stimuli created aversion responses. Apparently all animals, including humans, are biologically prepared to learn some associations rather than others. It is as if nature prepares each species to learn what is best suited to its survival.

Operant conditioning

If the sole mechanism of learning were classical conditioning only a very limited number of responses could be learned. A dog may learn to salivate at the sound of a bell but how are new, voluntary responses learned? How does the animal learn to operate on its environment?

Operant conditioning provides some insight. In classical conditioning the animal is relatively passive. In operant conditioning the animal is an active part of its environment. It operates on the environment. Two pioneers of this approach are Edward L. Thorndike (1874-1949) and B. F. Skinner (1904-1990). At about the same time that Pavlov was performing his experiments with dogs, Thorndike began experimenting with cats. He devised a box from which a cat could escape only if it performed a particular action. For example, the cat would have to press a lever, which would, in turn, cause a rope to pull a bolt from the door and thus allow it to escape. Through trial-and-error the cat would eventually escape from the box. Thorndike noticed that over successive trials, it took progressively less and less time for the cat to solve its problem. Thorndike reasoned that the gratifying experience of being released from the box caused the correct response (pressing the lever) to occur more rapidly on the subsequent trials.

Skinner's research extended and elaborated this simple fact of life: behavior that is rewarded is more likely to recur.

Much of Skinner's research utilized laboratory rats and pigeons. He designed the now famous Skinner Box—a soundproof chamber with a bar or key, which, if pressed or pecked, would dispense a reward of food or water. Once the rat was placed into the box, the experimenter had total control over its environment. The equipment could be programmed to deliver positive or negative reinforcement. For example, the box could be rigged with a lever that, when pressed, turned off a mild electric shock (negative reinforcement). A negative reinforcer is one that strengthens a response by removing an aversive or unpleasant stimulus.

Before a response can be reinforced, it must first occur. Suppose you wanted to teach a dog to climb a ladder. Because this action has no probability of occurring spontaneously, you would wait forever for it to occur so that it could be reinforced. What to do? The solution is to

use a procedure known as shaping. When we shape a behavior, we define some ultimate target behavior and then reinforce all actions that are even remotely related to the target behavior. Thus the dog might receive a reward for placing a paw on the bottom rung of the ladder. The trainer then requires responses that are more and more similar to the final, desired response. These responses that are rewarded on the way to the final target behavior are called successive approximations. With shaping (and patience) various animals can be taught to produce extraordinary sequences of behaviors. There are bears in the Russian circus that drive motorcycles. Seeing eye dogs act as the “eyes” for the blind, and can also be taught to assist people with **spinal cord** injuries by turning on light switches or opening doors. The basic principles of operant conditioning have important practical implications. These principles are at the **heart** of behavior modification therapy—a treatment approach that has demonstrated some impressive successes in schools, prisons, mental hospitals, and rehabilitation wards.

Observational learning

While classical conditioning and reinforcement principles are powerful and ubiquitous determinants of behavior, they do not tell the whole story, especially when it comes to human learning. We do not always learn through direct experience. Indeed, we wouldn't survive for very long if we could not learn from watching others. Observational learning plays a role in almost every aspect of our activities, from learning how to hold a fork, drive a car, smoke a cigarette, or have sex. Observational learning occurs in fish, birds, and mammals too. For example, if given a choice, rats will prefer to eat food that they have seen other rats choose. Research has demonstrated that children imitate their parents' food aversions. After the first few months of *The Simpsons* television show, many young girls across the country began expressing an interest in playing the baritone saxophone—Lisa Simpson's instrument of choice.

The observational learning perspective emphasizes that what is learned is ‘knowledge’ about behavior, in addition to the behavior itself. Role models can be quite influential. If you want to encourage a child to read, read to them, surround him or her with books and with people who read them. Not surprisingly, modeling effects cut both ways. Antisocial role models can cultivate negative patterns of behavior in the observer. Children who grow up in households where wife abuse is common are “learning” that physical assaults and intimidation are effective ways of controlling others. Models are most likely to be imitated when they have status, when their actions are rewarded, when the modeled behaviors are in the observer's repertoire, and when the observer is moti-

vated to emulate the model. While it is disheartening to realize how easily antisocial behaviors can be acquired, the overall legacy from learning theories is one of hope. What is learnable is also (potentially) teachable. This fact inspires parents, teachers and therapists. And what is learned can also be unlearned. No matter how distressed we may feel, we are not stuck forever with our current state. Humans are remarkably capable of change through learning.

Leukemias, acute

Definition

Acute leukemia is a type of **cancer** in which excessive quantities of abnormal white **blood** cells are produced.

Description

Medical science further classifies acute leukemia by the type of white blood cell that undergoes mutation. The most common of these are:

- Acute lymphoblastic leukemia (ALL), in which excessive quantities of lymphoblasts, or immature lymphocyte white blood cells, are produced.
- Acute myeloblastic leukemia (AML), also known as acute nonlymphocytic leukemia (ANLL), in which excessive quantities of other types of immature white blood cells are produced.

Acute leukemias progress rapidly, while the **chronic leukemias** progress more slowly. The vast majority of the childhood leukemias are of the acute form.

The cells that make up blood are produced in the bone marrow and the **lymphatic system**. Bone marrow is the spongy tissue found in the large bones of the body. The lymphatic system includes the spleen (an organ in the upper abdomen), the thymus (a small gland beneath the breastbone), and the tonsils (a mass of lymphatic tissue located in the throat). In addition, the lymphatic vessels (tiny tubes that branch like **blood vessels** into all parts of the body) and lymph nodes (pea-shaped organs that are found along the network of lymphatic vessels) are also part of the lymphatic system. Lymph is a milky fluid that contains cells. Clusters of lymph nodes are found in the neck, underarm, pelvis, abdomen, and chest.

The cells found in the blood include red blood cells (RBCs) that carry oxygen and other materials to all tissues of the body; white blood cells (WBCs) that fight **infection**; and platelets, which play an important role in the clotting of the blood. White blood cells can be further subdivided into three main types: granulocytes, monocytes, and lymphocytes.

The granulocytes, as their name suggests, have particles (granules) inside them. These granules contain special **proteins** (enzymes) and several other substances that can break down chemicals and destroy microorganisms, such as **bacteria**. Monocytes are the second type of white blood cell. They are also important in defending the body against pathogens.

Lymphocytes are the third type of white blood cell. There are two primary types of lymphocytes—T lymphocytes and B lymphocytes—with different functions in the **immune system**. B cells protect the body by making antibodies. Antibodies are proteins that can attach to the surfaces of bacteria and **viruses**. This "attachment" sends signals to many other cell types to come and destroy the antibody-coated organism. T cells protect the body against viruses. When a virus enters a cell, it produces certain proteins that are projected onto the surface of the infected cell. T cells recognize these proteins and make certain chemicals that are capable of destroying the virus-infected cells. In addition, T cells can destroy some types of cancer cells.

Bone marrow makes stem cells, which are the precursors of the different blood cells. These stem cells mature through stages into either RBCs, WBCs, or platelets. In acute leukemias, the maturation process of the white blood cells is interrupted. The immature cells (or "blasts") proliferate rapidly and begin to accumulate in various organs and tissues, thereby affecting their normal function. This uncontrolled proliferation of the

immature cells in the bone marrow affects the production of the normal red blood cells and platelets as well.

As noted, there are two types of acute leukemias—acute lymphocytic leukemia and acute myelogenous leukemia. Different types of white blood cells are involved in the two leukemias. In acute lymphocytic leukemia (ALL), it is the T or the B lymphocytes that are involved. The B cell leukemias are more common than T cell leukemias. Acute myelogenous leukemia, also known as acute nonlymphocytic leukemia (ANLL), is a cancer of the monocytes and/or granulocytes.

Leukemias account for 2% of all cancers. Because leukemia is the most common form of childhood cancer, it is often regarded as a disease of childhood. However, leukemias affect far more adults than children. Half of the cases occur in people who are 60 years of age or older. The incidence of acute and chronic leukemias is about the same. According to the estimates of the American Cancer Society (ACS), approximately 29,000 new cases of leukemia are diagnosed each year in the United States. Of these, 27,000 will be diagnosed in adults, 2,000 in children.

Causes and symptoms

Leukemia strikes both sexes and all ages. The human T-cell leukemia virus (HTLV-I), a virus with similarities to the human **immunodeficiency** virus (HIV), is believed to be the causative agent for some kinds of leukemias, but this has not yet been proven, and the cause of most leukemias is not known. Acute lymphoid leukemia (ALL) is more common among Caucasians than among African-Americans, while acute myeloid leukemia (AML) affects both races equally. The incidence of acute leukemia is slightly higher among men than women. People with Jewish ancestry have a higher likelihood of getting leukemia. A higher incidence of leukemia has also been observed among persons with **Down syndrome** and some other genetic abnormalities.

Reports in *Science News* cited studies that found a gene that regulates folic acid **metabolism** in the body to be more prevalent in acute lymphocytic leukemia (ALL) patients. **Folic acid** is known to be involved in the process of DNA maintenance and repair, and this gene diverts folic acid from this function. It is therefore hypothesized that this gene plays a role in the development of ALL, and that folic acid supplementation could lower the risk for developing ALL. This gene has not been found to play a part in other leukemias, such as AML.

Exposure to ionizing radiation, such as occurred in Japan after the atomic bomb explosions, has been shown

to increase the risk of getting leukemia. Electromagnetic fields are suspected of being a possible cause, as are certain organic chemicals, such as benzene. Having a history of diseases that damage the bone marrow, such as aplastic anemia, or a history of cancers of the lymphatic system puts people at a high risk for developing acute leukemias. Similarly, the use of anticancer medications, immunosuppressants, and the antibiotic chloramphenicol are also considered risk factors for developing acute leukemias.

The symptoms of leukemia are generally vague and non-specific. A patient may experience all or some of the following symptoms:

- weakness or chronic fatigue
- fever of unknown origin, chills and flu-like symptoms
- weight loss that is not due to dieting or **exercise**
- frequent bacterial or viral infections
- headaches
- skin rash
- non-specific bone **pain**
- easy bruising
- bleeding from gums or nose
- blood in urine or stools
- swollen and tender lymph nodes and/or spleen
- abdominal fullness
- night sweats
- petechiae, or tiny red spots under the skin
- more rarely, sores in the eyes or on the skin

Diagnosis

For a successful outcome, treatment for acute leukemia must begin as soon as possible, but there are no screening tests available. If the doctor has reason to suspect leukemia, he or she will conduct a very thorough **physical examination** to look for enlarged lymph nodes in the neck, underarm, and pelvic region. Swollen gums, enlarged **liver** or spleen, bruises, or pinpoint red rashes all over the body are some of the signs of leukemia. Urine and blood tests may be ordered to check for microscopic amounts of blood in the urine and to obtain a complete differential blood count. This count will give the numbers and percentages of the different cells found in the blood. An abnormal blood test might suggest leukemia; however, the diagnosis must be confirmed by more specific tests.

The doctor may perform a bone marrow biopsy to confirm the diagnosis of leukemia. During the biopsy, a

cylindrical piece of bone and marrow is removed. The tissue is generally taken out of the hipbone. These samples are sent to the laboratory where they are examined under a **microscope** by a hematologist, oncologist, or pathologist. In addition to the diagnostic biopsy, another biopsy will also be performed during the treatment phase of the disease to see if the leukemia is responding to therapy.

A spinal tap (lumbar puncture) is another procedure that the doctor may order to diagnose leukemia. In this procedure, a small needle is inserted into the spinal cavity in the lower back to withdraw some cerebrospinal fluid and to look for leukemic cells.

Standard imaging tests, such as x rays, computed tomography scans (**CT scans**), and **magnetic resonance imaging** (MRI) may be used to check whether the leukemic cells have invaded other areas of the body, such as the bones, chest, **kidneys**, abdomen, or **brain**. A gallium scan or bone scan is a test in which a radioactive chemical is injected into the body. This chemical accumulates in the areas of cancer or infection, allowing them to be viewed with a special camera.

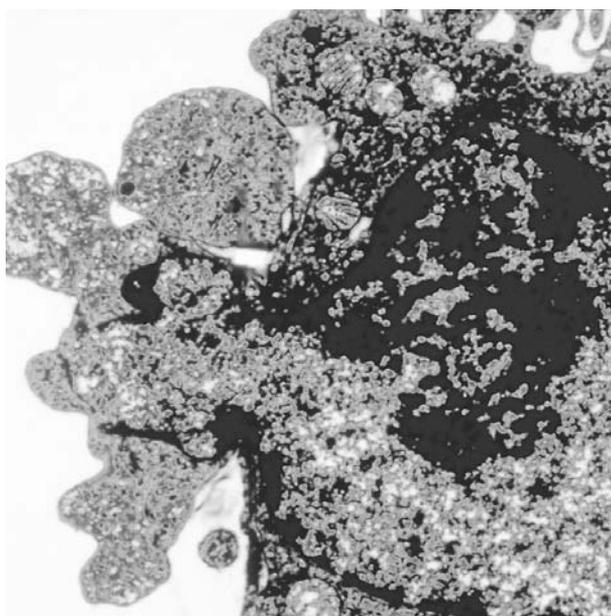

Treatment

As noted, treatment must be begun as soon as possible. The goal of treatment is remission, or an arresting of the disease process of the leukemia. There are two phases of treatment for leukemia. The first phase is called induction therapy. As the name suggests, during this phase, the primary aim of the treatment is to reduce the number of leukemic cells as much as possible and induce a remission in the patient. Once the patient shows no obvious signs of leukemia (no leukemic cells are detected in blood tests and bone marrow biopsies), the patient is said to be in remission.

The second phase of treatment is then initiated. This is called continuation or maintenance therapy, and the goal is to kill any remaining cancer cells and to maintain the remission for as long as possible.

Chemotherapy

Chemotherapy is the use of drugs to kill cancer cells. It is usually the treatment of choice in leukemia, and is used to relieve symptoms and achieve long-term remission of the disease. Generally, combination chemotherapy, in which multiple drugs are used, is more efficient than using a single drug for the treatment. Some drugs may be administered intravenously through a vein in the arm; others may be given by mouth in the form of pills. If the cancer cells have invaded the brain, then chemotherapeutic drugs may be put into the fluid that surrounds the brain through a needle in the brain or back.

An enhanced transmission electron microscopy (TEM) of acute myelogenous leukemia cells. (Photograph by Robert Becker, Ph.D., Custom Medical Stock Photo. Reproduced by permission.)

This is known as intrathecal chemotherapy. Because leukemia cells can spread to all the organs via the blood stream and the lymphatic vessels, surgery is not considered an option for treating leukemias.

Radiation

Radiation therapy, which involves the use of x rays or other high-energy rays to kill cancer cells and shrink tumors, may be used in some cases. For acute leukemias, the source of radiation is usually outside the body (external radiation therapy). If the leukemic cells have spread to the brain, radiation therapy can be given to the brain.

Bone marrow transplantation

Bone marrow transplantation is a process in which the patient's diseased bone marrow is replaced with healthy marrow. There are two ways of doing a bone marrow transplant. In an *allogeneic* bone marrow transplant, healthy marrow is taken from a donor whose tissue is either the same as or very closely resembles the patient's tissues. The donor may be a twin, a brother or sister (sibling), or a person who is not related at all. First, the patient's bone marrow is destroyed with very high doses of chemotherapy and radiation therapy. Healthy marrow from the donor is then given to the patient through a needle in a vein to replace the destroyed marrow.

KEY TERMS

Antibodies—Proteins made by the B lymphocytes in response to the presence in the body of infectious agents, such as bacteria or viruses.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Chemotherapy—Treatment with drugs that act against cancer.

Computerized tomography (CT) scan—A series of x rays put together by a computer in order to form detailed pictures of areas inside the body.

Cytokines—Chemicals made by the cells that act on other cells to stimulate or inhibit their function. Cytokines that stimulate growth are called growth factors.

Immunotherapy—Treatment of cancer by stimulating the body's immune defense system.

Lumbar puncture—A procedure in which the doctor inserts a small needle into the spinal cavity in the lower back to withdraw some spinal fluid for testing. Also known as a spinal tap.

Magnetic resonance imaging (MRI)—A medical procedure using a magnet linked to a computer to picture areas inside the body.

Maturation—The process by which stem cells transform from immature cells without a specific function into a particular type of blood cell with defined functions.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Remission—A disappearance of a disease as a result of treatment. Complete remission means that all disease is gone. Partial remission means that the disease is significantly improved by treatment, but residual traces of the disease are still present.

In the second type of bone marrow transplant, called an autologous bone marrow transplant, some of the patient's own marrow is taken out and treated with a combination of **anticancer drugs** to kill all the abnormal cells. This marrow is then frozen to preserve it. The marrow remaining in the patient's body is destroyed with high-dose chemotherapy and radiation therapy. The marrow that was frozen is then thawed and given back to the patient through a needle in a vein. This type of bone mar-

row transplant is currently being investigated in clinical trials.

Biological therapy or immunotherapy is a mode of treatment in which the body's own immune system is harnessed to fight the cancer. Interferon is a biological therapy that is increasingly being used. Substances that are routinely made by the immune system (such as growth factors, hormones, and disease-fighting proteins) are either synthetically made in a laboratory or their effectiveness is boosted and they are then put back into the patient's body. This treatment mode is also being investigated in clinical trials all over the country at major cancer centers.

Prognosis

Like all cancers, the prognosis for leukemia depends on the patient's age and general health. According to statistics, more than 60% of the patients with leukemia survive for at least a year after diagnosis. Acute myelocytic leukemia (AML) has a poorer prognosis rate than acute lymphocytic leukemias (ALL) and the chronic leukemias. In the last 15 to 20 years, the five-year survival rate for patients with ALL has increased from 38% to 57%.

Interestingly enough, since most childhood leukemias are of the ALL type, chemotherapy has been highly successful in their treatment. This is because chemotherapeutic drugs are most effective against actively growing cells. Due to the new combinations of anticancer drugs being used, the survival rates among children with ALL have improved dramatically. Ninety-five percent of all childhood ALL patients will enter remission, and 60–75% will remain in remission after five years, depending upon the type. T-cell ALL is considered curable in half of all cases, while B-cell ALL is rarely, if ever curable. The worst prognosis is for non-tytable ALL, whose victims are usually below one year of age.

Health care team roles

In most cases, a diagnosis of leukemia is made in a physician's office, a general medical clinic, or emergency room by a primary care practitioner. Children and adolescents with leukemia are likely to be diagnosed by their primary care physician, or pediatrician. However, oncologists, or physicians that specialize in the diagnosis and treatment of cancer are also often involved. Hematologists, physicians that specialize in the diagnosis and treatment of disorders of the blood and the organs that produce blood cells, may become involved through consultation. A pathologist, or physician who specializes in studying tissue and cell samples, often to assist other

physicians in reaching the correct diagnosis, also may be consulted.

Both registered nurses and licensed practical nurses provide direct care to leukemia patients in general hospitals, homes, or other healthcare facilities. Good supportive nursing care and observation are necessary to:

- Prevent or monitor for the infections to which leukemia patients are so susceptible.
- Monitor for anemia and bleeding.
- Assist in treatments such as chemotherapy, radiation, bone-marrow transplantation, or in giving blood transfusions.
- Monitor vital signs.
- Provide teaching regarding the prevention of infection, the normal course of leukemia, including the fatigue so many patients feel, the signs and symptoms of anemia, and good dental care (both leukemia and chemotherapy are apt to cause sensitivity in the mouth, vulnerability to infection and bleeding).

Clinical laboratory scientists draw blood samples that are ordered by the physician to monitor the leukemia from the outset, during treatment, and also during remission. Radiologic technologists take x rays to visualize and monitor parts of the body that may be affected by the leukemia.

Prevention

Most cancers can be prevented by changes in lifestyle or diet, which will reduce the risk factors. However, in leukemias, there are no such known risk factors. Therefore, at the present time, no way is known to prevent leukemias from developing. People who are at an increased risk for developing leukemia because of proven exposure to ionizing radiation or exposure to the toxic liquid benzene, and people with Down syndrome, should undergo periodic medical checkups.

Leukemias, chronic

Definition

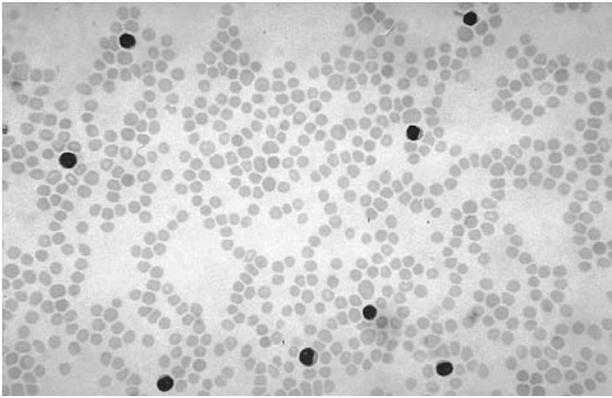

Chronic leukemia is a type of **cancer** in which excessive quantities of abnormal white **blood** cells are produced, usually slowly, often over a period of years.

Description

Medical science further classifies chronic leukemia by the type of white blood cell that undergoes mutation. The most common of these are:

- Chronic lymphocytic leukemia (CLL), in which mature-appearing white blood cells called lymphocytes are produced.
- Chronic myeloid (or myelogenous) leukemia (CML), also known as chronic granulocytic leukemia (CGL), is the result of uncontrolled proliferation of white blood cells called granulocytes.

Chronic leukemias are much less rapid-growing than acute leukemia, and affect adults far more often than children. In fact, nearly all the people who develop CLL are over 50 years of age. CML is also a disease primarily of middle-aged to elderly people, but 3% of all childhood leukemias are classified as CML, and the average age for developing CML is between ages 10 and 12.

A magnified stain of chronic lymphocytic leukemia cells.
(Custom Medical Stock Photo. Reproduced by permission.)

The cells that make up blood are produced in the bone marrow and the lymph system. The bone marrow is the spongy tissue found in the large bones of the body. The lymph system includes the spleen (an organ in the upper abdomen), the thymus (a small organ beneath the breastbone), and the tonsils (an organ in the throat). The lymph vessels (tiny tubes that branch like **blood vessels** into all parts of the body) and lymph nodes (small pea-shaped organs that are found along the network of lymph vessels) are also part of the lymph system. The lymph itself is a milky fluid that contains cells. Clusters of lymph nodes are found in the neck, underarm, pelvis, abdomen, and chest.

The cells found in the blood are the red blood cells (RBCs), which carry oxygen and other materials to all tissues of the body; white blood cells (WBCs), which fight **infection**; and the platelets, which play an important role in the clotting of the blood. The white blood cells can be further subdivided into three main types: granulocytes, monocytes, and lymphocytes.

The granulocytes have particles (granules) inside them that contain special **proteins** (enzymes) and several other substances that can break down chemicals and destroy microorganisms such as **bacteria**. Monocytes are the second type of white blood cell. They are also important in defending the body against pathogens.

The lymphocytes form the third type of white blood cell. The two primary types of lymphocytes, T lymphocytes and B lymphocytes, have different functions within the **immune system**. The B cells protect the body by making antibodies, which are proteins that can attach to the surfaces of bacteria and **viruses**. This attachment sends signals to many other cell types to destroy the antibody-coated organism. The T cells protect the body against viruses. When a virus enters a cell, it produces certain proteins that are projected onto the surface of the

infected cell. The T cells recognize these proteins and make certain chemicals that are capable of destroying the virus-infected cells. In addition, the T cells can destroy some types of cancer cells.

The bone marrow makes stem cells, which are the precursors of the different blood cells. Stem cells mature into RBCs, WBCs, or platelets. In chronic leukemias, blood cells suddenly begin to proliferate rapidly and begin to accumulate in various organs and tissues, thereby affecting their normal function. This uncontrolled proliferation of the immature cells in the bone marrow affects the production of the normal red blood cells and platelets as well.

Different types of white blood cells are involved in chronic lymphocytic leukemia and chronic myeloid leukemia. Although some blasts, or immature cells (the hallmark of acute leukemia), are also present in chronic leukemia, it is the T or B lymphocytes that gradually mutate and become cancerous. The scenario is similar for chronic myelogenous leukemia, also known as chronic granulocytic leukemia (CGL), which occurs when unusually large numbers of granulocytes begin to appear in the bloodstream.

Leukemias account for 2% of all cancers. According to the estimates of the American Cancer Society (ACS), approximately 29,000 new cases of leukemia are diagnosed each year in the United States. Of these, 27,000 will be diagnosed in adults, 2000 in children. Leukemia is the most common form of childhood cancer, and it is often regarded as a disease of childhood. However, leukemias, especially chronic leukemia, affect far more adults than children. Half of all leukemia cases occur in people who are 60 years of age or older, and the overwhelming majority of chronic leukemias occur in adults. The incidence of both acute and chronic leukemias is about the same.

Causes and symptoms

Leukemia strikes both sexes and all ages. The human T-cell leukemia virus (HTLV-I), a virus with similarities to the human immunovirus (HIV), is believed to be the causative agent for some kinds of leukemias, but this has not yet been proven. To date, the cause of most leukemias is not known. Lymphoid leukemias are more common among Caucasians than among African-Americans, while myeloid leukemias affects both races equally. The incidence of leukemia is slightly higher among men than women. People with Jewish ancestry have a higher likelihood of getting leukemia. A higher incidence of leukemia has also been observed among persons with **Down syndrome** and some other genetic abnormalities. Patients with chronic myeloid leukemia often show a

chromosome abnormality called the Philadelphia chromosome, that occurs when one chromosome attaches to another.

Exposure to ionizing radiation, such as occurred in Japan after the atomic bomb explosions, has been shown to increase the risk of getting leukemia. Electromagnetic fields are suspected of being a possible cause, as are certain organic chemicals such as benzene. Having a history of diseases that damage the bone marrow, such as aplastic anemia, or a history of cancers of the **lymphatic system** puts people at a high risk for developing leukemias. Similarly, the use of anticancer medications, immunosuppressants, and the antibiotic chloramphenicol are also considered risk factors for developing leukemias.

The symptoms of chronic leukemia are generally vague and non-specific, and are frequently overlooked until they are noticed on routine **physical examination**, especially when a routine blood test such as a **complete blood count** (CBC) is performed. A CBC may show unusually large numbers of a certain type of lymphocyte in the blood. Chronic leukemias may go for years without manifesting any symptoms at all, but also can develop symptoms similar to **acute leukemias**. Chronic myeloid leukemia, in particular, has two phases, a chronic one that can last for several years, and a malignant phase in which immature granulocytes are suddenly generated in huge numbers, producing similar symptoms to acute leukemia. In such cases, a patient may experience all or some of the following symptoms:

- weakness or chronic fatigue
- fever of unknown origin, chills, and flu-like symptoms
- unexplained weight loss
- frequent bacterial or viral infections
- viscous (sticky) blood (which slows down the supply to various organs)
- headache
- non-specific bone pain
- easy bruising
- bleeding from gums or nose
- blood in urine or stools
- swollen and tender lymph nodes and/or spleen
- abdominal fullness
- night sweats
- petechiae, or tiny red spots under the skin
- priapism, or persistent, painful erection of the penis
- rarely, sores in the eyes or on the skin

Diagnosis

As noted, there are often no symptoms present for chronic leukemia, and there are no screening tests available. If the physician has reason to suspect leukemia, a very thorough physical examination will be conducted to look for enlarged lymph nodes in the neck, underarm, and pelvic region. Swollen gums, enlarged **liver** or spleen, bruises, or pinpoint red rashes all over the body are some of the signs of leukemia. Urine and blood tests may be ordered to check for microscopic amounts of blood in the urine and to obtain a complete differential blood count, which gives the numbers and percentages of the different cells found in the blood. An abnormal blood test might suggest leukemia. However, the diagnosis has to be confirmed by more specific tests.

The physician may perform a bone marrow biopsy, during which a cylindrical piece of bone and marrow is removed, generally taken from hipbone. A spinal tap (lumbar puncture) is another procedure that may be ordered. In this procedure, a small needle is inserted into the spinal cavity in the lower back to withdraw some cerebrospinal fluid and to look for leukemic cells.

Standard imaging tests such as x rays, computed tomography (CT) scans, and **magnetic resonance imaging** (MRI) may be used to check whether the leukemic cells have invaded other areas of the body, such as the bones, chest, **kidneys**, abdomen, or **brain**. A gallium scan, or bone scan, is a test in which a radioactive chemical is injected into the body. The chemical accumulates in the areas of cancer or infection, allowing them to be viewed with a special camera.

Treatment

The need for treatment is assessed according to the degree of enlargement of the liver and spleen, a serious decline in the number of platelets in the blood, and whether or not anemia is present, and if present, how severe. Once begun, the goal of treatment is the same as for acute leukemia: remission, or an arresting of the disease process. There are two phases of treatment for leukemia. The first phase is called induction therapy, in which the main aim is to reduce the number of leukemic cells as much as possible and induce a remission in the patient. Once no leukemic cells are detected in blood tests and bone marrow biopsies, the patient is said to be in remission.

The second phase of treatment is then initiated. This is called continuation, or maintenance therapy, and the aim in this case is to kill any remaining cells and to maintain the remission for as long as possible.

KEY TERMS

Antibodies—Proteins made by the B lymphocytes in response to the presence of infectious agents in the body, such as bacteria or viruses.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Chemotherapy—Treatment with anticancer drugs.

Computerized tomography (CT) scan—A series of x rays put together by a computer in order to form detailed pictures of areas inside the body.

Immunotherapy—Treatment of cancer by stimulating the body's immune defense system.

Lumbar puncture—A procedure in which the doctor inserts a small needle into the spinal cavity in the lower back to withdraw some spinal fluid for testing; also known as a spinal tap.

Magnetic resonance imaging (MRI)—A medical procedure using a magnet linked to a computer to picture areas inside the body.

Maturation—The process by which stem cells transform from immature cells without a specific function into a particular type of blood cell with defined functions.

Radiation therapy—Treatment using high-energy radiation from x-ray machines, cobalt, radium, or other sources.

Remission—A disappearance of a disease as a result of treatment. Complete remission means that all disease is gone; partial remission means that the disease is significantly improved by treatment, but residual traces are still present.

Chemotherapy

Chemotherapy is usually the treatment of choice in leukemia, and is used to relieve symptoms and achieve long-term remission of the disease. Generally, combination chemotherapy, in which multiple drugs are used, is more efficient than using a single drug for the treatment. Some drugs may be administered intravenously (through a vein), while others may be given by mouth in the form of pills. If the cancer cells have invaded the brain, then chemotherapeutic drugs may be put into the fluid that surrounds the brain through a needle in the brain or back. This is known as intrathecal chemotherapy.

Radiation

Radiation therapy, which involves the use of x rays or other high-energy rays to kill cancer cells and shrink tumors, may be used in some cases. For leukemias, the source of radiation is usually outside the body (external radiation therapy). If the leukemic cells have spread to the brain, radiation therapy can be given to the brain.

Bone marrow transplantation
